And whereas conditions of labour exist involving such injustice, hardship and privation to large numbers of people as to produce unrest so great that the peace and harmony of the world are imperilled; and an improvement of those conditions is urgently required: as, for example, by

*the protection of the worker against sickness, disease* and injury arising out of his employment, the protection of children, young persons and women.

Preamble to "Labour" Part of the Treaties of Peace.
LE MINIERE DEL RAME

(Galleria degli Uffizi - Firenze)
In the brief introduction which the collaborators in this Encyclopædia of Industrial Hygiene have written for their work, the origins of the publication are clearly stated.

In 1919 the International Labour Conference at Washington requested the International Labour Office "to draw up a list of the principal processes to be considered as unhealthy". But it was impossible in practice to draw up such a list, at least in a complete or final form, on account of the number and complexity of the operations which in some aspects could be considered unhealthy, the continuous evolution of industrial technique which does away with causes of disease in one direction while giving rise to fresh possibilities of disease in another, and the indefinite character of the conception of "unhealthiness" which varies at different times and in different countries.

These considerations led to the idea of substituting for the list of unhealthy processes requested by the Conference, a sort of encyclopædia which would analyse from the triple point of view of the work to be done, the worker employed, and the environment in which he worked, the various tasks involved in human labour, the properties of the substances dealt with, the operations involved in handling and working up these substances, the possible sources and carriers of intoxication and disease, the statistical data on the effects as far as known, the symptoms, the diagnosis, the therapeutic and prophylactic treatment, and the protective legislation already in existence.

It was a difficult task, and one which was bound to be open to the reproach of being neither complete nor final. But how could it be otherwise? No one can hope to fix once for all something which is living, evolving, progressive. Although, as was mentioned above, the evolution of technical practice in industry may create new dangers for the worker every day, yet the progress of this same technique and of industrial hygiene may, on the following day, do away with certain existing dangers, which must, notwithstanding, be recorded and analysed in this work. One of the virtues of this work is just the fact that it is not final. It seized one moment in social life and
in the progress of industrial hygiene, but it requires to be kept con-
stantly up to date precisely because it is a scientific as well as a practical
work.

This is its dual nature, as it is that of every piece of research
undertaken by the International Labour Office, the strict purpose of
which is to make science the servant of practical action. This
Encyclopaedia is not a work of pure propaganda; it never sacrifices
scientific objectivity to the ideas which the authors naturally have
at heart. On the other hand, it is not purely a treatise on medicine
or hygiene; it claims no originality in the treatment of the various
questions; it does not claim to be an exhaustive study; on each subject
it merely gives a summary of the existing position of science, with
figures taken from statistics for the sake of example and not in
support of any argument. It has tried to keep a middle path
between a purely scientific work intended for the expert, and a popular
manual. It is meant to supply workers, employers, their organisa-
tions, and practising doctors with the information necessary to enable
them to discover, combat, and prevent occupational diseases, the
economic consequences of which are as harmful to production as
their social consequences are to the world of labour.

In carrying out this plan it has been the privilege of the Inter-
national Labour Office to have the collaboration during the last few
years of eminent experts who have taken part in the compilation or
the supervision of the Encyclopaedia. The International Labour Office
takes this opportunity of expressing its sincere and warm gratitude
to them. They must, however, have already found the first and
greatest recompense for their work in the work itself. Each of them
is an apostle as well as an expert in his own country. All are
living illustrations of the fine, comprehensive definition of "social
medicine" given by Pieraccini: "Social medicine purifies, if one may
say so, the work of doctors; its programme and its essence are purer
and more homogeneous; it removes doctors from contact merely with
individuals and makes them benefactors of the whole human race".

The International Labour Office, in collaborating with these
scientists for some years, has obtained a clearer consciousness of the
scope of its mission. The Preamble to Part XIII of the Peace Treaty
included among the urgent tasks of the Office the protection of
workers "against sickness, disease and injury arising out of their
employment". The signatory States, in agreeing to this statement
of principle, seem to have accepted the dictum of Lord Beaconsfield,
that the health of the people is the most important of all problems.
The Office has put at the disposal of those concerned a statement as
to the actual position of science and has conveyed to the legislator
the elements of physiology and physio-pathology necessary to him
for setting up a code of industrial health; by collecting and concentrat-
The Office is continuing the work of those who, since the inception of "large-scale" industry, have endeavoured to protect human life, openly or insidiously menaced by new technical processes. The fact that the Office was able to secure the collaboration of a good number of these persons is the best proof of its international utility. For many years before the war, the studies of social savants had led to the partial and more or less sporadic introduction of legal protection for the worker against the harmful consequences of his employment. But this edifice, like so many others, was still incomplete and on an insecure basis, so that it was overthrown, if not actually swept away, by the torrent of war. The willing workers on the original building found numerous obstacles in their path when they tried to resume their work, and especially to reunite the bonds of international collaboration. The Office is proud to think that it may perhaps claim the merit of having provided for the first time since the war the means and habit of intellectual co-operation, irrespective of frontiers, for the welfare of all. And it is just because this work was for the welfare of all, and for the protection of human health, that the Office rejoices in the resumption of this co-operation, and in its share in bringing it about.

The Introduction to this Encyclopaedia bears the motto of Ramazzini: Medici munus plebeios curantis est interrogare quas artes exerceant - "The duty of a doctor attending the common people is to enquire what trades they practice". The old practitioner knew well that a knowledge of the patient's trade might be a valuable factor in arriving at a diagnosis. This simple practical piece of advice throws a strong light on industrial civilisation. It is only when dealing with the "common people" that the doctor must think of their occupation. There are numerous sources of disease which do not affect the privileged classes of society, but only that class which Saint-Simon called "the most numerous and the poorest" and which nevertheless by its work gives rise to all wealth, all progress, and all happiness. For a long time this work, which is indispensable to the prosperity of the community, brought the worker nothing but physical, intellectual and moral poverty. But the conscience of the modern world has been awakened to this monstrous social paradox. Too much misery lies behind humble daily tasks; they lead to too much physical, and hence also moral, suffering. "We live", says Pierre Hamp, "on the sufferings of others. Everyone makes life a torment for some of his fellow-men. How many people earn their living pleasantly? All do so in unpleasant and often intolerable conditions. To love one's occupation is to be happy, but where are the occupations which one can love?"

In ancient societies, dangerous and disagreeable tasks were
reserved for criminals. Fourier, for all his fertile imagination, dared not foresee that the progress of industrial technique would one day lead to the suppression of unhealthy or dangerous occupations: he reserved filthy or dangerous work for his "small gangs". Nowadays the problem is entirely different: the conscience of modern society realises that occupational diseases should not be reserved for certain persons, but that they should be made to disappear. The origins and the causes are now known, and all that is wanted is will and organisation. There are plenty of other sufferings and plenty of other infirmities to which mortals are exposed. As Puccinotti has said: "Life must be preserved for labour, and labour must be made harmless to life". Work must be healthy if it is to be pleasant and agreeable and if some of the causes of that "unrest" which, as Part XIII of the Peace Treaty says, is "so great that the peace and harmony of the world are imperilled" are to be done away with.

It is hoped that this modest work which the International Labour Office has prepared by patient toil and now offers to the judgment, and still more for the service, of workers, employers, and society as a whole, may contribute its share to realising this high ideal. The efforts of its editors have been directed towards rendering science a guide to practical action. This aim will have been achieved if the work appears to be an indispensable part of that edifice, the erection of which will be the next task: the international code of hygiene and industrial health.

ALBERT THOMAS.
INTRODUCTION

Medici munus plebeios curantis est interrogare quas artes exerceant.
RAMAZZINI.

ORIGIN OF THE WORK

During the First International Labour Conference, which met at Washington in October 1919, the Commission on Unhealthy Processes adopted the following resolution:

"It should be referred to the International Labour Office to draw up a list of the principal processes to be considered as unhealthy."

The Commission admitted, however, that it felt embarrassed by the absence of any definition of what constituted an "unhealthy process".

On the proposal of one of the delegates, the Conference recommended that the Health Section (the creation of which within the International Labour Office was then contemplated) should be entrusted with the work of drawing up the list in question, since such work was naturally one of its functions. "So far as the injurious processes are concerned it is not primarily a case of investigating main principles. As a rule, it is the detailed examination of how to apply particular precautions to varied and different industries, and that means an examination of a great mass of statistics and analysing chemical and medical data."

For some years the question of unhealthy industries has attracted the attention of experts and even of public opinion, which has demanded legislative action, sometimes international action, on lines likely to produce the best possible results both for industry and for the worker himself. Such action for the diminution, and in some cases the entire abolition, of all serious occupational dangers is a worthy task, but cannot but be slow, since unhealthy occupations are very numerous and often very complicated. Although certain industries cannot for the time being be made completely innocuous, the progress of modern science and technique enables far-sighted employers, conscious of the advantage to be gained therefrom by industry, to adopt measures and new processes which tend to make dangerous processes less dangerous. It should not be forgotten, however, that scientific progress leads to the discovery or creation of products and processes which, when adopted in industry, are often a source of new dangers to the worker. Unfortunately, occupational risks do not lurk only in the raw materials, in the finished product,
or in by-products, but are often concealed in intermediate manufacturing operations and are only detected by the experts when disease has already attacked the worker.

The expression "Prevention first" is often heard. That is all very good, but in order that adequate and complete prophylaxis may be organised, it is first necessary to examine the patient, know the disease, its etiology, its pathogenesis, its symptoms, its evolution, and, above all, its extent in the strata of society affected — in this case amongst the working classes. Without this preliminary knowledge, there can be no question of prevention.

**EARLIER EFFORTS**

Even before health experts considered the question of drawing up lists of unhealthy processes (see, for example, Layet's work, published in 1875), legislators had contemplated similar lists, though from a different point of view. Such lists of undertakings classified as dangerous, unhealthy, or obnoxious are more concerned with the nuisances and dangers which such undertakings may involve for the neighbourhood (e.g. smells, smoke, fumes, waste water, danger of fire or explosion) than with the health of the workers in the factory itself. Later, under pressure of public opinion, legislators were compelled to draw up a list of the processes on which the employment of children, women, or young persons should be prohibited, or only permitted under certain conditions.

It is impossible to refer here to all the pioneers in industrial hygiene and pathology who dealt with this question, or all the treatises on the subject [see article "Occupational Diseases: Historical Review"]. It will be sufficient to mention some of the "lists of industrial poisons".

The earliest to appear were the list drawn up at the instigation of the International Association for Labour Legislation and those published on their own initiative by certain scientists; for example, that drawn up in 1908 by Sommerfeld in collaboration with Oliver and Putzeys (Jena, Fischer, 1908) and revised in 1910 by Fischer (Frankfort-on-Main, Aug. Weisbrod), and Sommerfeld's later list of 1910 (Jena, Fischer). More recently there have been the lists of Müller, of Zurich (1919), of Kober and of Wadsworth (in Kober and Hayhurst's treatise on industrial hygiene), the pamphlet of the Metropolitan Life Insurance Company (New York, 1921); that of the Bureau of Labour Statistics (U. S. Department of Labour, Bulletin No. 206, Washington, 1922), the pamphlet drawn up by Dr. Robertson, of the Industrial Health Division of the Australian Ministry of Health (Melbourne, 1923), and finally, Industrial Diseases: Rapid Reference Manual for the Use of the Medical Profession, arranged by C. T. Graham-Rogers, M.D., Inspector of Factories, New York State Department of Labour, Division of Industrial Hygiene (1924). The Industrial Poisons Committee (Chemical Section) of the National Safety Council of the United States submitted to the 1924 Annual Congress a study entitled *Summary of Present Practice in Industrial Poisoning Prevention*. In 1925 there appeared the second edition of the *Aerztliche Merkblätter*, dealing with occupational poisoning and injuries resulting from chemical substances, edited by the Association
INTRODUCTION

of Factory Doctors in the German Chemical Industry (Verlag Springer, Berlin).

The lists, which were at first confined to giving in tabular form the data concerning industrial poisons (e.g. industries and processes in which poisoning may occur; mode in which poison enters the system; symptoms; special measures), have little by little been extended to include all other causes of disease, such as temperature, compressed air, humidity, dust, infection, etc. This logical and necessary development of the lists shows clearly that the term “unhealthy” is not limited to its former restricted sense, which only covered poisons.

Scope of Present Volume

In these circumstances, and for other reasons which need not be urged here, the compilation of an international list such as that contemplated by the Washington Conference becomes extremely difficult, not to say impossible. It may be considered that the most practical solution would be the preparation of national lists drawn up by each country separately; but at the same time it is the function of the International Labour Office to collect and publish all information which will enable experts and the authorities concerned to learn what has been done and suggested in this field in the various countries. Such information, which would be the objective result either of a permanent investigation in the various States Members of the International Labour Organisation or of data drawn from published works and carefully checked, is of the utmost interest to manufacturers, workers, medical inspectors and industrial experts, medical practitioners, experts, etc.

Acting in accordance with the spirit, if not the letter, of the Washington resolution, and in agreement with its Correspondence Committee on Industrial Hygiene, the Office decided to interpret the

1 The treatises on occupational diseases and industrial hygiene of Pieraccini, Loriga, Carozzi, Giglioli, Ranelletti, Ferrannini, for Italy; of de Mosny, Sergent, Balthazard, etc., for France; of Hope, Hanna and Stallybrass, Oliver, Prosser White, etc., for Great Britain; of Weyl, Rambousek, Lehmann, Gotstein, Schlossmann and Teleky (Vol. II. of Treatises on Social Hygiene, 1928), of Chajes (1929), etc., for Germany; of Löwy, for Czechoslovakia; of Hejermans, for the Netherlands; of Kober and Hayhurst, Alice Hamilton, etc., for the United States; the reports of the proceedings of national and international congresses on occupational diseases and hygiene; of original articles appearing in technical periodicals: Journal of Industrial Hygiene (Great Britain and United States); Public Health Reports, the American Journal of Public Health, the Industrial Doctor (United States); La Medicina del Lavoro, La Rassegna di Previdenza Sociale (Italy); Zentralblatt für Gewerbehygiene (Germany); Zeitschrift für Gewerbehygiene (Austria); Annales d’Hygiène publique, industrielle et sociale (France); Bulletin de l’Inspection médicale du Travail (Belgium); Bollettino del Lavoro e della Previdenza (Italy); Higjena Pracy (Warsaw); Gigiena Besopastnost i Patologia Truda (Russia), etc.; the medical press of various countries, etc.; the theses; the chapters dealing with the factor “work” in treatises on special subjects; the treatise by Oppenheim, Ulman and Rille on skin diseases of occupational origin (Verlag Voss, Leipzig, 1926); the treatise on toxological chemistry by Kober (Germany), by Ogier and Kohn-Abrest (France), etc.; the treatises on diseases of women, diseases of the eyes, etc.; the most important publications on technology and industrial chemistry, etc.
word “unhealthy” in the widest possible sense, so that in addition to toxic, infectious, and parasitic causes of disease the articles cover all other causes capable of endangering the health and life of the workers.

**Scheme of Compilation**

The series to which this forms an introduction deals therefore with three main groups of questions:

1. The work.
2. The worker.
3. The environment.

The work is analysed into its constituent elements, such as materials, industries, trades, and causes of disease (chemical, biological, etc.). Each article is prepared on a uniform plan, which in the case of causes of disease includes the following subdivisions: chemistry or biology; sources of poisoning or of infection; uses of the dangerous product; its mode of action; statistics; symptoms; diagnosis; method of detection in the environment or the individual; prevention; legislation; bibliography.

Industrial technique is described in the order of the operations involved, showing in each case the peculiar dangers involved and the requisite preventive measures. The scope of the technical descriptions is determined, on the one hand, by the nature of the unhealthy conditions and, on the other, by the preventive measures employed or prescribed by legislation.

Among the numerous and often detailed statistics in the possession of the Office, those have been selected which are the most recent and deal with the essential facts.

In general, the figures selected are restricted to absolute figures or relative values cited by authors or factory inspectors, without any attempt being made to interpret or compare these. The statistical methods followed being very varied, the number of workers engaged in a given factory visited or exposed to a given risk being unknown, it would be highly imprudent to analyse these figures with a view to arriving at any conclusion whatsoever. On the other hand, these figures represent nevertheless an interesting aspect of the question or an indication which deserves to be brought to the attention especially of those desirous of engaging in the study of any given problem.

The subdivision “Dangers” describes the characteristic forms of disease in each industry. In cases of the more important forms of poisoning the reader is referred to the special article on this poison; for example, in the article on “Hair Cutting” a reference will be found to the article on “Mercury Poisoning”. In the paragraph headed “Pathology” the reader is given an account of the morbid forms noted amongst workers engaged on the processes in question. Similarly, as regards legislation, a brief summary, is given of measures for the protection of women, young persons, and, where such exist, of adult men, with information as to provisions on the notification and compensation of industrial diseases, special legislation, etc.

The worker is considered in relation to the products with which, and the environment in which, he works. The object of the articles
on the physiology and pathology of the various organs and systems, personal and collective hygiene (including medical or social welfare within the factory), etc., is mainly to recapitulate the data given under the headings of industries and causes of disease. They are, to some extent, a more complete review of problems which could not be dealt with in detail in the technical articles (e.g. an article on the eye summarises the various diseases of that organ encountered in the various industries).

Under environment fall general studies on subjects such as atmosphere, premises, heating, lighting, removal of dust, gas and fumes, humidification, etc. Sanitary accommodation (cloak-rooms, lavatories, privies, etc.) is dealt with in a single article entitled "Personal Hygiene". These studies, based on data furnished by up-to-date industrial hygiene, are treated separately with a view to avoiding repetition.

Limitations

Every effort has been made to make as complete a statement as possible on each subject, but obviously it is very difficult, for example, to classify the dangers which threaten the worker in their order of gravity: there are too many factors involved, even in a single country. This is an essentially national question, indeed, in some cases a local one, which cannot be taken into account here.

In fact, the same industry, the same process even applied in two different factories, though these may be for instance in the same town, will exert different effects on the health of the workers in accordance with the special conditions under which the work is carried out (workrooms, varying methods of work, up-to-date plant or otherwise, health supervision, etc.).

It is equally difficult to make a distinction between definitely established facts and data which may seem doubtful or inaccurate. In each individual case enquiries are made of qualified experts on any point which, on revising the articles, the members of the Correspondence Committee on Industrial Hygiene think doubtful. After this consultation, the Office takes the final decision that it thinks proper. It should nevertheless be emphasised that all the data published, although the result of the most detailed research and of information collected with the utmost care, cannot be considered as final.

The hygienic and health conditions dealt with in the various articles must not be considered as the result of a permanent enquiry at present conducted by the Office. They merely represent the results of investigations conducted by experts or by factory inspectors in the most varied localities and also at very different dates. Obviously these results are neither comparable one with another, nor can they be regarded as a "photographic" representation of the present state of the industry in question, and still less that of any one factory in particular, which could have no ground whatsoever for imagining that the conditions as stated in the articles might imply criticism of its methods.

It has been said that science is revolutionary. Like matter, it is always in process of transformation; therein lies its great strength and its raison d'être. Science lives only because it doubts, because
it refuses to accept as fixed and final the truths enunciated even by
the most eminent authorities. In science there exists no authority
which can settle a question finally, putting one party in the right
and the other in the wrong. This being so, in preparing the *Encyc-
lopaedia* the custom of placing in parentheses after a statement of
opinion the name of the author responsible therefor has been generally
followed.

The section dealing with "legislation", which is as up-to-date as
possible, is not intended of course to include all legislative measures
on any given subject, but merely seeks to give the most characteristic
or important provisions as examples. Similarly, in the "bibliogra-
phies" at the end of each article there are only mentioned the most
recent and important works, which will enable the reader to refer to
general bibliographies on the subject. In this connection it may be
recalled that the Office publishes quarterly a very detailed *Bibli-
ography of Industrial Hygiene* classified by subject and by author.

It was further decided to illustrate certain parts at least of this
publication (e.g. articles dealing with industries and hygiene) with
photographs, sketches, diagrams, plans, etc., showing recent innova-
tions and improvements. The work is completed by a series of cross-
references and an alphabetical table of contents which will facilitate
readers' enquiries.

The publication, therefore, will have neither the systematic form
of a list nor the scope of a large treatise on hygiene; its only object is
to furnish as wide and accurate information as possible on questions
which are of daily occurrence in the world of labour, in connection
with hygiene, pathology, and medical aid.

In order not to make the work too voluminous, it has been thought
well to condense the articles, though without sacrificing any essential
matter, in effect to adopt a somewhat telegraphic but nevertheless
clear and intelligible style. The technical and medical sections in
particular are made neither too concise for the uninitiated to under-
stand them, nor so detailed as to be unintelligible except to one or two
experts, who in any case are already acquainted with the subject or
could look it up in other documents.

Medical men will no doubt note omissions in the various articles
and sections on occupational diseases (especially in the data relative to
morbid anatomy and therapeutics). These omissions are deliberate,
since the work is intended not solely for doctors, who can, if necessary,
find the information they require in any medical handbook, but also,
and above all, for workers, manufacturers, and their organisations.
The chief object is to disseminate as widely as possible the informa-
tion required for the detection of occupational diseases, to indicate
the steps to be taken for their cure and prevention, and to lay down
general principles for the better protection of the workers.

**Expert Collaborators**

In view of the extensive knowledge and experience required for
this publication, and of the responsibility assumed by the Office in
preparing and issuing it, it has been judged essential, in drawing-
up the plan of work and in drafting certain articles, in addition to
enlisting the aid of the members of the Correspondence Committee on
Industrial Hygiene, to appeal to certain of the foremost experts in the various countries who were considered as being particularly fitted to write one or other of the articles.

The articles written by collaborators or by the Health Service are submitted for consideration to the members of the Correspondence Committee on Industrial Hygiene and to experts in the particular subject. The final text of each article has been drawn up on the basis of the information and suggestions received by the Service.

Each article has been signed by the author of the original report. The signature replaces the formula adopted in the brochure edition: "According to an original report by ........................., revised by the Correspondence Committee on Industrial Hygiene of the International Labour Office". Where the original text has been prepared by the Hygiene Service under the responsibility of Professor L. Carozzi, Chief of the Hygiene Service, it is marked thus ***. This sign replaces the above-mentioned formula.

The work appeared at first in the form of separate brochures. The present edition in volume form contains many modifications and additions rendered necessary by subsequent discoveries, new conceptions and observations furnished by science and technology subsequent to the publication of certain articles. It may therefore be said that this volume represents a new, revised and extended edition of the work already published in pamphlet form.

The Office takes this opportunity of acknowledging the valuable assistance given by Dr. Legge, formerly Senior Medical Inspector of Factories in Great Britain, and by Professor E. L. Collis, University College of South Wales and Monmouthshire, Cardiff, in the preparation of the English translation of the articles, a task which, in view of the many technical terms employed, was one of unusual difficulty and responsibility.

Like the pamphlets, the volume appears in the two official languages of the Office, English and French.
List of Collaborators

* Agasse-Lafont, Dr. Head of the Department of Pathology, Professor at the Institute of Industrial Hygiene, Faculty of Medicine, Paris.

Allevi, G. Lecturer in Industrial Pathology, University of Milan.

* Atzler, E. "Kaiser Wilhelm" Institute of Industrial Physiology, Dortmund.

Atterbom, Aksel. First Engineer, Department of Industry and Social Insurance, Stockholm.

Balthazard, V. Professor of Forensic Medicine, Faculty of Medicine, Paris. Member of the Academy of Medicine.

† Bargeron, L. Factory Inspector, Paris.

Bayer, Dr. Professor of the Free University of Brussels.

Belli, C. M. Lecturer on Colonial and Naval Hygiene in the Faculty of Medicine of the University of Naples.

Biondi, C. Director of the Institute of Forensic Medicine, University of Sienna.

* Boulin, P. Divisional Factory Inspector, Lille.

* Brezina, E. Professor of the Polytechnic School, Vienna.

Cathcart, E. P. Professor of Physiological Chemistry at the University of Glasgow.

* Chajes, B. Lecturer at the Charlottenburg Polytechnic School, Berlin.

Clark, J. Director of the Medical Department of the Norton Company, Worcester (Mass.).

* Collis, Edgar L. Talbot Professor of Preventive Medicine, University of South Wales.

* Cristiani, H. Director of the Institute of Hygiene, University of Geneva.

Dearben, W. F. Certifying Surgeon, Secretary of the Association of Certifying Factory Surgeons, Manchester.

Delabrière, L. Director of the Belgian Industrial Association for the Prevention of Accidents.

Desent, O. Medical Inspector of Factories, Namur (Belgium).

Devoto, L. Director of the Clinic for Occupational Diseases, University of Milan.

Drinker, Philip. Assistant Professor in the Faculty of Public Hygiene of Harvard University (Mass.).

Duckering, G. Works Inspector, Director of the Wool Disinfection Station at Liverpool.

1 The names of the members of the Correspondence Committee on Industrial Hygiene and the Safety Committee of the International Labour Office are preceded by an asterisk.
ENGEL, Dr. Of the Federal Public Health Office, Germany.
FERRANINI, Prof. Catania.
FILIPPINI, A. Director of the Hygiene Laboratory of the Central Health Office of the State Railway, Rome.
FISCHER, Dr. President of the Council of the Federal Insurance Office, Germany.
FREY, Dr. Director in the Federal Public Health Office, Germany.
Fuss, Mme. Doctor of Medicine.
† GASTER, L. Secretary of the Illuminating Engineering Society of Great Britain, London.
GERRIS. Works Medical Consultant, Erfurt.
GIOVANNI, De J. Director of the Medical Department of the Sicilian Sulphur Mines Consortium, Caltanissetta.
* HAMILTON, Alice. Assistant Professor of Industrial Medicine, Harvard Medical School, U.S.A.
HAYHURST, Emery R. Professor of Hygiene, Ohio State University, Columbus, Ohio, U.S.A.
HERLITZKA. Professor of Physiology at the Faculty of Medicine of Turin.
HERMANN, M. Director of the Hainault Provincial Institute of Hygiene and Bacteriology, Mons.
HEYERMANS, L. Director of the Health Department of the City of Amsterdam.
HOFFMANN, Dr. Statistician, Prudential Insurance Company, New York.
HOLTZMAN, Prof. Medical Inspector, Karlsruhe, Baden.
JELLINEK, S. Director of the Electropathological Museum, Institute of Forensic Medicine, University of Vienna.
KALMUS, E. Honorary Lecturer on Industrial Hygiene at the German Higher Technical School, Prague.
KOBEL, G. Professor of Hygiene, Georgetown University, Washington, D.C.
* KOELSCH, F. Medical Inspector of Factories, Bavaria; Lecturer at the University of Munich.
KON-ABREST, E. Director of the Toxicological Laboratories of the Prefecture of Police, Paris.
* KRANENBURG, Dr. Medical Adviser to the General Labour Department, The Hague.
KRANTZ, Dr. Ministerial Councillor, Dresden.
KRAUZ, C. K. Professor at the School of Higher Technical Studies, Prague.
LANGELEZ, A. Chief Medical Inspector of Factories, Brussels.
LEHMANN, H. K. Director of the Institute of Hygiene, University of Würzburg.
* LEYMAN, H. Former Counsellor of State, Berlin.
* Lorange, O. Director of the Factory Inspectorate, Oslo.
* Löwy, J. Assistant at the Medical Clinic, University of Prague.
Malvoz, Dr. Director of the Provincial Institute of Bacteriology, Liége.
* Martin, E. Professor of Forensic Medicine, Faculty of Medicine, Lyons.
Di Mattei, E. Director of the Hygiene Institute of the Faculty of Medicine, University of Catania.
Mori, A. Lecturer in Industrial Pathology, University of Pisa, Italy.
* Myers, Ch. S. Director of the National Institute of Industrial Psychology, London.
Oblath, O. Lecturer in Ophthalmology, Trieste.
Orenstein, A. J. Superintendent, Department of Sanitation, Rand Mines, Johannesburg.
Ottolenghi, D. Director of the Institute of Hygiene, University of Bologna.
Perussia, F. Professor of Röntgenology, Faculty of Medicine, University of Milan.
* Pieraccini, G. Lecturer on Occupational Diseases at the University of Florence.
Pittaluga, G. Professor in the Faculty of Medicine at the University of Madrid.
Preti, L. Assistant Professor, Clinic for Occupational Diseases, University of Milan.
Price, G. M. Director of the Joint Board of Sanitary Control in the Ladies' Garment Industries, New York.
Prinzing. Sanitary Consultant, Ulm.
Ranelletti, A. Lecturer in Industrial Pathology. Formerly Medical Inspector of Factories, Municipality of Rome.
Rasch, H. Director of the Factory Inspectorate, Hamburg.
Ritchie Rodger, T. Hull (England).
Rolants, E. Chief of Service at the Pasteur Institute, Lille; Member of the Superior Council of Public Hygiene of France.
Sand, R. Secretary-General of the League of Red Cross Societies, Paris.
Schmidt, P. Director of the Medical Clinic, University of Halle, Germany.
Scialvo, A. Director of the Institute of Hygiene, Faculty of Medicine, University of Sienna.
Scott, Dr. A. Broxburn, West Lothian (Scotland).
Silberschmidt, Dr. Director of the Institute of Hygiene, Faculty of Medicine, University of Zurich.
Stassen, M. Chief Medical Adviser to the National Association of Belgian Railways, Brussels.
Sternberg, Max. Professor at the Faculty of Medicine, and Hospital Surgeon, Vienna.
Tekey, Prof. District Industrial Medical Officer, Düsseldorf.
Thiele, Prof. District Industrial Medical Officer, Dresden.
THOMPSON, Gilman. New York.
ULLMANN, K. Sanitary Consultant, Vienna.
VERSON, H. M. Research Worker on the Committee for the Study of Industrial Fatigue.
VIALE, G. Professor of Physiology at the University of Genoa.
WADE WRIGHT, Dr. Medical Chief of the Metropolitan Life Insurance Company, New York.
WEISBACH, W. Director at the Academy of Hygiene, Dresden, and of the Courses in Hygiene at the University of Halle.
WENZEL. Industrial Councillor, Berlin.
WHITE, R. Prosser. Dermatologist and Senior Physician, Royal Albert Edward Hospital, Wigan, Lancashire.
* WINSLOW, C. Professor of Public Health, Yale School of Medicine, U.S.A.
* VIRGIN, Dr. Professor of Hygiene and Bacteriology, Faculty of Medicine, University of Upsala, Sweden.

Abattoirs — Slaughterhouses

Abattoirs are the premises where butchers slaughter animals intended for food.

On these premises are carried on all the operations required for the preparation of butcher's meat; and here also are temporarily accommodated animals awaiting slaughter.

The slaughtered animal passes to a workman, who makes an incision following a ventral line the full length of the body and then two others at right angles to the preceding line, one for the fore-limbs and the other for the hind-limbs; these incisions sever the skin of the limbs right up to the extremities. The flaying is usually done with a knife, but the men who undertake this work are specialists. One skins the front legs, another the head, another the shoulder, etc. Each is supplied with a knife designed for the particular work which it has to do. These workmen rapidly acquire extraordinary dexterity. In five or six minutes an animal is flayed and the hide is always undamaged (United States). In some abattoirs (for example, at Zurich) the flaying of animals is done by means of an apparatus which enables the work to be done without the fatigue occasioned by skinning with a knife.

Slaughtering, cutting up the meat, the various changes it undergoes, the waste, blood, offal, and guts are all causes of unhealthiness in this industry.

It may be mentioned here that the work done in abattoirs is also done, especially in small centres and in the country, at the house of the butcher or pork-dealer.

The knacker kills, skins and cuts up dead or injured animals. In towns the knacker's work is done in municipal yards under strict supervision.

The knacker's trade, especially the part relating to the hygiene of food, ought to be regulated on a uniform system. Too often the knacker is also a butcher; too often the meat from the knacker reaches the sausage factory; too often animals who have died of disease are buried at the risk of infecting the land.

Knacker's work includes treatment in closed vessels by steam under pressure, by chemical reagents, incineration, dry distillation, and burying in special enclosures authorised for this purpose and closely supervised.

Sources of Danger

In addition to the smells arising from animal material in a state of putrefaction and from decomposing water, there are, it must be recalled, also risks from escaping animals and especially from contamination by animals affected with diseases transmissible to man, e.g. anthrax, glanders, Bang's disease (bac. abortus), erysipelas, actinomyces, and trichinosis, which attack slaughterers, cutters-up, cattle-yard men, veterinary officials, and others.

Traumatic lesions from accidents caused by the animals are also common.

Statistics

According to some figures, a little out of date (1903-1905), dealing with 2,150 female members of the local society of butchers of Berlin, 620 persons were sick with incapacity for work; 5.6 per cent. of members showed lesions arising from accident, 3 per cent. from troubles of the genital organs (menstruation, abortions, etc.), 2.4 per cent. from digestive troubles, 2 from acute infections, 2 from respiratory diseases, 2 from anaemia, 0.9 from nervous diseases, and 0.8 from diseases of the circulation. A group of 4,200 men had 2,125 sick with incapacity, i.e. 50 per cent.; traumatic lesions (accidents) figure as affecting 19.5 per cent. of members; venereal diseases, 9.8; respiratory dis-
eases, 3.6; rheumatism, 2.7; dermatitis, 2.4; digestive troubles, 2.3; infections, 2; nervous diseases, 0.9; and diseases of the circulation, 0.8 (Leiser). According to the last report of Leipzig (1910), butchers, as regards length of illnesses, show figures of less than the average invalidity rates; the records being equal to half the average for infections for circulatory diseases and digestive troubles, equal to a third of the average for respiratory diseases, and equal to a tenth of the average for tuberculosis. More frequent than the average, on the contrary, are troubles due to infectious diseases of the skin, where a small wound easily becomes infected, and eczema.

Some American statistics (United States, 1910) dealing with about 125,185 butchers give the following results:

**PATHOLOGY**

Persons employed in abattoirs and butcheries are generally young, healthy and strong, without defects of organs of sense. Where women are concerned, vigorous young girls are met with, of strong constitution, able to lift heavy weights, and even employed at strenuous work for long hours.

If, as statistics show, pneumonia and tuberculosis are rare, nevertheless a certain frequency is found of bronchitis, tracheitis, and diseases of the throat, caused by the sudden changes of temperature. Rupture of muscles, hernia, varicose conditions, and flat foot are in strict proportion to the efforts required by the work and to the amount of standing. Pathology is, however, especially concerned with infections. According to Boxeden (1904) pemphigus of butchers, called by Colcott Fox "acute febrile pemphigus", is a general infectious disease due to handling the skins of certain diseased animals; it is only the human form of aphthous fever (foot and mouth disease). But the latter infection seems much less serious than pemphigus. It usually starts with a prick on the fingers; it shows itself by an erythematous rash, an eruption localised to the throat, accompanied by headache, and followed by desquamation. Brocq has collected 25 cases, of which 17 were fatal in 10-15 days. In 1873 some cases of erysipelas among butchers had already been noticed (Morrant Baker). So called migratory erythema, chronic erythema and, by V. Redwitz, "erysipeloïd". Gilchrist, in his clinic at Munich, 26 cases in 1922 and 46 in 1923, generally among persons who by their trades are brought in contact with the carcasses of fish or of animals, and particularly those of pigs, who in about half the cases, without being ill themselves, are carriers of the bacillus of erysipelas in the intestines or on the tonsils. The illness may be caused by hypnocytes (the "cladothrix", Rosenbach, 1884), and the clinical features caused by this fungus appear similar to those seen among laboratory workers who handle cultures of the erysipelas of pigs. It has thus been possible to identify the two diseases, and it is even reported that their causative agent has a singular resemblance to "bacillus murisepticus".

Among the 46 cases of V. Redwitz, 8 had slaughtered pigs suffering from erysipelas, 3 diseased pigs, 16 had handled pigs' meat, 2 the meat of hares, and 9 had worked in kitchens. Some cases have also been caused by the bites of lobsters, crabs or cray fish, which are liable to come in contact with the carcasses of animals.

The affection is generally confined to the hand and especially to the fingers, sometimes to the neck and abdomen. It does not become generalised and it is only in 10-15 per cent. of cases that such symptoms of generalisation are encountered as superficial lymphangitis of the arm or forearm. The prognosis is favourable; a fatal issue is rare.

Secrétan in one case of rhinoscleroma attributed the contagion to the fact that the sick woman sorted dried guts sent into Switzerland from Hungary and Russia; other writers have reported
cases of contamination from contact with the carcases of animals.

Matzenauer, of Vienna, in 1908 described a palmar hyperkeratosis among butchers due to the handling of pig bristles. Some cases have also been reported of tuberculosis verrucosa, dermatomycosis, and folliculitis, due more particularly to ectothrix trichophyton affecting horses, cows and pigs; of taenia and trichinosis from the consumption of uncooked meat; of actinomycosis, bovine tuberculosis, and of Bang's disease due to the bacillus abortus (case of Viviani, 1925) among butchers or stable boys who come in contact with cows affected with this disease. More important and more serious are the cases of anthrax infection which in Germany, for example, showed, for the period 1910-1921, the following figures:

<table>

In 1923 the number of cases of anthrax was 26 of which 25 (with two deaths) occurred among the abattoir workers and butchers, and one among the flayers.

**Hygiene**

Without entering into details concerning the construction of abattoirs, their locality, the installation of light, ventilation, and of water under pressure, which belong to the domain of municipal hygiene, certain points in the hygiene of abattoirs and butcheries may be reviewed here which have reference to the prevention of diseases affecting persons occupied in this trade.

It is a fact that the abattoirs and butcheries of small communities are usually in a worse condition than those of the average community and big towns. They should comply with certain minimum conditions of working in order to ensure good hygienic conditions: water under pressure should be laid on; the floor should be impermeable, smooth and washable; drainage is needed for washing down and for blood; the walls, exposed timber and woodwork should be washable; and general daily cleansing should be practised. The keeping of pigs and poultry in abattoirs and feeding them with offal should be prohibited; war should be waged against rats on the premises.

Animals should be prevented from wandering freely into the yard; they should be fastened securely during their stay in the cattle-market pens; a method should be adopted to enable them to be easily seized; there should be a system of movable barriers to direct the animals when disembarked from the cattle trucks into the slaugh- terhouses without any possibility of their escaping.

All the large towns have special regulations for abattoirs and special measures for cow-houses, pigsties, purifying houses where waste offal is burnt, and where meat to be stored is hung up, and for tripe shops.

Abattoirs, in some countries, often possess apparatus for extracting and rendering down fats, and scalding houses where parts of animals suitable for food and offal intended for industrial purposes are submitted to the action of hot water.

In this case every precaution for the most efficient condensation of gaseous products must be taken and for recovering any which have not been condensed in the drying gazogene. They should be made to pass out through the furnace. Efficient ventilation of the knackers' premises is required; and also daily removal of hair, horns, hooves, skins, etc., in impermeable, water-tight carts which are completely closed. The materials coming from the purifying tanks and those which have escaped the cooking process should be converted into manure by mixing them with absorbent substances.

Eating, drinking, or sleeping in the workshops should be prohibited. There should be placed at the disposal of the staff lavatories with efficient disinfectant solutions, together with a service of sanitary supervision both for the animals and workmen.

A campaign must be undertaken against nauseating smells (see article "Odours"); and also with a view to obtaining efficient removal of offensive smelling steam. Offal, such as horns and hooves, must be stored in well-ventilated places and covered with quicklime.

Thorough daily cleansing and weekly disinfection, with chlorine or formaldehyle, of places soiled by debris and slop water must be carried out.

Treatment of debris in special apparatus, every operation being done in a closed vessel, is essential and prevents any inconvenience.

The question of waste water charged with organic matter and able to infect rivers is also important. The water, after having been decanted into
a special tank, is submitted to the action of anaerobic microbes in a septic tank and passed successively over bacteria beds by means of a distributing system carried out by pipes and channels, which run the water on to the fields; there it is subjected to the action of nitrous and nitric aerobic microbes (see article "Waste Waters").

Compulsory notification should be required from every owner of an animal which dies of any disease; while the possibility of an owner destroying a dead animal without having recourse to a knacker's yard, if one is not available within a fixed radius, should be provided against; measures must be taken for burying carcases especially when infected animals are involved (Martel).

Legislation

Women are rigidly excluded from stores of animal debris, of manure of animal origin, from washing and preparing of guts (Argentina), and from the inflation of guts (France). Youths of less than 14 years are excluded from public and private abattoirs for slaughtering work and other work carried out on these premises (France); of less than 16 years from cutting-up departments, storerooms of animal offal, animal manure works, public and private abattoirs, gut-cleaning places, and knackers' yards (Belgium); of less than 17 years from public and private abattoirs and slaughtering of animals (Portugal) and of less than 18 years from the workshops for inflating and drying bladders (France). Boys of less than 16 years are forbidden to handle the debris of abattoirs, to slaughter animals, and to work in glue works (Quebec, Canada); to work in private abattoirs, out-houses and storehouses of offal with a view to the extraction of various nitrogenous substances; to clean and remove bladders and guts; in the rooms where the work of cleaning and blowing up is carried on (Spain). Young girls of less than 18 years are excluded in Canada (Quebec) and those of less than 21 years in Spain from scalding houses where intestines, offal and other animal debris are prepared and cooked, and where the heads and feet of animals are treated to separate the hair; from stores and the drying of blood; and from separation of mucous membrane of guts by putrefaction in catgut factories.

For notification or compensation of diseases, see the articles concerning them. Notification of cases of inflammation of the skin and of the subcutaneous cellular tissue among gut cleaners is also provided for in Holland.

Compensation for septicemia in all work involving the handling of meat, or the manufacture of food products, or of animal by-products is provided for in Queensland and in the State of Victoria.

***

Abrasives (Artificial) and Grinding Wheels

Raw Material

The two artificial abrasives in most common use are emery and carborundum in crystalline form. The wedge-shaped crystals are almost as hard as diamonds. Considered from the point of view of their physical characteristics, these crystals in dust size should be equal in danger to any type of dust met with in industry.

Emery (French : émeri. — German: Schmirgel, Potterstein. — Italian: smeriglio. — Spanish: esmeril) is an aluminium oxide manufactured from bauxite in a water-cooled furnace, the heat being very intense and produced by an electric arc. The fused crystals of aluminium oxide form a large mass or "pig" in the furnace after cooling. This pig is removed from the furnace and broken up by men wielding sledge hammers. The ore is then crushed to a fine grain which in turn is screened to different sizes. The number of the powders corresponds to the number of wires to the inch in the sifting machine. The reddish brown dust is sold as emery and the white dust is retained as alundum which serves for the manufacture of refractory products. The grain is stored in kegs and either shipped direct to customers, or is used in the manufacture of grinding

Fig. 1. — Dust from artificial abrasives (enlarged sixteen times).
wheels. Emery is also got from emery rock (in Smyrna and the Island of Naxos) which is likewise an anhydrous oxide of aluminium (Al₂O₃).

In the manufacture of carborundum, which is a carbide of silicon (Si₃C), sand, coke and sawdust are mixed and packed around a carbon core. According to Acheson, a mixture of 455 parts of coke, 365 of sand and 180 of salt is used. Sea salt does not participate in the reaction but serves to remove the impurities of the silicon and of the coke in the form of chloride. Sawdust acts as a support for the porous mass and serves to facilitate the elimination of carbon-monoxide. The whole mass is then sided with brick, and the two ends of the carbon core connected with a high-power electric current for 7 to 8 hours. A resistance type of furnace is thus formed. The intense heat along the carbon core causes a chemical change in the coke and sand resulting in a deposit of crystals of carbide of silicon.
along the core of the furnace. The metal thus recovered consists of concentric masses which, the further one recedes from the axis of the apparatus, that is, the line uniting the electrodes, are composed of: a layer of impure carborundum; a layer of the same product (pure enough to furnish the commercial product); a layer of amorphous carbide of silicon; and a layer of the mixture which has not been attacked. Treatment of this mixture produces a quarter of its weight of commercial carborundum.

While the furnace is active a large amount of carbon monoxide gas is generated which, unless the ventilation is good and the process carried on in spacious buildings, produces headache and other symptoms of mild carbon monoxide poisoning.

The resulting pig of carbide of silicon is broken up and reduced to grain under steel grinding mills placed in cast-iron tanks. The grinding does not involve undue wearing of the apparatus because the carborundum is fairly easily broken. It is then left
for seven days in sulphuric acid diluted with its own volume of water in order to reduce the iron produced by the mills, then washed in water. The carborundum crystals are then classified according to size, a process rapidly and accurately executed by depositing the various grades in a series of reservoirs increasing in size, and through these is made to pass a current of water in which the crystals remain in suspension. According to the time taken in depositing, the material is divided into the “six minutes” powder (which is the finest and is sold to the lapidaries for diamond polishing), the “four minutes” powder (which is used for polishing glass), etc.

The crystallised-carborundum in a pure state is in form of colourless transparent crystals, while commercial carborundum is opaque and blackish in colour on account of the impurities which it contains (especially carbon). Hardness: 9.5; 70 per cent. content of silica and 30 per cent. of carbon; density: 3.12. Amorphous carborundum, obtained as a by-product in the manufacture of crystalline carborundum, is infusible, and is resistant to most chemical reagents except caustic potash.

**Uses**

It is very widely used in powder or in moulds as a substitute for emery in polishing, sharpening and pointing metals; cutting, polishing, engraving glass; polishing of diamonds, precious stones, and mother of pearl; polishing of leather, marble, hard stones (granite); and mounting of drilling and boring machines in quarries and mines. It is used in the making of wireless crystals, and in the construction of refractory materials and apparatus. Mixed with coal and silica, it is used for the manufacture of such products as “Cryptol” and “Carbofrax” for finishing the grinding wheel (on the left is seen the small cutting wheel), with the suction duct which catches most of the dust generated.
stoves, and electric apparatus, lining of metal ovens, manufacture of crucibles, bricks, etc. It serves to preserve from undue wear and tear cement hearths when strewn over the cement in the form of a surface layer before hardening.

DANGERS

The manufacture of these two abrasives in the electric furnace presents three health hazards: the exposure of the worker to intense heat, the exposure of the worker's eyes to the ultra-violet and infra-red of the arc furnace, and the exposure of the worker to carbon monoxide gas. There are in addition two physical hazards: the danger from large flying pieces or chunks of abrasive when the "pig" is broken up, and the danger to the eyes of flying particles of abrasive in the air.

The above hazards, however, apply only to a very small proportion of the workers in the abrasive and grinding wheel industry, and are such that they can be readily guarded against, so that as a matter of fact these hazards have not resulted in unfavourable health and accident experience.

The manufacture of grinding wheels presents no health hazards except that of the crystalline dust of the artificial abrasives above described. The process of making a typical grinding wheel is as follows:

Suitable proportions of grain of required size and character are mixed with clay and water (generally 70 per cent. carborundum and 30 per cent. clay) in a mixing kettle. Gum lac, gum arabic, oil, soda, soda silicate are also used as cohesive agents, but they are not so good as clay. They, however, offer the advantage of being more elastic and less susceptible to breaking. After having been thoroughly mixed, the resulting semi-liquid mass is poured into rings which are approximately the size of the wheel to be manufactured and subjected to hydraulic pressure. To prevent breaking, a copper wire ring is introduced. The ring containing the abrasive clay mixture is then put in a drying room which is heated to about 120° Fahrenheit. In this baking heat the wheel rapidly dries and is then shaped to its approximate size on a potter's wheel. This is a dusty operation and special dust-removing apparatus is necessary for the protection of the worker.

The wheel is now ready for burning and is packed in sand, surrounded by fire brick, and placed in a kiln where it is subjected to continuous heat running in the region of 2,000° Fahrenheit for a week or more. The kiln is allowed to cool and the wheel removed. It is now stone hard and resembles the finished product.

The next process consists in truing the wheel. This shaping to exact dimensions is done on a lathe, the cutting being done by a specially treated steel cup. During this process a large amount of dust is produced which must be removed by suction apparatus built into the truing machine. After the wheel is trued, it is balanced and the hole bushed with lead. This bushing is free from danger of lead poisoning as the hands of the worker do not come in contact with the lead, and the molten lead pots are not kept at a temperature high enough to produce fumes. Although men working at bushing should be cautious of the danger of lead poisoning, in thirteen years' experience in a large grinding wheel factory in America no case of lead poisoning which could be traced to the bushing process has ever been noted. Having been balanced and bushed, the wheel is tested for faults and breaking. This test is effected in a metal drum at a speed of 7,000 revolutions per minute and a grinding mill capable of resistance can be guaranteed.

It will be seen from the above brief description that the only hazard peculiar to the grinding wheel industry is the dust which is produced at various stages of production. The quantity of dust produced is always of great importance; thus, for instance, Winslow found in an American abrasive factory up to 780 mgrm. per 28.52 cubic metres.

The dust produced in the manufacture of abrasives and grinding wheels, as previously stated, consists of hard, wedge-shaped grains. The chemical composition of these grains consists of aluminium oxide, or carbide of silicon, with very slight traces of silica and iron. The trace of silica only appears in the dust of the truing room where it is largely the result of the vitrified clay in the wheel. The amount in the air is too small to have any physiological effect.

The danger of work in the dusty departments is that the continued inhalation of the dust may produce silicosis. (See articles "Dust" and "Tuberculosis").

Tuberculosis often accompanies sclerosis caused by these dusts. In a
large manufacturing plant which has been producing artificial abrasives and grinding wheels for 23 years, the number of cases of tuberculosis among the workers is considerably lower than the reported cases in the city in which the factory is located. In the same factory (Norton Company, Worcester, Mass.), all workers are kept under medical supervision and those working in the dusty departments are frequently re-examined. During the past 12 years there have been three cases of definite silicosis discovered, or less than one-half, of the number of nine years occurring among employees who had worked for over ten years. Probably the result of dust inhalation. From the above experience and the statistics of the 29 cases of tuberculosis discovered at this factory, it is believed that other factories where prophylactic measures had been adopted, bronchitis and emphysema among the workers (26 per cent.) engaged on dusty operations, whilst the rate for the staff as a whole was only 8 per cent. There was no sign of pulmonary tuberculosis.

From the above experience and the experience of others, the dust produced in the manufacture of artificial abrasives and grinding wheels does not appear to be anything like as dangerous as the dust from sandstone, granite cutting, or other trades in which the dust has a high silica content. It is important, however, that the hazard, even though not great, should be minimised by the employment of adequate and efficient hoods and suction apparatus where these can be used, and that all workrooms should be large and well ventilated.

**Hygiene**

The hygienic precautions for workers in the manufacture of artificial abrasives should, therefore, be as follows:

1. For workers about the high temperature arc furnaces where aluminium oxide is fused:
   (a) Protection of eyes by suitable goggles which will cut out the ultra-violet and infra-red rays.
   (b) Protection from heat by hanging chains or screens.

2. For workers in preparation of abrasive grain:
   (a) Protection of eyes from particles of flying abrasive by the compulsory wearing of goggles.
   (b) Protection of the lungs from fine particles of dust by adequate ventilation, and wherever possible dust removal by suction.

3. For workers in the manufacture of carborundum, protection from carbon monoxide fumes by adequate ventilation.

4. For workers in the manufacture of grinding wheels:
   (a) Protection of lungs by adequate dust removal.
   (b) Protection from possible lead poisoning by instruction in the proper cleansing of hands, etc., after handling lead in the bushing departments.
   (c) Protection of the eyes by compulsory wearing of goggles in the truing departments.

5. For all workers in artificial abrasives and the manufacture of grinding wheels:
   (a) A complete physical examination prior to employment.
   (b) Re-examination of men employed in dusty and lead working departments at regular intervals.
   (c) Elimination from the dusty departments of any employees suffering from pulmonary tuberculosis, active or quiescent.
   (d) Good supply of clean, cool drinking water.
   (e) Proper bathing and locker facilities (workers become very dirty from abrasive dust) and provision of working suits.
   (f) Encouragement of outdoor games and sports after working hours.

**Legislation**

Exclusion of young persons under 18 years of age from all work demanding the use of emery, tripoli, corundum, carborundum, for the manufacture and use of polishing wheels or mills in the United States in the States of Delaware, Maryland, Massachusetts, New York, Ohio, Pennsylvania, Wisconsin. (For reporting and compensation of cases of silicosis, see articles "Dust" and "Tuberculosis").

The illustrations have been kindly supplied by the author.

(Worcester, U.S.A.)
Accidents in Industry and the Human Factor

ACCIDENT FREQUENCY

The frequency with which industrial accidents occur is much greater than is generally supposed, and they are so numerous as to constitute a tremendous toll, not only on the health and happiness of the industrial classes, but on economic production. It is stated that in 1907 there were no less than 35,000 fatal accidents amongst the industrial population of the United States, and 2,000,000 cases of injury. These numbers have been considerably reduced of recent years, for the fatal accidents numbered 25,000 in 1913 and 22,000 in 1917, whilst the serious accidents were 700,000 and 500,000 respectively (Tolmann and Kendall).

However, a study of more recent American statistics shows that the tendency towards a reduced death-rate and the period 1912–1924 is not a marked one, for it is about 1 per cent. per annum, and the mortality rate due to accidents caused by machinery in industry has fallen by about 4 per cent. per annum.

Taking as basis the statistical returns for the State of New York, one is even forced to ask if the number of accidents has not increased, for though their number remained about the same for the years 1922–1923 and 1923–1924 (346,845 and 293,844), it increased considerably for the years 1922–1923 and 1923–1924 (346,845 and 371,708), an increase, that is to say, of 26 per cent. in two years. The number of fatal accidents increased for the same period by 60 per cent. (Hatch).

It is not always possible to find an explanation for the annual variations in the number of accidents reported for the various countries. The phenomenon is too complicated to admit of simple explanation. Resumption of industrial activity, increase in the number of employees, the introduction of compulsory notification of accidents, the more vigorous application of this measure, the application of the law regarding accidents to further occupational categories, the substitution of mechanical processes for manual processes, etc., are factors which, by themselves or in conjunction, may serve to explain the variation in the annual accident figures.

It is not even possible to draw general conclusions from the statistical data available, for though it may be said that in certain countries the number of accidents has a tendency to diminish (which, however, is not the case with regard to serious and fatal cases), in other countries, on the other hand, it is found that the figure for fatal accidents and permanent total disability has reached a fixed rate or has fallen, though there is an accompanying increase for temporary or partial permanent disability.

Since, further, the other factors have not varied, the first of these phenomena may doubtless be explained by the more extensive application of technical means of prevention. On the other hand, slight accidents which are more numerous, and the total of which constitutes a social loss of indissoluble value, are more frequently in proportion to the health conditions of the community and the conditions of the individual worker.

Statistical returns for certain countries provide the following figures:

In Austria, in 1923, 22,258 accidents, of which 185 were fatal, were reported, as against 22,443, 170 of which terminated fatally, in 1922.

In Belgium (for five districts which completed the requisite returns) there were 46,357 accidents, 211 being fatal, in 1923, as against 57,195, with 233 fatal, in 1922.

In Czechoslovakia the number of accidents mounted from 36,975 in 1923 to 47,021 in 1924. The construction of machines, metal founders, and the building industry showed the highest figures. The reports of the inspectors, however, emphasise the fact that the number of accidents is to be attributed to a resumption of industrial activity and to the increased personnel employed.

However that may be, it is nevertheless true that these accidents in their aggregate represent a sum total of pain and discomfort coupled with a temporary reduction of manual skill which is very large indeed.

In France, excepting the railways and mines, accidents in 1920 amounted to 658,350 with 1,932 fatal, in 1922 there were 682,830 with 1,857 fatal, and in 1923 777,975, 2,082 of which terminated fatally.

In Germany, in 1910, 484,097 cases of accidents were reported (5.16 per 100 insured), 5,292 of which terminated fatally (5.6 per 10,000 insured); in 1920 there were 433,049 accident cases (4.54 per 100 insured), 5,061 or 6.3 per 10,000 insured terminating fatally; in 1923, 346,950 cases (or 3.70 per 100), of which 5,243 (or 5.6 per 10,000 insured) resulted in death.

In Great Britain statistical returns for fatal accidents for the year 1924, for instance, are not comparable to those of the preceding years, because of the amendment to the Act passed in 1925. The increase in the total number of accidents is also to be in part attributed to the resumption of industrial activity.

In 1924 the total number of accidents was 169,723 as against 125,551 for 1923: 9,556 fatal accidents were reported as against 867 in 1923. In Great Britain there have been, during the last few years, about 1,200 fatal accidents per annum in factories and workshops, and another 1,200 in
coal mines and quarries, besides several hundred accidents on railways and elsewhere. Non-fatal accidents of sufficient severity to cause disablement for a week or more number about 120,000 a year in coal mines. In addition, there are about ten times this number of more trivial accidents which cause only a brief disablement, and often, indeed, involve only the time lost in putting on a bandage.

In Japan industrial factory accidents, which amounted to 48,582 (with 335 fatal) in 1913, did not exceed 32,973 (314 fatal) in 1921, and 31,314 (229 fatal) in 1922.

In the Netherlands there were, in 1922, 77,443 accidents, 151 of which were fatal, as compared with 78,490, with 167 fatal, in 1923.

In Sweden the number of accidents was 35,234 in 1922, with 223 fatal cases, and in 1923 41,996, with 239 fatal cases.

**Causes of Accidents**

To what extent are these accidents preventable? The word "accident" implies an event which takes place without one's foresight or expectation, and it follows that, if only this foresight is sufficiently clear and is adequately acted upon, there should be no accidents at all. Though it is impossible that such an ideal state of things as this will ever be attained in practice, there is no doubt that by taking suitable precautions the frequency of accident occurrence can be, and has been, enormously reduced in many instances, and actual figures in proof of this statement are quoted below.

In order to determine the most effective means of prevention, it is desirable to identify, so far as is possible, the various factors concerned in accident causation and roughly estimate the varying degrees of importance to be attached to them. Nearly all the factors are ultimately human in origin, but it is useful to draw a distinction between those which are due directly to the subject who suffers the accident, because of his own carelessness, lack of knowledge, or lack of skill, and those which are caused indirectly by his employer or someone else in authority because of the dangerous conditions under which he is compelled to carry on his work. Accidents due to unguarded machinery would fall into this class, although they form but a small proportion of the whole. Thus of the 162,154 factory and workshop accidents reported in Great Britain in 1918, only 53,491, or a third of the whole, were attributed to machinery, and not more than 35 per cent. of these machinery accidents were due to the absence of guards. Hence it was concluded that the provision of more adequate safeguards could not be expected to cause a reduction of more than 10 per cent. in the accident rate. Of the remaining 90 per cent. of accidents incurred it is supposed that practically all were due in greater or less degree to some failure on the part of the human subject involved, the result of carelessness and inattention, lack of proper appreciation of danger, or lack of skill. These factors will be discussed separately, so far as is possible, but they are usually bound up together so closely that it is impossible to disentangle them completely. More often than not an accident is due to the combined action of several factors, some of which may be acting in opposite directions, and it is difficult to obtain even a rough idea of their relative importance.

It was for long held that the causes accountable for almost all industrial accidents were connected with defective plant, insufficient safety devices and above all the so-called "carelessness" of the workers. Yet if statistics be carefully examined, demanding of course the most rigorous precision of these as well as general standardisation, the surprising result will be found that in Germany, for instance, the "unforeseen" factor being neither attributable to the worker or employer nor to the two together occurred in the proportion of 37-43 per cent. for the period 1887-1907, and in Norway it happened in as often as 90 per cent. of the cases from 1895 to 1906.

If a more detailed study of the statistics is made it will be seen, for instance, that out of 200,000 accidents assembled by the United States Steel Corporation 8.83 per cent. only related to machinery; that of the 4,969 accidents reported by the North Dakota Workmen's Compensation Bureau, and which occurred from 1920 to 1923, 12.6 per cent. only were caused by machines; that, according to German statistical returns, out of a total of 53,476 accidents which gave rise to permanent incapacity lasting at least thirteen weeks, 14,489, or 27.1 per cent., were due to machinery; that in Belgium and in France the same percentage was met with, whilst in Great Britain the so-called "negligence" of the worker was said to constitute the cause of the accident in 80 per cent. of the cases. Similarly in Italy, it was found that out of 1,000 accidents 200 were exclusively due to machinery, though the individual
factor also played a part in the accident, and the remaining 800 were caused by the human factor. According to a report dated 1924, the responsibility of the victims is said to have constituted an important factor in the production of 3,822 accidents reported in the Saar Basin. Of this number 254 were serious and 37 fatal.

The Human Factor

The development of social medicine has led specialists to a clearer study of the factors which play a part in accident causation, and whilst Imbert in 1905 drew attention to fatigue as one of the most important causes of industrial accidents, Pieraccini two years later brought to light other factors, such as the length of the working day, lack of rest during the day, etc. The factors giving rise to accidents can be classified as "external factors" and "individual" or "personal" factors. In the first group are included: the kind of work, the nature of the processes, the length of the working day, night work, arrangement of the working week, meteorological conditions, the area and cubic space allotted to each worker, the surrounding temperature, ventilation, lighting, the humidity, the speed of the work, the occupational risks pertaining to each class of work or operation, the wage, etc. Amongst personal factors should be classed the worker's origin (race, birth, etc.), his place of residence, age, education and training, length of service, physical, psychic, and endocrine constitution.

In this connection, the Americans have emphasised the importance, in regard to accident frequency, of newly arrived immigrants generally employed in the most trying and dangerous occupations. According to the Industrial Commission of Ohio, 50 per cent. of the fatal accidents affected this class of worker. It is evident that all accidents do not depend on the human factor. Of 2,678 accidents reported in Illinois in 1910, Bogardus found that 17.2 per cent. did not depend on the worker. Of 100 fatal accidents, Frois found that 25 were due to fortuitous circumstances impossible to foresee, 32 to insufficient protective measures, and 43 to faulty adaptation on the worker's part (lack of technical faculty 18, of physiological faculty 15, of psychological faculty 18).

If the phenomena connoted by the word "accident" be studied in accordance with modern scientific data, the conclusion is reached that accidents due to unforeseen causes impossible to forestall are very rare and that in nearly every case the true cause is the "man" himself, owing to some congenital lack of physical or psychological balance (it is now even permissible to talk of the lack of balance of the endocrine functions) or to such lack of balance deriving from intercurrent disease in a latent state of which the subject is but too often unaware himself.

The constitution, by its reaction on the nutritional exchanges, on the tonicity of the neurovegetative functions as well as on the hormonal type dominant in the individual on the one hand, and on the other the psychic temperament, which is in direct relation to the factors above referred to, exercises a remarkable influence on accident causation, on the evolution of lesions as well as on individual reactions, especially in regard to resumption of work and settlement of compensation (Biondi).

Hence arises the importance of the physio-psychic examination and of individual selection, on engaging workers, which has been prominently advocated in the United States, for instance. In fact an examination carried out with psychological tests proved that 70 per cent. of those examined had a childish mentality and that of these 15, or 31.5 per cent. of the total, were declared by the examiners to be incapable of self-control. It is, however, very difficult in practice to draw a hard demarcation line between accidents due to the human factor, accidents due to the mechanical factor, and those due to a combination of both these factors.

Sargent Florence classifies industrial accidents as follows:

1. Accidents due to unusual action of the material:
   (a) which no human capacity could have foreseen or escaped at the time;
   (b) which great attention might just have foreseen;
   (c) which through quick reaction might have been escaped;
   (d) which either by attention might have been foreseen or by quick reaction might have been escaped.

2. Accidents due to unusual action on the part of the worker owing to his lack of co-ordination or to positive inattention:
(a) extenuated by unusual conditions surrounding the work; 
(b) without such extenuation.

3. Accidents due to unusual action of material, due in turn to the injured man himself, e.g. shell dropped by man on his own toes.

It must be admitted that there exists in certain individuals impossibility of adaptation to their work as the result of physio-psychic reasons. It suffices to recall in support of this view the declaration recently made by Schridde of normal subjects:

Peri has classified as follows the causes of this impossibility of adaptation to a given kind of work:

- Constitutional weakness.
- Insufficient or inadequate feeding, especially in the case of people engaged on hard work.
- Internal diseases, diseases of nutrition or of toxic origin not however involving incapacity for work.
- Mutilation, effects of lesions, functional disturbances not however involving incapacity for work.
- Diminution in the function of certain organs (vision, hearing).
- Imperfection of muscular sense.
- Deficient intellectual faculties.
- Criminality.
- Abnormal states of conscience amongst neuropathic workers.

Special psychic moods in apparently normal subjects:

(a) difficulty in directing and maintaining the requisite attention; (b) imperfect mental lucidity due to slight intoxica
tion or as the result of serious chronic intoxication (especially alcoholism) amongst individuals not showing characteristic symptoms of chronic poisoning.

Individual predisposition to become easily fatigued or exhausted in course of work.

Various preoccupations not connected with work.

Inadequate estimate of danger inherent in the work: the worker becomes bold, imprudent, and negligent.

Exaggerated fear of accidents; the work is hindered and becomes tiring and dangerous for the individual and his fellow-workers; Insufficient sleep during the day (for the night shift workers).

The following gives a more detailed study of the factors just referred to.

**Diurnal Variations in Accident Frequency**

The frequency with which accidents occur from hour to hour during the course of the working day has been investigated in a large number of industries, and usually it is found that the variations show a considerable resemblance to one another. In the morning spell of work, which usually lasts four and a half or five hours, the accidents occurring in the first hour are comparatively infrequent. Other authors hold that accidents are relatively frequent in the first hour. In succeeding hours they rise rapidly till they reach a maximum in the last hour but one of the spell; whilst in the last hour they may fall off somewhat. This fall is due, partly or wholly, to the fact that the workers are apt to knock off work a few minutes before the end of the spell and make preparations for departure. Hence we are justified in saying that, having regard to the work done, the accident frequency tends to increase throughout the morning work spell, and it may be two to four times greater towards the end of the morning than it is at the beginning.

In the afternoon work spell it is more steady than in the morning, but usually it starts rather low in the first hour, works up to a maximum in the middle of the spell, and then falls off. It is often suggested that these variations of accident frequency are due chiefly to the fatigue incident to manual labour, for this fatigue must increase gradually during the course of work, whilst the fall of accident frequency which occurs between the end of the first work spell and the beginning of the next may be due to the recuperative effect of the meal hour.

Undoubtedly most industrial workers do get moderately fatigued by their daily round of work, but it appears that, as a rule, this fatigue is not sufficiently marked to account for more than a small fraction of the diurnal rise of accidents. This statement is substantiated by observing what happens to accident frequency when the workers are on night shift instead of on day shift. During the war there was plenty of opportunity for observing such shifts; and in the accompanying diagram are reproduced some of the results obtained by Vernon at a large
FUSE FACTORY OF 10,000 WORKERS. THESE RESULTS RELATE TO THE VERY NUMEROUS CUTS (USUALLY OF FINGERS AND THUMBS) WHICH WERE INCURRED BY THE WORKERS, AND TO THE LESS NUMEROUS EYE ACCIDENTS, DUE USUALLY TO SMALL METAL TURNINGS OR OTHER FOREIGN BODIES GETTING INTO THE EYE. IN THE STATISTICAL PERIODS STUDIED 13,251 OF THE FORMER ACCIDENTS OCCURRED AND 1,772 OF THE LATTER.

CONFINING ATTENTION FOR THE PRESENT TO THE YEARS 1916-1917, WHEN THE WORKERS PUT IN TWO 5-HOUR SPELLS OF WORK WHEN THEY WERE ON DAY SHIFT, AND THREE SPELLS, LASTING RESPECTIVELY 4½, 3½, AND 3 HOURS, WHEN THEY WERE ON NIGHT SHIFT, IT WILL BE SEEN THAT THE DAY SHIFT ACCIDENTS (CUTS) MORE OR LESS CONFORMED WITH THE PICTURE DRAWN ABOVE. THEY WERE AT A MINIMUM AT THE BEGINNING OF THE MORNING SPELL, AND RAPIDLY ROSE TILL THEY REACHED A MAXIMUM AT THE END OF IT. THEY DID, AS A MATTER OF FACT, FALL OFF DURING THE LAST FEW MINUTES, BUT IN THESE DATA THE ACCIDENTS OCCURRING DURING THE FIRST AND LAST QUARTER-OR HALF-HOUR OF EACH WORK SPELL HAVE BEEN IGNORED, BECAUSE THEY WERE INFLUENCED SO MUCH BY THE WORKERS NOT HAVING SETTLED DOWN PROPERLY TO WORK, OR BY THEIR HAVING CEASED TO WORK IN THE AFTERNOON WORK SPELL THE ACCIDENTS WERE MORE NUMEROUS THAN IN THE MORNING, AND THEY FIRST ROSE AND THEN FELL FOR THE MEN, THOUGH THEY FELL STEADILY FOR THE WOMEN. PASSING NOW TO THE NIGHT SHIFTS, IT WILL BE SEEN THAT, SO FAR FROM THE ACCIDENTS BEING AT A MINIMUM AT THE BEGINNING OF THE FIRST WORK SPELL, THEY WERE AT, OR NEAR, A MAXIMUM, AND THEN GRADUALLY FELL. THEY CONTINUED TO FALL FOR MOST OF THE NIGHT, AND IN THE LAST WORK SPELL THEY WERE ONLY TWO-THIRDS AS NUMEROUS AS IN THE FIRST WORK SPELL. THAT IS TO SAY, THE VERY SAME WORKERS WHEN THEY CHANGED FROM DAY SHIFT TO NIGHT SHIFT, SHOWED ALMOST A COMPLETE REVERSAL OF ACCIDENT FREQUENCY.

A SIMILAR RESULT WAS OBSERVED WITH OTHER GROUPS OF MUNITIONS WORKERS, BOTH IN ENGLAND AND IN AMERICA, AND THE EXPLANATION OF THE APPARENT CONTRADICTION IS PROBABLY TO BE FOUND IN THE PSYCHOLOGICAL STATE OF THE WORKERS. WHEN THEY CAME ON THE DAY SHIFT THEY WERE IN A DULL AND LETHARGIC CONDITION AS THEY HAD ONLY RECENTLY GOTTEN OUT OF BED, BUT THEY BRIGHTENED UP DURING THE COURSE OF THE MORNING AS THEY USUALLY HAD A CUP OF TEA AFTER TWO HOURS' WORK, AND THEY HAD THEIR DINNER BREAK TO LOOK FORWARD TO. CONSEQUENTLY, THEY BECAME MORE CARELESS AND INATTENTIVE, AND ACCIDENTS MULTIPLIED. THE NIGHT SHIFT, ON THE OTHER HAND, GOT UP THREE OR FOUR HOURS BEFORE THEY WERE DUE AT THE FACTORY, AND SPENT THESE HOURS IN RELAXATION AND AMUSEMENT, AND IN HAVING A SUBSTANTIAL MEAL. CONSEQUENTLY, THEY CAME TO THE FACTORY IN A LIVELY AND EXCITED STATE, AND THE CARELESSNESS THEREBY INDUCED CAUSED A MAXIMUM OF ACCIDENTS. THEY CALMED DOWN DURING THE COURSE OF THE NIGHT, AS THEY HAD NOTHING BUT BREAKFAST AND BED TO LOOK FORWARD TO, AND ACCIDENTS CONSEQUENTLY DIMINISHED.

IN STUDYING THE PRODUCTION CURVE OF WORKERS IN THE FACTORY ITSELF, PIERACCINI AND MAFFEI IN 1906 CAME TO THE CONCLUSION THAT THE FIRST STAGE OF THE WORK IS MORE UNCERTAIN AND LESS PROFITABLE THAN THE SECOND, DURING WHICH THE WORK ATTAINS AN EXCEPTIONALLY HIGH DEGREE REGARDED BOTH QUALITATIVELY AND QUANTITATIVELY AND THEREAFTER FOLLOWS A PERIOD OF HIGH AND STEADY PRODUCTION. THIS STATE, HOWEVER, SHOWS A PROGRESSIVE TENDENCY TO REDUCTION, AND WITH A CONTINUOUS SPELL OF WORK WITHOUT A REST INTERVAL IT LEADS MORE OR LESS RAPIDLY, ACCORDING TO THE TYPE AND RHYTHM OF THE WORK, TO A DETERIORATION IN THE QUALITY AND QUANTITY OF THE WORK ACCOMPLISHED.

EVIDENTLY GIVEN SIMILAR OBJECTIVE CONDITIONS — CONDITIONS OF RHYTHM AND OF WORK — THE ANTHROPOLOGICAL FACTOR PLAYS A HIGHLY IMPORTANT ROLE WHICH CANNOT BE IN GENERAL PRECISELY DEFINED. IT IS CERTAIN THAT PHYSIOLOGISTS AND HYGIENISTS SHOULD DEVOTE THEIR ATTENTION RATHER TO THE COST OF THE WORK TO THE SYSTEM THAN TO THE QUANTITY OF WORK WHICH THE ORGANISM IS CAPABLE OF ACCOMPLISHING. AN EQUAL QUANTITY OF USEFUL WORK REPRESENTS A VERY DIFFERENT EXPENDITURE OF ENERGY FOR DIFFERENT ORGANISMS (TREVES).

THE CURVE JUST REFERRED TO GIVES AN ACCURATE REPRODUCTION OF THE WEEKLY AND EVEN THE ANNUAL CURVE. IT, HOWEVER, SHOWS VERY MARKED SPECIAL FEATURES WHEN SEASONAL OCCUPATION OR RUSH WORK IS IN QUESTION.

THE FATIGUE FACTOR

THAT FATIGUE DOES NOT, AS A RULE, PLAY MUCH PART IN ACCIDENT CAUSATION IS WELL SHOWN BY COMPARING THE ACCIDENT FREQUENCY SHOWN IN THE DIAGRAM FOR THE YEAR 1915 WITH THAT IN 1916-1917. IN 1915 THE OPERATIVES WERE WORKING FOR 12 HOURS A DAY INSTEAD OF FOR 10 (I.E. FOR WORK SPELLS OF 5, 4½ AND 2½ HOURS' DURATION), AND IT WILL BE SEEN THAT THE MEN SUFFERED RATHER FEWER CUTS THAN THEY DID SUBSEQUENTLY, SO THEY CANNOT HAVE BEEN GREATLY FATIGUED BY THE EXCESSIVELY LONG HOURS OF WORK. WITH THE WOMEN IT WAS VERY DIFFERENT,
for the long hours threw them into a state of excessive fatigue. It will be seen from the diagram that though their accident frequency was about the same, for the first two hours, as that observed subsequently during the 10-hour working day, it rapidly mounted during the latter portion of the work spell, and on an average for the whole working day it was nearly three times greater than in the 10-hour day period. In men was very little affected. However, at a fuse factory in America it was found that men engaged in muscular work showed a greater increase of accidents as the day wore on than the machine workers, and this increase was presumably due to the fatigue entailed by the harder work. At the present day, when the hours of work seldom exceed 48 per week, the effect of fatigue on accident causation must be small in the great majority of industries. Undoubtedly extreme fatigue is a potent cause of accidents in men no less than in women, and striking instances of this are occasionally met with on the railways. Owing to unforeseen circumstances, a signalman or an engine-driver may have to work for an unduly long number of hours on end, and in consequence of his fatigue he may make a mistake which results in a terrible accident.

As an indication of the fatigue of the women, it may be mentioned that during the 12-hour day period they were treated for faintness at the factory surgery nine times more frequently than the men, whilst in the subsequent 10-hour day period they were treated only three times more frequently. Observations made at other factories confirmed the conclusion that whilst the accident frequency in women was increased by long working hours, that
**The Speed of Production Factor**

It is evident that accident frequency must be affected to some extent by the speed with which the articles are produced by the industrial worker. Each article may need the application of sharp tools, against which the hands or other parts of the body may be cut, and the more frequently the process is repeated the greater the risk.

Determinations of the hourly output during the course of the work spell generally show a relatively low output during the first hour, followed by a gradual rise which reaches a maximum towards the middle or end of the spell. For instance, the output curves recorded at the bottom of the above diagram, which represent the hourly output of the lathe and drill sections at the fuse factory during the years 1916 and 1917. During this time the rate at which certain typical articles were produced increased by 27 per cent. for the men and by 19 per cent. for the women, and at the same time the accident frequency increased by 48 and 14 per cent. respectively.

Modern scientific organisation is called on to revolutionise industry, to lead it towards a system of production superior to that followed at present; it must, however, take account of the “human factor”, for the speed of machinery, the sustained close attention demanded, and furthermore, the monotony of uniformly repeated operations characteristic of modern industry are all elements which tend towards wastage if not destruction of human energy.

**The Temperature and Ventilation Factors**

The degree of attention bestowed by a worker on his job is greatly influenced by the conditions under which he works, and atmospheric conditions are amongst the most important. Evidence on this point is troublesome to obtain, but during the war Osborne and Vernon regularly recorded the temperature at two large shell factories and at a fuse factory by means of the application of thermographs for a period of nine to twelve months. They found that the number of accidents (cuts) reached a minimum at a temperature of 18.3° to 20.6° C. (65° to 69° F.). At higher temperatures they rose rapidly, till at temperatures above 28.9° C. (75° F.) they were 23 per cent. more numerous than at the optimum temperature mentioned. This rise was presumably due to the workers getting more careless and inattentive during the hot weather, and confirmatory evidence of this hypothesis was obtained at a gold mine in Brazil. This mine (the Morro Velho) has reached the amazing depth of 6,400 feet, or 1½ miles, and it is, in fact, the deepest mine in the world. The working conditions were almost insupportable until a cooling plant was erected to cool down the intake air and thereby bring it towards a system of production that is superior to that followed at present; it must, however, take account of the monotony of uniformly repeated operations characteristic of modern industry are all elements which tend towards destruction of human energy.
numeros. There can be little doubt that this rapid increase of accidents at low temperatures was due to the workers losing some of their manual dexterity owing to the numbing of the fingers, for they were constantly handling shells and other metal objects.

The Lighting Factor

Accidents are often found to be considerably more numerous under conditions of artificial lighting than daylight. A Government enquiry into the lighting of factories was made in Great Britain, and it was found that on an average the accidents in a number of industries were 25 per cent. more numerous during hours of artificial lighting. Accidents due to "persons falling" were 75 per cent. more numerous, workers in docks showing an increase of no less than 120 per cent., whilst shipbuilders and ironfounders showed an increase of 99 per cent. In most industries it is found that night shift workers suffer more accidents than the day shift. In some steel works they were 16 per cent. more numerous on an average, but the workers in the yards showed an excess of 128 per cent., and those in the mechanical department one of 118 per cent. Probably this excess was due chiefly to defective lighting, for observations made in four large munition factories consistently showed fewer accidents by night than by day, the average difference being 17 per cent. However, the eye accidents were somewhat more numerous by night, those occurring in the least well lit factory being 41 per cent. in excess.

There can be no doubt that an adequate system of artificial lighting, even though it may be expensive to install, very soon pays for itself. Not only is accident frequency diminished, but there is an improvement of output which may amount to from 5 to 20 per cent.

The Experience and Age Factors

Inexperience is a very frequent cause of accidents, for it implies some lack of foresight and knowledge on the part of the worker and, in addition, a lack of manual skill and dexterity. Striking evidence was obtained by Chaney and Hanna concerning workers employed on stamping presses and other metal trade occupations. They found that on the first day of their work the operatives suffered 460 accidents, and in the next five days they suffered them at the rate of 83 per day. In the next three weeks the rate fell to 17 per day, and in the next five months to 5.2 a day. In the subsequent six months it fell to 1.8 per day, so the accidents were 235 times less frequent than at first. Data collected by Kitson and Campbell in factories where cutlery, railway-cars, and motor-cars were manufactured showed marked fluctuations of accident rate which corresponded closely with the numbers of new employees engaged; and it was concluded that if the labour turnover could be reduced to zero the number of accidents would probably be diminished by at least 75 per cent. As it is usually impossible to avoid some labour turnover, it would probably be worth while, from the economic point of view as well as on humanitarian grounds, to give new employees a preliminary week or two of training on fool-proof and dummy machines before they are put on to operate dangerous machinery.

Accident frequency continues to fall with increase of experience and age; at a large steel works, for instance, Chaney and Hanna found that whilst the employees had an accident frequency of 106 during their first year, the rate fell to 42 after four years' service, and to 9 after twelve years' service. Finally, the workers of over fifteen years' service suffered no accidents at all. This complete immunity is exceptional, especially considering the considerable number of men involved, namely, 37 affected workers employed for under six months, 14 workers employed for three to five years, and 3 only those employed for three to ten years.

However, though the accident frequency appears to diminish with the advance in the worker's age, the mortality and invalidity rates from accident increases with advanced age (Newbold). Newbold also found that though the accident frequency rate decreased with the advance in age of the worker and partly also with increase of experience, there was at similar ages no relation between the accident frequency rate and the amount of experience, whilst with a similar amount of experience the relation between the frequency rate and the worker's age was still maintained.

Recent statistics show that out of 54 accidents which occurred in a million working hours in the unhealthy trades 37 affected workers employed for under six months, 14 workers employed for three to five years, and 3 only those employed for three to ten years.

Even amongst operatives of the same age and experience the risks of accident are not equal. Thus Greenwood and Woods, in their observations on munition workers, found that some operatives were much more liable to suffer accidents than others who were employed...
on the same job. Apparently they possessed an innate clumsiness or carelessness.

In course of recent research, Newbold has shown that the average number of accidents amongst groups of workers was very markedly influenced by a relatively small number of workers who suffered from repeated accidents, and the distribution seemed far from being fortuitous. Certain workers are more subject to accidents than others, whether the cause may lie in varying working conditions, in the way in which the work is effected, or in the existence of a particular individual susceptibility which is besides persistently manifested by frequently recurring accidents at different periods, frequency of different types of accidents, frequently occurring accidents both in the factory and in the home. A closer study of such individual susceptibility calls for the application of psychological methods.

Accident frequency is similarly connected with slight indispositions attended to at dressing stations and first-aid posts, which again bear witness to the influence of the personal factor.

One of the factors which is of primary importance in accident causation is without doubt the course of employment. The accident rate rises and falls with the “up and down” of employment, the two corresponding closely in direction and duration. Increased employment brings increase of hazard growing out of the human element in accident causation (Hatch).

The Carelessness and Inattention Factors

No industrial worker can concentrate all his mental energies on his task for the whole of his working hours. His attention is bound to wander at times, and the more monotonous the task the more will his attention tend to scatter. In many types of industrial work such daydreams are harmless, for they may cause no reduction in the speed with which the task is performed and yet they will greatly diminish the feeling of boredom and monotony. When, however, the worker is employed on certain types of machinery, or is using sharp tools, carelessness and lack of attention may result in cuts to fingers and thumbs, or in more serious accidents. Hence it is necessary for him at almost all times to pay a certain amount of attention to the work in hand, though it is frequently found that he need not concentrate his mind fully upon it, except at certain critical periods.

Though the inattention of individual workers fluctuates a great deal from time to time, it is probable that, taking the workers as a group, their inattention tends to increase or decrease at certain times and under certain conditions, with consequent variations in their liability to accident. By studying these variations in accident frequency and the conditions which induce them much can be learned about accident causation and prevention.

Before, however, attributing an accident to carelessness or inattention it is necessary to make sure that other physio-pathological causes are excluded. The problem of accident causation is as complex as the human organism. Peri conducted, a few years ago, a very detailed enquiry in regard to a large total of accidents which occurred in a big Italian steel factory.

The frequency of accidents was found to affect those workers who lacked the requisite elements to ensure their physical integrity for instance (age, wages, experience, etc.).

The individual acquires adaptation to his task by learning the movements appropriate to its execution, forming special aptitude calculated to render such execution more perfect, and by avoiding all causes liable to harm his physical integrity.

Whilst the majority of workers forming the subject of Peri’s study had only had one or two accidents during four years, 393 workers had been ten to eleven times the victims of accidents. In fact, 2,338 workers had had 4,200 accidents or an average of 1.7 accidents per capita. These cases were distributed as follows (per 1,000 workers):

<table>
<thead>
<tr>
<th>No. of Accidents</th>
<th>0</th>
<th>1</th>
<th>2</th>
<th>3</th>
<th>4</th>
<th>5</th>
<th>6</th>
<th>7</th>

<td>6.8</td>
<td>3.4</td>
<td>2.1</td>
<td>1.2</td>
<td>1</td>
</tr>
</tbody>
</table>

One worker had been eleven times the victim of an accident. It is necessary, therefore, to accept Peri’s theory that certain individuals find adaptation to a given type of work impossible. This impossibility of adaptation is not only personal, it may affect an entire family. Peri, in fact, has succeeded in assembling data affecting one family of ten members with sound constitutions and enjoying excellent health from a physical and psychic point of view, but who nevertheless in a period of four years of short spells of work had a total of 25
accidents, certain of which were fairly serious. Not one of the ten persons in question was able to retain his constitution unimpaired.

It is certainly difficult to arrive in every instance at the precise determination of the cause of an accident for in the majority of cases several causes play their part. Negligence is in many instances the source of violent injury, but when the medical man investigates carefully the facts leading up to the production of the accident in question, he very often discovers deep-seated agents other than mere carelessness on the part of the worker. It may be found, for example, that the cause of the accident has been the worker’s unwillingness to adopt certain means of protection provided (mask, glasses, etc.), a mistaken idea, a lack of appreciation of the risk involved.

After a certain length of service the worker is apt to neglect paying the same attention to his work as at first. His movements become automatic unconscious, especially where it is a case of machine work. Consciousness is not called into play or should only be called into play for giving the alarm. It is usual to find in a workshop a series of several accidents of the same nature occurring, the explanation being fear and uncertainty which spreads from the victim of the first accident to his companions. Work is spoilt, movements become uncertain and lacking in precision.

How many accidents, however, of which the victim is the involuntary cause are due to serious nerve troubles or to defective senses the presence of which are unknown to the individual in question? How many railway mechanics, for instance, have suffered from colour blindness or other visual defects caused by latent diabetes or the result of syphilitic infection which they imagined had healed? How many accidents have their origin in psychic epilepsy which is so hard to detect or in psychoneurosis, etc.?

Dupuy and Schiff after examining in 1925 the mental state of 36 taxi-drivers found that 35 suffered from serious neuro-pathological troubles, 12 from psychasthenia, 2 from manic-depression, 5 from epilepsy, 5 from chronic alcoholism, 5 from alcoholism with symptoms of dementia, 10 from general paralysis, etc.

Similarly as regards alcoholism the danger is not so much from workers who enter the factory slightly intoxicated as frequently happens after an unduly large meal, but from those workers who are in a chronic state of intoxication. It is such workers who constitute a real danger to themselves and others. Peri was able to collect data in relation to twenty-seven such workers who had met with 150 accidents; four of them had each had 12 accidents.

Undue indulgence in alcoholic liquors is a potent cause of industrial accidents, for it increases carelessness and inattention and may cause a reduction of manual skill. In a critical survey of available evidence, Voionmaa came to the conclusion that chronic alcoholism is a much more important cause of accidents than acute alcoholism. Persons medically certified as excessive drinkers have been found to be about three times more liable to accidents than other persons, and to injure themselves more seriously. Again, by merely controlling the sale of liquor in certain factories, or by stopping the supply of free beer, accident rates were decreased by 30 to 70 per cent.

Criminality is also a factor which should not be overlooked. It is not, however, possible to evolve general conclusions from the restricted data available. Peri nevertheless enquires whether it would not be of interest to study this aspect of the problem in detail in order to ascertain the existence of a possible relation between individuals incapable of adaptation to their social surroundings and those possessing a like incapacity as regards working conditions.

THE PREVENTION OF ACCIDENTS

The above discussion of accident causation has revealed a number of ways in which accident frequency may be reduced. Taking the evidence as a whole, it appears that by far the most fruitful method of eliminating accidents is to influence the physical state of the worker by diminishing his carelessness and inattention. The "Safety First" movement, which has spread so widely of recent years, depends fundamentally on the principle of cultivating what may be termed a "safety habit of mind" in the workers. To this end, it is necessary to take every possible opportunity of impressing on the workers the importance of observing precautions to avoid accidents.

The conclusion which can be drawn from what has just been said is that the problem of producing a general level of safety conditions high enough to prevent the rather paradoxical phenomenon of an increase in industrial accident hazards in times of rising business prosperity is mainly a problem...
of safety education rather than of mechanical safeguarding (Hatch).

To protect a machine by guards is not an extended process, and once done the machine stays safe so far as the purely mechanical element is concerned. But teaching good housekeeping and safe conduct in work places is a slow process of education both of workers and supervising authorities, and the results—stay put—only under continuous maintenance of teaching and morale of old employees, while with the advent of new employees the whole slow process has largely to be built again from the bottom, as it were.

In all prophylactic effort the main object is to understand the risk and be able to analyse it into its primary elements. Since a machine does not always and everywhere give rise to the same kind of accident, and the reaction of the individual to an injurious influence varies according to the personality of the subject, it is indispensable to have exact and detailed knowledge of each case in order to arrive at a scientifically established system of prevention. Precautions of a general character will never suffice in daily practice unless enforced in conjunction with a well organised system of social protection. For this reason Mr. Davis, Secretary to the Labour Department of the United States, recently (1925) demanded from Congress authority and an appropriate grant in order to assemble all available data concerning accidents and their prevention, for which purpose a statistical method on a uniform basis is required for this purpose is that the chem-

Accumulators (Storage Batteries)

GENERAL REMARKS

The term "electric accumulator" is given to a galvanic element which, acting as a reversible cell, can accumulate electric energy. It owes this property to the fact that after running down it can be restored to its initial state by simply passing a current, the charging current, in the opposite direction to that of the current of discharge. The condition required for this purpose is that the chem-
ical reactions are similar, but reversed, during the two operations, discharging and charging.

It was the French physician Gautherot who noticed for the first time in 1801 the reversibility of cells. Plante made the discovery of the lead accumulator (1859), to which Faure in 1881 added important improvements.

Single accumulators are rarely used. As a general rule a number are grouped together in tension to form a battery of accumulators. Their uses are various and are extending from day to day.

This fact is due to two causes.

The first is that batteries can be used in a fixed position, for example, for motor-power in factories, for central lighting stations, for central telegraph and telephone offices, for scientific or industrial laboratories, or for workrooms for galvanoplastics; or can be quite easily carried about, for example, movable batteries for tramways, pleasure boats, submarines, and automobiles.

The second is that they have various uses. As accumulators properly so called they are used in electric traction on tramways, boats, automobiles, and railways, or in workshops or dwelling houses where their use is easy to supervise, which is not the case with dynamos or moving machinery. As transformers of electric energy the combinations to which they lend themselves in coupling allow the two factors of power from a given source to be varied at will, namely, the tension and the volume of the current, while at the same time the energy which they have accumulated can be stored for either a long or short period. As supply regulators in installations for continuous current, they serve to keep constant the factors of power from a source to which they are connected. Finally, as emergency aids they are installed to make good momentary defects in the irregular working of motor-generators.

In consideration of their many advantages and the ever increasing number of uses to which they are being put, electric accumulators have been the subject of numerous investigations in order to perfect and adapt them to required conditions by fresh modifications: and in this way a great variety of types has been invented.

From the special point of view in question in this article, namely, consideration of processes and dangers arising in their manufacture, accumulators may be divided into two main groups: first, lead accumulators, and, secondly, accumulators in which metals other than lead are used.

The second group do not exact much attention. As a matter of fact, accumulators which have not a lead base have up to the present, in spite of their interest, proved generally inferior to others and consequently their use remains very limited. This is all the more to be regretted in that their manufacture does not expose the workmen to lead poisonings, which, as will be seen, constitutes the chief danger in the manufacture of accumulators. It is to be hoped, then, that a type of accumulator of this second group may one day be evolved in a form in which it can be substituted for the first type. By way of example the following may be cited:

Gas accumulators with electrodes of platinum or palladium; these cannot be put to practical use owing to the extraordinary high price of the materials used.

Accumulators with an alkaline electrolyte, such as potash, in which the cathode consists of a thin plate of zinc, and the anode of oxide of copper or oxide of nickel: they present disadvantages owing to solubility of the metal of the cathode and of partial solubility of the anode.

Halogen accumulators use for the cathode an incorrodable metal, for the anode an incorrodable conducting substance, and for the electrolyte a metallic haloid salt, e.g. chloride of zinc, bromide of zinc, chloride of iron, chloride of bromium, or chloride of silver. But these accumulators are of inferior efficiency, or their price is too high.

Finally, there are accumulators with an unvarying electrolyte, in which the electrolyte does not take part in the reactions; they operate on discharge by oxidation at the cathode and reduction at the anode, and in charging by a reversed condition of things. A type of this variety has been applied to some industrial uses: this is the iron-potash-oxide of nickel accumulator of Jungner and Edison. It is used especially for movable batteries; it has the advantage of having electrodes that last longer than those of lead accumulators, but the disadvantage of being of higher net cost and entailing an additional expense in current, in consequence of the low output of energy.

**MANUFACTURE OF LEAD ACCUMULATORS**

An accumulator is essentially made up by electrodes set in a cell which encloses the electrolyte as well. Different accessories are added.

A description of the manufacture of the plates or electrodes, and of the other elements, as well as the putting together of the accumulator, will be considered successively.

First of all it must not be forgotten that formerly most makers each used a single type of plate which was supposed to respond to all uses. It is thus that a firm constructs several types of plate and elements, intended to be used for different purposes. However, the processes of manufacture, and especially the composition of the active materials, vary considerably from one make to another, and it is these peculiarities which have to be pointed out.
**Preparation of the Metal**

Lead intended for the making of accumulators is received at the factory either in the form of ingots or in that of old plates or disused scrap metal.

The utilisation of old plates and scrap metal require to be preceded by a process, the object of which is not only to ensure the melting of the grids, but also to effect the destruction, by reduction, of the oxides of lead which these elements may contain.

This operation is carried out in a reducing furnace, heated generally by coal.

The lead obtained is then run into the ingot moulds with a view to using it later on in combination with commercial metal.

In some factories the positive plates are treated mechanically in special apparatus, with a view to extracting, for commercial purposes, any peroxide of lead which they may contain.

**Manufacture of Plates**

Two varieties of lead plates are used for electrodes. One type of plate has a large surface; it is made of soft lead, and is characterised by the development of as large a surface as possible; the shape most commonly made has fairly strong horizontal ribs and fine vertical ribs close together. The second type of plate has renewable oxide; it is made of so-called unoxidisable lead, generally an alloy of lead and antimony, and has interstices which are subsequently filled with material in paste form. In this case the plate is in lattice-work, like a grid, with a simple frame surrounding a large lozenge of active material.

In order to obtain the plates, lead ingots are worked up either by the processes of casting, that is to say, at a temperature at least equal to that of melting, or by the low temperature process.

For casting plates, which is the process most commonly employed, lead ingots and old plates that can be re-used, are melted in cast iron pots at a temperature which should reach that at which pure lead melts, about 327°C. Then the metal is poured into steel or copper moulds, which are sometimes powdered with finely crushed steatite, and sometimes covered with lamp-black by means of acetylene jets. Each process has the disadvantage of discharging into the air either dust or smoke.

This work is done, sometimes by machinery, occasionally under pressure or in a vacuum with an exhaust, and sometimes by hand, which necessitates the moulder standing close to the melting pot in order to remove the dross and pour out the melted lead from a ladle.

The process at a low temperature is intended for obtaining, in the case of large surface plates, a development as extensive as possible and also a very homogeneous lead. Sometimes plates are made like lead tubes by thrusting the lead, brought to a malleable state by heat, through a die of the required shape. Sometimes a smooth plate of soft lead is taken and the surface is worked mechanically to produce fine active ribs by means of a Heimann machine, or that of Majert or by special milling tools.

After being made, plates must be submitted to accessory operations. Rough edges from the casting and seams are removed by means of files, scrapers, and iron-wire brushes. When the plates have been cast two at a time, they must be separated by a saw. Some are only supplied afterwards with the lugs for taking the current and suspension hooks; these parts are fixed by autogenous welding.

The plates of the second category, i.e. plates of the Faure kind, or those filled with active material, must be completed after making by the addition of a mixture called paste.

The pastes are of different composition depending on the requirements. They have as their basis either oxides of lead (litharge, minium, or a mixture of them); or, more rarely, pulverised lead, obtained by projecting a strong current of hot air on to a fine jet of melted lead; or, yet again, a salt of lead, usually chloride of lead, used in the softened or melted state. To these are added either substances designated as binders whose rôle is to cement the mass and to make it mechanically sufficiently resisting, or other substances which are removed after the pasting and leave the mass more porous. Whatever paste may be used it generally has for a base sulphuric acid, and it is owing to the sulphuric acid that the material consolidates and hardens, in consequence of the formation of lead sulphate in the mass. Sometimes the oxides are worked up first with water, and it is only after the pasting that the plates are soaked in the acid. Sulphuric acid can also be replaced entirely or partially by alkaline sulphates or alkaline earths. As agglutinating substances the following are freely used: phenol dissolved in water (especially in the case of
plates with frames), glycerine, glue, and ammonia.

The materials which are used in the preparation of the paste are received as powder, dry or mixed with liquid, and are weighed, mixed and blended under very different conditions according to the factories. Sometimes the mixing and blending is done in a hermetically closed apparatus; sometimes the materials are emptied into an enclosed space where they are weighed and mixed by a workman who stands outside and carries out these operations through an opening made in the side of the protecting box; sometimes the work is done in glass receptacles connected with a large chimney used for an exhaust draught; sometimes the weighing, mixing and kneading is done in the open air on ordinary scales in open apparatus; sometimes even without any exhaust arrangement and without any protecting apparatus.

In order to use the paste, that is to say, in dressing the plate with active material there are two quite distinct processes.

The first, which is more usual, consists in introducing active material into the prepared frame, that is to say, into the spaces of lattice work. This operation is often used in which the plate is arranged in position, the melted lead being poured on the plate. Sometimes the work is done in a glass spatula or the palm of the hand, or mechanically; sometimes by means of a hydraulic press.

The second method consists in making lozenges of active material around which, after they have been arranged in position, the melted lead is run to form a lattice pattern. This method is used particularly when the active material can be moulded into lozenges at a higher melting point than that of lead, as is the case with chloride of lead. With it the reverse process cannot take place, for chloride of lead cannot be cast into a lattice-patterned plate since lead melts at a lower temperature.

Pasters work under quite different conditions in different factories. Their work-benches may or may not be supplied with exhaust draughts. These work-benches are sometimes made entirely of wood; they then become impregnated with lead dust and cannot be thoroughly cleaned. Tables covered with plate glass are preferable, especially when a wooden edge prevents dust from the paste and debris from falling on the floor.

After pasting, the plates must be dried. This operation is done either in the actual workshop where the pasting is done or in special rooms, or in a stove. Sometimes, to speed up the drying, after the pasting, strips of paper are put on the plates and these are subsequently torn off and often actually thrown on the ground of the workshops.

Finally they are scraped, brushed and polished with the special object of freeing their edges and points of connection from irregularities of active material, which work is carried out mechanically or by hand.

Both types of plates, plates with large surfaces and plates charged with active material, must be subjected before being put into use to an electric treatment known as "forming" (first charging), which consists essentially in exposing them for a sufficient time to the action of an electric current which gives them their definite chemical composition.

This is an extremely delicate operation.

In the case of pasted plates, the first charge has for its object the transfer of them into peroxide if they are positive, and if negative into spongy lead. It simply consists of one charge in weak sulphuric acid or in an alkaline sulphate, the plate being put as anode in the first case, and as cathode in the second. When the paste has been prepared with chloride of lead, formation consists in a reduction of the salt into spongy lead, a reduction which can be effected by putting the plates to be reduced in contact with sheets of zinc.

For plates with large surfaces the method usually adopted consists in producing the active material at the expense of the soft lead of which the plate is composed; one part of this soft lead is transformed either into peroxide or into spongy lead, whilst the resisting part acts as support and conductor. This is autogenous formation in opposition to the heterogeneous formation of pasted plates.

Different processes are employed for autogenous formation. Planté formation is often used in which the plate is subjected to successive periods of charge and discharge, with a reversal of the direction from time to time; this method has the disadvantage of being long and costly. Electro-chemical formation only requires a charge in one direction, in order to cause sufficiently deep peroxidation of the active soft lead; it is obtained by the addition of sulphuric acid to different substances: either to nitric acid or alkaline nitrates or to organic acids, or to chlorates, bichromates, permanganates, etc. It is necessary there-
after to remove completely from the prepared plate all trace of added material which may be injurious to its preservation: this is done by washing in appropriate solutions. Formation by purely chemical action, such as by nitric acid, or by electrolytic deposit obtained by decomposition of a lead salt, are two methods very little used.

Mounting Lead Accumulators

The plates, or electrodes, as well as the electrolyte, are brought together by means of different accessories and joined up to make the accumulator. The most important of the accessories is the receptacle which holds the parts. Its principal quality is to resist attack by sulphuric acid, which condition very much limits the choice of substances which can be used to such things as glass, ebonite, celluloid, lead, and gummitite. Glass is used if the cells are of small or medium dimensions and the batteries are fixed in position; ebonite and celluloid are used for transportable batteries; lead for batteries in fixed positions. These last are generally made of a case of wood with a lining of lead; more rarely they are entirely of lead containing antimony. Ebonite cells are those most used in transportable batteries. Celluloid is only used when there is no danger from sparks which might set it on fire. Celluloid has the advantage of being very easily stuck together by special glues obtained by dissolving celluloid in acetone or acetate of amyl.

The connecting up of plates of the same polarity must be made, secure with bolts or autogenous welding; this latter is done electrically or by a hydrogen blowpipe. The men who do this welding or burning proceed in different ways. Sometimes they bring together the ends of the plates and a lead cap, upon which the blowpipe is directed, and, in order not to diminish the thickness of the metal where the burning is done, the worker holds in the other hand a stick of lead, from the extremity of which, as it melts, drops fall on to the parts already in apposition. Sometimes the ends of the plates are arranged in a special mould into which very hot lead from a ladle is poured.

The plates are arranged vertically in the cells which are filled with acid; they rest on grooved bars or are suspended by hooks, and are separated one from another by rods or sheets of glass, wood, ebonite or celluloid, or by porous sheets of wood, peat, porous earth, etc. The plates are then fixed to the cover of the accumulator and to the external connections. This last operation again requires lead burning.

Sources of Danger

The above technical details show that workmen are exposed to many troubles and numerous dangers in the course of the manufacture of accumulators. The most common and most serious arise, according to all evidence, from the handling of lead, and of its oxides and salts. Experts in different countries are all of opinion that this industry is to-day the one which causes the greatest number of cases of lead poisoning.

Risk of Lead Poisoning

It may be said that all operations required for the manufacture of lead accumulators expose the workmen to this serious poisoning, either by direct contact with lead and its compounds or by the inhalation of lead fumes and dust.

In one factory the dust collected in the yard contained 40 per cent. by weight of metallic lead. The proportion was 12 per cent. outside the premises in front of the entrance gate. Inside the workshops on account of frequent cleaning, this proportion is decidedly less, but still quite appreciable. In one workshop where plate-casting is done, the dust contained 0.2 per cent. of lead on the ground and 0.1 per cent. at a height of one to two metres above the ground (Agasse-LaFont). A primary risk occurs at the very moment when the metal and its alloys are prepared, that is to say, during the manipulation of new ingots or old plates; in the course of analysis undertaken to determine the exact quality of the ingots used; during the charging of the reducing furnace; during the casting of the metal in ingot moulds; during the collection of the slag drawn off from the reducing furnace after casting. This last operation, although done in the open air, is a source of lead-laden dust. In the course of an enquiry, an estimation was carried out in the open air, in the vicinity of workmen carrying on charging, by Heim de Balsac, Agasse-LaFont, Feil and Pouilbot, who observed the presence of 0.0002 gm. of lead per cubic metre of air.
The work of casting and moulding plates brings the workman into contact with fumes and dust. It has undoubtedly been maintained that melted lead in the cauldrons should be below the evaporating point. But it has been proved that fumes come off when the lead reaches 450° C. Moreover the extreme thinness of certain parts of accumulator plates makes it necessary for casting that the alloy should reach a high temperature which in practice frequently reaches 700° C. The evolution of lead fumes is greatly facilitated by this high temperature.

Various samples and estimations made in plate foundries by the above-mentioned experts gave the following results:

**Plate Foundry**:

- **(a) Sample taken under ventilating hood**:  
  - Fumes per cubic metre of air: 0.0024 grm.  
  - Dust: 0.00025 grm.  
  - Total: 0.00065 grm.

- **(b) Sample taken outside ventilating hood**:  
  - First test:  
    - Fumes per cubic metre of air: 0.0012 grm.  
    - Dust: 0.000768 grm.  
    - Total: 0.001988 grm.  
  - Second test:  
    - Fumes per cubic metre of air: Traces.  
    - Dust: 0.0004 grm.

In the first test the melting pots were supplied with ventilating hoods in which the exhaust was clearly insufficient. In the same workshop at a distance of about six metres from the melting pots, the presence of 0.0007 grm. of lead fumes per cubic metre of air was also found.

**Foundry for Accessories**:

- **Fumes per cubic metre of air**: 0.00047 grm.  
- **Dust**: 0.000082 grm.  
- **Total**: 0.000552 grm.

Often after having skimmed the melting pots the moulder throws the dross on to the floor, where it is trampled on and reduced to dust, which spreads into the air. The danger varies in the melting shop according as to whether suitable precautions are taken or not, to whether the number of melting pots is greater or less, and to whether exhaust installation is used or not.

Operations, which are auxiliary to the work at the foundry, such as scraping and brushing the plates, and soldering the attachments, also give rise to dust and lead fumes. At the level of the face of a workwoman, whose work was to do the scraping, the authors quoted found 0.0012 grm. of lead per cubic metre of air. The extent of the danger from burning is variously estimated; by some it is regarded as one of the most dangerous operations; by others, on the contrary, it is held to be less harmful than pasting and other operations in which dry oxides are used. Nevertheless it happens that burning may be carried on in the same place as melting, when the burners are exposed, in addition, to danger from fumes arising from melting pots.

For certain plates the formation of grooves and ribs is done by machines, the plates being kept cool by means of oil and water. Although this method eliminates fumes and dust, direct contact with the metal, which may soil the hands, offers some danger if attention is not paid to the cleanliness necessary.

Pasting and smearing (tartinage) the plates, which are preceded by the preparation of the paste or the mixing of the oxides, litharge and minium, are two equally dangerous processes.

The preparation of the paste deals with the oxides of lead in a pulverised state. This operation is usually done by hand, and there is no doubt but that it gives rise to the liberation of lead dust, which is all the more dangerous from the fact that it is produced at the breathing level of whoever has to carry on the work.

On the other hand, this dust appears to fall again very rapidly on to the ground on account of its density. Some tests made in a place used for the preparation of paste gave these results:

- **(a) Before the operation of weighing and mixing the oxides of lead**: traces which could not be estimated.
- **(b) During the weighing and mixing of the oxides**: 0.0018 grm. of lead per cubic metre of air.
- **(c) During wet mixing**: traces.

Sometimes the workman, to prevent the paste from sticking, throws handfuls of dry litharge on to the tray where the mixing is done; this proceeding increases considerably the amount of dust.

In the operation of smearing the materials are used in the state of paste; there is then little to fear from dust in the course of the operation. Nevertheless fragments of paste remain stuck to the worktable, where they dry and, combined with the handling of the plates, can lead to the generation of dust. At the workplace of a man employed on smearing, 0.0012 grm. of
lead dust per cubic metre of air was found.

The facing of the plates with lead powder is a particularly dusty operation.

The drying of plates in stoves necessitates the workman entering these places, where the temperature may reach 80° C., in order to put in or take out the plates. In one factory some samples of air taken in a drying stove while in use gave the following results:

<table>
<thead>
<tr>

<td></td>
</tr>
</tbody>
</table>

The formation (first charging) of plates does not give rise to any dust. Apart from contact of workers' hands with lead, a point which will be referred to later, the conditions of hygiene and safety in workshops in which formation is done are of the same kind as are observed in the rooms where accumulators are in use.

Burning of the connections on the finished plates must receive attention. For one thing the temperature required to assure autogenous burning of the various parts may cause the emission of lead fumes, and then also the handling of dry plates may facilitate the deposit on the worktables of particles detached from the spaces and capable of giving rise to dust.

Some tests carried out in Germany, which consisted in suspending a moistened filter paper above a blowpipe, have shown that volatilisation of lead occurs with the oxyhydrogen flame (see also questions "Lead" and "Oxidising").

According to Hamilton, the operations in the manufacture of accumulators may be classified from the viewpoint of risk of industrial lead poisoning as follows: mixing, pasting, assembling, and soldering. Much less dangerous are the operations of melting and trimming. According to Drancourt (France, 1904) those most affected were the men employed in mixing, next in order those who cast the electrodes, those who did the sawing and the trimmers. English statistics give a table of figures of which show the gradation of risk of lead poisoning in this industry.

It is stated that in the United States a mixture of hydrogen and air is used for burning, whilst in other countries the oxyhydrogen flame is used which is hotter and in consequence liable to produce greater volatilisation of lead.

Besides, from the fact that a large number of other operations are carried on in the burning workshop, it is generally difficult to estimate exactly the quantity of lead volatilised or to determine in what measure the poisoning of burners is due to the generation of dust or the volatilisation of lead.

Scraping, brushing, and polishing of the attachments and edges of plates, operations which complete the preparation of certain elements, set free a good deal of dust. Done by hand and without an exhaust they would be very dangerous. On the other hand, when done by means of mechanical brushes fitted with an exhaust they seem to be hardly injurious at all. A sample of air from a workshop in which this work was done gave a negative result from the point of view of the presence of lead. But the presence of 0.0026 grm. of lead per cubic metre of air found at the exit of the ventilator, in spite of the great volume of air evacuated and the presence of a drum of water intended to arrest the dust, showed the danger with which this operation would be accompanied if the dust were not evacuated and carried off as quickly as it is produced (Heim de Balsac, Agasse-Lafont, Feli, and Pouillot).

Finishing, which necessitates lead burning by means of the oxyhydrogen flame in order to fix the electrodes to the lid of the accumulator and to external connections, involves dangers which have already been pointed out.

It is the same as regards the construction of cells of large dimensions, made of wood lined inside with sheets of lead, the edges of which must be soldered together. During this work the workman is obliged to put his head inside the box in order to make sure the joints are good and will not allow liquid to leak.

An enquiry made by the principal chemist of the English Government to determine the quantity of lead fumes and dust set free in the accumulator industry gives the following rates:

<table>
<thead>
<tr>
<th>Number of tests</th>
<th>Duration of test in hours</th>
<th>Number of cubic feet of air aspirated</th>
<th>Quantity of lead in aspirating apparatus, grm.</th>
<th>Weight of sample in grm.</th>
<th>Percentage of lead</th>
</tr>

</table>
In order to interpret accurately these figures it is necessary to take into account the observations made by the medical inspector in his report for 1908 (pages 119-120).

The presence and quantity of lead and lead fumes have been demonstrated not only in the air of workshops, but also in the nasal cavities and on the hands of workmen.

The French experts already quoted have collected dust, by swabbing the nasal fossae with a swab of absorbent wool, of which the lead content was found to be as follows:

Other Sources of Danger

Although less important and only affecting a group of workmen here and there, a number of other causes of industrial ill-health due to the manufacture of accumulators should at least be enumerated.

First comes the inhalation of sulphuric acid fumes. This danger exists particularly at the time of first charging, the bubbles which then rise carrying with them drops of acid.

The action of these acid fumes has been the object of several enquiries. The acid droplets which are suspended in the atmosphere irritate the mucous membrane and, without doubt, cause a certain number of cases of irritation, but serious injury to the respiratory passages is not known. Bottrich (1916) has even affirmed that these acid fumes exercise a favourable action on the system, which is denied by Chyzer, who found, in 1908, that the quantity of acid deposited on 1 m. of surface can be estimated at 1.28 grm. (with open windows) and even at 2.97 grm. (with closed windows). Rambousek attributed dental lesions found among workmen in this industry to these fumes. However, regrettable consequences, such as bronchitis and epistaxis, are to-day doubted by most experts.

The irritating action of sulphur dioxide has also been pointed out among persons employed in the formation department.

Inhalation of ammoniacal vapours occurs when preparing the paste; most of the liquids used for moistening contain a variable proportion. In a place used for preparing paste 0.35 grm. of ammonia gas (N H) per cubic metre of air was found.

The use of illuminating gas or coal, particularly during casting with the use of compressed air, introduces a risk of carbon monoxide poisoning. The use of autogenous solder may cause the injuries described in the article "Soldering".

Mercury is used in the state of an amalgam, since, in order to avoid corrosion of zinc electrodes, they are dipped in a solution of mercury in nitric or nitro-hydrochloric acid. Attention has been drawn to several cases of mercurial poisoning by Teleky. A mixture of lead and mercury for soldering has also been used, especially during the war. During this operation mercurial fumes are set free, which have given rise to several cases of subacute mercurial poisoning (Devoto, etc). Sublimate, about 30 grm. per kilogram of metal, is also used for dry batteries.

The possible presence of arsenic in lead ingots is considered as the cause of arsenical poisoning by some authors. But if this ever occurs it must be rare, for it appears that lead containing arsenic would not be suitable for making accumulators.

Kober and Hayhurst mention some cases of poisoning by arseniuretted hydrogen.

The manufacture of small cells for portable accumulators by means of
celluloid compels men or women to handle celluloid powder, which is very inflammable and gives off a strong smell of camphor; and also a cement in the preparation of which is kept secret and which gives off a tart, acridulated smell, rather like that of English acid drops. Without knowing its exact composition, it is made up chiefly of a mixture of acetate of amyl and acetone (Zapon lacquer).

An investigation made by Heim, Agasse-Lafont, and Feil among workmen employed on this work led to the following observations:

Cephalalgia seemed to constitute the only clinical symptom: it was especially acute in the early days of employment before the workwomen had become accustomed to the smell of the camphor; later, when they were inured to it, the headaches were slighter and even completely disappeared in many cases.

Examination of the blood showed eosinophilia five times out of a total of eight sick persons examined: the eosinophilia was equal to, or above, 4 per cent.; like the cephalalgia, it must be attributed to the effect of the poisonous substances used.

It is probable, without it being possible to bring certain proof, that the cephalalgia is attributable to camphor fumes which seem particularly to trouble the patients.

Eosinophilia must rather depend on the action of acetone and acetate of amyl on the blood.

Finally, as rarer manifestations and of less importance, attention should be drawn to pneumoconiosis, caused by the inhalation of the various dusts and in particular of talc used frequently in the foundry (0.6 grm. per cubic metre has been found in the atmosphere of a workshop); to trade eczematous dermatitis, from the use of gum arabic and rectified spirit for the making of insulating plates in mica; to burns, from melted lead or acids; to eye troubles, from the action of ultra-violet rays which certain methods of heating emit; to brassfounders’ ague, when there is in the factory a department making brass objects (Kober); and to electric accidents, from discharge among those who test apparatus.

During the manufacture of dry batteries, workmen are required to handle benzoil, sulphuric acid, phenol, pitch, chloride of zinc, and mercury.

Attention must be specially drawn to cutaneous lesions, which are quite frequent and generally are due to the irritating action of these products. Rare and even doubtful are cases of cancer of the skin described among these workmen, which some would attribute to the action either of coal dust or the chemical products handled.

**STATISTICS**

In Germany the statistics which are available are rather out of date. Those of Wagener (1902) deal with a factory (unknown) in which cases of sickness occurred at the following rates among the workmen of different classes: casters, 10 per cent.; burners, 37.5 per cent.; pasters, 30 per cent.; mounters, 0.3 per cent. It is curious to notice that the expert in question emphasised the rarity of lead poisoning in this factory.

In Prussia, 28 cases were noted (out of a total of 619 cases of lead poisoning), in 1910, 26 in 1911 (total 738), 17 in 1912 (total 1,119).

In 1913 an enquiry made by Schultze enabled him to report that the hygienic and sanitary conditions in the factories visited, and even in the small factories, were good.

Yet according to the reports of inspectors it is stated that at Berlin in a factory employing 1,100 workmen, 40 cases were reported in 1920 with a duration varying from one to three weeks; in 1921, still at Berlin, 29 cases of lead poisoning were reported from accumulator factories out of a total of 48 cases of lead poisoning. Of these 29 cases, 18 were pasters, 6 casters, and 3 formers. In 1922 a factory reported 45 cases against 25 in 1921. Generally it was the unskilled workmen who were affected.

In Austria during an enquiry made in 1921 by the factory inspectorate in an accumulator factory, all the workmen much exposed to risk of lead poisoning showed marked signs of lead absorption.

Some States of the United States of America furnish us with statistics on the frequency of lead poisoning in the accumulator industry. In the State of Illinois, for example, from 1 July 1920 to 30 June 1922, out of 318 cases of lead poisoning reported, 29 occurred among workmen in accumulator factories.

During his enquiry in the State of Ohio, Hayhurst visited nine accumulator factories and reported employment on a large scale of untrained workmen, ignorant of the simplest hygienic measures. He also noticed that methods for carrying off dust, vapours, and poisonous fumes did not exist or were inadequate, which explained the very large number of workmen affected with lead poisoning. According to Hayhurst the manufacture of accumulators is the industry in which causes the greatest number of cases of lead poisoning, after that of the oxides and salts of lead. The same conclusions have been drawn from an enquiry into dry-battery factories. From 1 July 1920 to 30 June 1925, out of 443 cases of lead poisoning, 145 had been observed in accumulator factories.

In the State of New York from 1912 to 1925, 722 cases of lead poisoning were
notified, of which 152 were from accumulator factories. The enquiry of Hamilton (1914), dealing with the most important factories of the United States, which was repeated in 1918, also brought to light some interesting figures, showing that five factories employing (during the previous year) 915 workmen had notified 164 cases (17.9 per cent.) of lead poisoning. Moreover, the work was generally — according to Hamilton — such as did not require any special qualification on the part of the workman, who also received very poor wages. In consequence the changes in personnel (labour turnover) were very great. Cases of lead poisoning occurred after quite a brief exposure to the poison: in 3 cases after less than a month's work, in 41 before six months, and in only 7 (out of 70) after a year's employment. Statistics arranged by categories were as follows:

<table>

</table>

Generally, the illness takes the form of lead colic. In 40 cases, closely studied, there were noticed colic 24 times, abdominal pains 9 times, intestinal trouble 7 times, marked anaemia 22 times, constipation 27 times, diarrhoea 3 times, muscular pains 7 times, vomiting 7 times, headache 9 times, persistent nausea 4 times, nervous symptoms 23 times of which there were 3 cases of paresis, 4 cases of paresis of the hand, 1 case of delirium, and 1 case of epileptic convulsions.

In France as early as 1904 Drancourt, an inspector of factories, drew attention to danger of lead poisoning in the accumulator factories of the Department of the Seine. Those most affected were workmen employed on mixing, and those who cast the electrodes, the cutters and trimmers.

The application of compensation legislation to lead poisoning enables the following figures to be given: in 1921 there were 18 cases in the accumulator industry out of 144 cases of lead poisoning (12.5 per cent.); in 1922, 180 cases out of a total of 797 (22.58 per cent.); in 1923, 250 out of 1,025 (24.29 per cent.); and in 1924, 250 out of 1,343 (31.79 per cent.).

Two recent investigations by Heim de Balsac, Agasse-Lafont, and Feil give an idea of the danger which threatens these workmen, varying with the nature of their work. A group of 50 workmen employed on various kinds of work gave the following figures which relate to clinical and haematological indications of lead poisoning as well as the number of acute attacks:

<table>
<thead>
<tr>
<th>Classification</th>
<th>Persons employed</th>
<th>Number of cases of lead poisoning</th>

These investigations have led to the following conclusions:

(1) Workmen employed in the manufacture of accumulators show a very high percentage of symptoms and acute attacks of lead poisoning which far exceeds that found in other lead industries.

(2) It is among smeealers (tartineurs) and pasters, and also the mixers, that indications of lead absorption most frequently occur. This group especially needs medical supervision.

(3) Among haematological indications, in addition to the very frequent presence of red blood cells with basophilic granules, a condition almost pathognomonic of lead poisoning, the importance of which is today well known, there are sometimes found nucleated red cells (normoblasts). It is also quite characteristic for the blood in lead poisoning to include these elements apart from any serious anaemia. Experimentally this fact has been for a long time fully established. 1

1 According to some experts (Biondi, for example) the presence of normoblasts in the blood of cases of lead poisoning cannot be denied, but this fact, indicative of an excessive formation of red cells, is also an expression of the anaemic state, the gravity of which must be carefully estimated in connection with the number of normoblasts present in the blood. It is therefore advisable in all these cases to test the urine of the patient for the presence of lead.
(4) Moroccan subjects, who are less capable than the French workmen of understanding and adopting the rules of prophylaxis, show signs of lead poisoning in a proportion distinctly higher than the others. On the other hand a smaller proportion of lead colic is noticed in their case histories.

These enquiries agree in general with those of a previous enquiry which was able, in addition, to establish that:

(5) Women are proportionately less affected, without doubt due to the effect of a variety of causes, such as stricter hygiene and prophylaxis, less harmful work, shorter periods of carrying on the trade.

(6) Old workmen show a higher percentage of ill-effects, without however such a marked difference as one would a priori expect: doubtless this is due to the principle of selection, the careless workmen, or those predisposed to attacks of lead poisoning are found to be rapidly eliminated, and do not come into an enquiry of this sort, which deals exclusively with workmen at work at the time of the enquiry.

No surprise need be entertained at conclusions slightly different from those arrived at by investigators in other countries, for in the same factory a change in the system may cause considerable variation in the proportion of the manifestations of lead poisoning. It has been enough, for instance, in a factory where the preparation of the paste and the smearing were originally carried out in the same place, by separating the two operations to obtain a reduction of about 50 per cent. in the cases of poisoning.

In Great Britain a very detailed investigation made by Price and Bridge in 1924 dealt with 34 accumulator factories which employed at the end of June 1923 about 2,490 workmen.

The number of cases of lead poisoning notified to the Factory Department from 1904 to 1924 in accumulator factories was as follows:

<table>
<thead>
<tr>
<th>Year</th>
<th>Persons</th>
<th>Per 1,000</th>
</tr>
</thead>
<tbody>
<tr>
<td>1904</td>
<td>33</td>
<td>33.3</td>

<td>31</td>
<td>26.5</td>
</tr>
<tr>
<td>1911</td>
<td>24</td>
<td>19.6</td>
</tr>
</tbody>
</table>

These figures show that lead poisoning in this industry has no tendency to decrease in proportion to the number of persons employed, the rate remaining almost the same as is shown by the following table:

<table>
<thead>
<tr>
<th>Year</th>
<th>Persons</th>
<th>Per 1,000</th>

The cases notified and the attacks of illness are distributed by occupational classification as follows (per 1,000 employed from 1916 to 1922):
two symptoms appear very of lead poisoning, and 78 paleness of the workmen had a complexion characteristic in the department; while 84 per cent, of all among 42 per cent, of workers in the form-

material were the processes offering most that pasting and manipulation of lead in 1925 into accumulator factories showed in 1920.

among pasters was 160 per 1,000 the air was recorded. In this factory in 1919 presence of 10.1 mg. of lead per 10 mc. of pasting and mixing department the pre-
ed lead dust in the sections of the industry explained by the presence of finely divid-

A Japanese Government enquiry made in 1925 into accumulator factories showed that pasting and manipulation of lead material were the processes offering most exposure to lead poisoning. As a matter of fact signs of absorption were noticed among 44 per cent. of paste workers and among 42 per cent. of workers in the forming department; while 84 per cent. of all workmen had a complexion characteristic of lead poisoning, and 78 paleness of the conjunctiva; 78 per cent. showed basophilic granules and 24 paresis of the extensors of the hand. Whilst the first two symptoms appear very early, the third only appears at the end of from one to three years' service. The investigators much regret the slight effort made to instruct workmen against the danger of lead poisoning.

The high averages of this table are explained by the presence of finely divided lead dust in the sections of the industry most affected. Thus, for example, in the pasting and mixing department the presence of 10.1 mg. of lead per 10 mc. of air was recorded. In this factory in 1919 the estimated rate of lead poisoning among pasters was 160 per 1,000 and 157 in 1920.

A Japanese Government enquiry made in 1925 into accumulator factories showed that pasting and manipulation of lead material were the processes offering most exposure to lead poisoning. As a matter of fact signs of absorption were noticed among 44 per cent. of paste workers and among 42 per cent. of workers in the forming department; while 84 per cent. of all workmen had a complexion characteristic of lead poisoning, and 78 paleness of the conjunctiva; 78 per cent. showed basophilic granules and 24 paresis of the extensors of the hand. Whilst the first two symptoms appear very early, the third only appears at the end of from one to three years' service. The investigators much regret the slight effort made to instruct workmen against the danger of lead poisoning.

Pathology

It is not necessary to describe here, or even to enumerate, the diseased conditions originating from lead poisoning noticed among workmen employed in the accumulator industry; that would imply reviewing again the complete story of the absorption of, and poisoning by, lead (see article "Lead Poisoning"). In the same way reference may be made to the corresponding articles for injuries caused by arsenic, mercury, etc.

Hygiene

With regard to prophylaxis against lead poisoning or other morbid conditions produced by the different causes enumerated above, measures of hygiene and improvements in the conditions of work in accumulator factories include, as in every unhealthy industry, the adoption (1) of means for collective protection, more especially directed against the risk arising from injurious fumes and dusts, and (2) of measures for individual protection, especially directed at reducing as much as possible ill-consequences arising in particular from direct handling of lead and its compounds.

Collective Protection

The handling of old plates should be done in the open air and with precaution as these plates, which are strongly charged with oxides of lead in powdered and easily detachable form, may lead to the liberation of poisonous dust.

The melting of these plates, as well as the reduction of the oxides, should be carried out in closed apparatus. Some very interesting contrivances have been devised for this purpose.

In some factories the reducing furnace is connected to the factory chimney. This arrangement causes inside the apparatus a lowering of the pressure which prevents the escape of dust or poisonous fumes into the workroom. The fumes drawn towards the chimney traverse a series of depositing chambers in which they get rid of the lead which they still contain. The emptying of these dust chambers should only be done after sprinkling with water which transforms the dust into paste which can be removed without danger.

In the absence of localised ventilation it is indispensable that running lead obtained from the reducing furnace into ingot moulds should only be done in a very large and well-ventilated place.

In the foundry special precautions should be taken as regards both preparation of plates and of accessories.

The carrying off of fumes emitted by the melting pots is indispensable. This is actually carried out in most works, or, at least, the melting pots are in every case fitted with exhaust hoods intended for removing directly to the outside fumes emitted by the pots of melted alloy.

In actual practice the efficiency of these exhaust hoods is generally doubtful: if, in the vicinity of some places in the works where casting is carried on, traces of lead fumes are only occasionally noted, in others, in spite of the presence of the exhaust hood, perceptible quantities of lead in the vapour state have been detected.

</table>
The draught of an exhaust hood must therefore be verified experimentally; visual examination is not sufficient.

In the same way if the gases withdrawn are not removed into a chimney with a strong draught and sufficiently high, it is indispensable to insure their neutralisation in an acid bath.

The replacement of hand casting by mechanical casting, by means of a special pump, constitutes a great hygienic advance, for the special apparatus can be more completely enclosed which reduces the possibility of lead fumes. The pump similarly dispenses with the use of ladles and all the evil consequences which spring from their use.

In order to prevent the melted lead from cooling too quickly and at the same time not to have to heat it to a very high temperature, heating the moulds before forming the grid patterns has been tried and it is a process which seems to give excellent results.

The use of mechanical moulding has the advantage not only of affording the workman more certain protection against fumes, but also of protecting him against the possibility of serious burns and of preventing the floor from getting covered with drops of lead which in time become dry and reduced to harmful dust. The last danger could be similarly avoided by insisting that workmen abstain from throwing dross on the floor.

Sawing machines are sometimes supplied with glass or celluloid screens which arrest the dust and prevent splinters from striking the faces of the workmen.

The obvious necessity of providing thorough ventilation of places in which the casting of plates and their accessories is carried out need hardly be insisted on. That is the only practical means for ensuring the removal of talc dust, which has been seen to be present in an appreciable quantity in the atmosphere of these places.

During the preparation of paste, dust of litharge and minium is set free. In spite of all precautions and good general ventilation, dust is difficult to avoid if these operations are carried out by hand.

Various firms are now studying means for performing the processes of weighing, mixing and kneading exclusively in closed receptacles and by mechanical means. The adoption of such processes would insure healthy conditions, which are much to be desired in this work. In the meantime it is indispensable for the work to be done only on a surface that can be washed and in a workroom the floor of which is kept constantly moist.

During pasting there is little to fear from dust beyond the special cases dealt with above, and which some factory owners have remedied by utilising perforated or open work tables, thus avoiding deposits of dust. Rooms where the pasting is done should be thoroughly ventilated; their floors should be made of washable material and kept constantly wet.

An old method, almost entirely abandoned, consisted in filling the cells of the plates by means of products previously reduced to powder and strongly compressed. This method of working gave rise to considerable quantities of dust and required the adoption of special measures for providing healthy conditions.

It is not necessary to refer again to these other operations, more or less productive of dust, such as trimming, soldering of connections, brushing of certain plates. The conditions in which the first two are carried out, in the absence of local ventilation which is to be desired, may be improved by carrying on the work on perforated or open worktables, through which the dust passes, as well as fragments of paste which are capable of giving rise to dust.

As regards brushing, its performance under healthy conditions in accumulator factories does not present any special characteristic.

The mixture of gases in the formation room may be dangerous and cause explosions; on account of this and also of the presence of harmful fumes of sulphuric acid, a system of ventilation is rendered necessary, preferably close to the floor where these last fumes have the greatest density.

The protection of the eyes of workmen against ultra-violet rays during autogenous welding justifies the use of special contrivances to combat these rays.

Mercury alloy should so far as possible be avoided, and also the use of impure sulphuric acid containing arsenic, which would lead, on contact with the metal plates, to a liberation of arseniuretted hydrogen.

To sum up, speaking generally, it may be asserted that the injurious nature of the various operations which we have dealt with is all the greater if they are done in combination with each other. In consequence an effort must be made to set apart a workroom or special room for each of them. Thus, in one factory, where the prepara-
tation of the paste and the pasting of the plates were carried on in the same place, it sufficed to separate these two operations in order to effect a reduction of morbidity by half.

Cleaning Workplaces

It is absolutely essential to insist on the necessity for prohibiting dry sweeping. Independently of the legal character of this prohibition it is sufficient, in order to justify it, to recall that dust deposited on the floor and on various objects in an accumulator factory is loaded with lead, as has been seen above.

If it be wondered what the effect of dry sweeping as a harmful factor may be, the answer may be given that samples have shown the presence of 0.0008 grm. of lead per cubic metre of air in the vicinity of a workman carrying out this work. Dry sweeping should be prohibited and replaced by wet sweeping. It is even necessary in some workshops, in particular in the pasting rooms, to arrange the floor in such a way that it can be maintained in a constantly moist state.

Individual Cleanliness

In addition to the collective measures described, precautions taken individually by each workman for his personal protection are also extremely important.

The constant presence in most of the workshops of fumes or lead-laden dust makes it essential to place at the disposal of the personnel warm baths or douche baths. Similarly, it is hardly necessary to show the need of lavatories, for the workmen, whatever their kind of work, have their hands soiled with lead.

In some places workmen are supplied with gloves particularly for smearing and for forming.

In the first case these gloves are intended to preserve the skin from contact with oxides of lead, in the second case they serve to protect the hands against acids.

This means of protection offers great advantages depending, however, on the condition that it is used methodically. Frequently protecting gloves are used intermittently and with the hands already soiled with oxides of lead. During an enquiry it was found that the workman on whose hands the largest quantity of lead was found was a workman employed in pasting, who took off his gloves before washing his hands with the help of a sulpho-tartaric solution.

In some workshops respirators are used, which do not in any way replace the need for local or general ventilation of places in which poisonous dust is set free.

These means of protection in order to be efficient require the direct collaboration of those concerned which is often lacking. Constant supervision of the respirators is also required in order to ensure not only that they are in good condition, but also that they fit perfectly on the faces of those who use them (see article "Breathing Apparatus").

It is certain that in practice most of these conditions, if not nearly all, are frequently ignored, for examination for lead deposited on the nasal mucous membranes of workmen supplied with respirators gave results of the same order as those for workmen not using any protecting apparatus.

The wearing of respirators creates a false sense of security which may have dangerous results. Without denying on that account the use which these articles can render under certain conditions, they should be reserved for the protection of workmen against heavy discharges of dust which are of short duration. In no case should they interfere with the adoption of collective means of protection.

Let it be added in conclusion that to all these measures for improving health conditions by both collective and individual precautions, it would be greatly preferable to introduce, as soon as the problem has been solved, the manufacture of accumulators having the same practical value as lead accumulators, but made without the use of this metal or its derivatives.

Legislation

The employment of women, children and young persons in accumulator factories is subject to rules which legislators lay down concerning work which exposes to risk of lead poisoning (see article "Lead Poisoning").

In Austria the Order of 8 March 1923 on lead compounds also applies to accumulators.

In France the Decree of 1 October 1913 on the particular measures of hygiene for industries where the personnel is exposed to lead poisoning includes also the manufacture of accumulators.

In Germany the Regulations of 6 May 1908 for accumulator factories lay down that the floor shall be impermeable, but not of wood or linoleum for the workshops where lead is handled; that the walls shall be smooth with a washable surface,
or whitewashed and re-done yearly; that the departments of melting, pasting and polishing shall be separate; that exhaust hoods be placed over melting pots and places where soldering is done as well as the mixing places; and that the floor be cleaned daily. The Regulations further provide for monthly medical examination of workmen exposed to risk of lead poisoning, as well as for the discharge of any person showing authenticated symptoms of lead poisoning or absorption.

In Great Britain the Regulations of 19 January 1925 (Statutory Rules and Orders, No. 28, 19 January 1925), which supersede those of 21 November 1903, No. 1,004, prohibit the employment of young persons of less than 18 years of age, in lead operations, except in two operations carried out under special conditions, and of women and young persons of less than 18 years of age, in places in which the manipulation of raw oxide of lead or pasting is carried on.

Manipulation of raw oxide of lead, pasting, drying of pasted plates, formation, with lead burning ("smearing") and melting down of pasted plates must be carried out in separate places, or in such a way that they may be carried on independently from one another and from any other process.

The Regulations provide for each person 500 cubic feet of air and adequate ventilation; the floor must be of impermeable cement or similar material, maintained in sound condition and cleaned wet; damping of the floor of places where lead oxides are handled and where pasting is done is required. Detailed measures are laid down for workplaces and for the various operations that workmen may have to carry out.

Efficient localised exhaust draught must be provided for the operations of melting lead or materials containing lead, for the manipulation of raw oxide of lead, unless done in an enclosed apparatus with ventilation so as to prevent the escape of dust into the workroom, for pasting, trimming, brushing, filing, or any other similar operation which may set free lead dust, and for lead burning.

The products of combustion produced in the heating of any melting pot must not be allowed to escape into a room in which persons work. Receptionists must be provided for the use of workmen in order to collect debris as well as the dose taken from the melting pots.

Persons exposed to the risk of lead poisoning must be medically examined each month, as well as on their return to the factory after a period of suspension from work.

Protective clothing must be provided for every person employed in the manipulation of raw oxide of lead, pasting and formation. This clothing must be impervious to water and, as well as other materials, must be renewed or washed weekly.

The Regulations further provide for canteens, separate changing rooms, lavatories with towels which must be changed daily, and with soap and nail brushes especially for workmen who handle raw oxides of lead.

The employer must allow at least ten minutes before each meal and before the end of the day's work in addition to the regular meal times, in order that workers employed in manipulating raw oxides of lead and in pasting may wash themselves.

Baths with hot and cold water and a liberal provision of soap and towels must be provided for all persons employed in the above-mentioned work.

In Holland measures are also laid down by the Decree of 21 August 1916, Category A.

In India the Act of 1911 lays down measures for mixing and pasting in accumulator factories.

In the United States the accumulator factories committee of the Association of the Edison Lighting Company in 1919 adopted some measures of hygienic protection, which have been approved by the American Safety Academy. The State of Ohio also published in 1914 instructions for workmen to be posted up in workplaces.

As regards the protection of women and children the First International Labour Conference (Washington, 1919) voted a Recommendation having for its object the protection of these persons against lead poisoning on account of the risks with which certain industrial operations threaten women from the maternity point of view, and with the object of allowing children to develop physically. The Recommendation requires that the employment of women and young persons below 18 years should also be forbidden in the operations of mixing or smearing, in the manufacture or repair of electric accumulators, and in the cleaning of workshops where this work is carried on; and that the employment of these persons at work in which lead salts are used is only authorised on condition that the following measures are taken:

Local ventilation of such a kind as to dispel dust and fumes as soon as formed; cleanliness of tools and workshops; notification to the public authority of every case of lead poisoning and awards of compensation to persons poisoned; periodical medical examination of persons employed on the work in question; the provision under satisfactory conditions of changing rooms, lavatories, canteens and of special protective clothing; prohibition of the introduction of food or drink into the workrooms.

On the other hand the Conference recommended that in industries where it is possible to replace soluble salts of lead by non-toxic substances, the use of the so-called soluble salts of lead shall be subjected to the strictest regulations. Any salt of lead is considered soluble which contains more than 5 per cent. of its weight in metallic lead soluble in an aqueous solution of hydrochloric acid of a strength of 0.25 per cent. of acid.
Notification and compensation of sickness arising from lead poisoning are laid down by the special provisions decreed for the notification or compensation of occupational diseases (see articles "Lead Poisoning" and "Occupational Diseases").

Special designing of accumulator factories is only required by French and Russian legislation.

BIBLIOGRAPHY

Hamilton, in Industrial Poisons in U.S. 1925.

D'Agasse-Lafont

(Paris).

Acetanilide

Acetanilide, the formula of which is C₆H₅N.H.CO.CH₃, exists in the form of white inodorous crystalline flakes which have a burning taste. It melts at 112-113° C. and reaches boiling point without decomposing at 295° C. Whilst it is only slightly soluble in cold water, it is soluble in boiling water and highly soluble in alcohol and ether. It often contains aniline as an impurity, and then it has a reddish orange colour.

Preparation. — It is obtained by heating for an hour at 180° C. equal parts of aniline and glacial acetic acid. It is isolated by fractional distillation in which only that which comes over at 295° C. is collected.

Use. — In industry it is used in preparing aromatic substances: principally para-nitroaniline and paraphenylenediamine. It is also used as substitute for camphor in the manufacture of celluloid, etc.

Toxicity. — Herczel affirms that acetanilide in strong doses has a poisonous effect similar to that of aniline. Experimentally (Lépine and Porteret), it has been found that a subcutaneous injection of acetanilide has the effect of increasing the quantity of glycogen in the muscles by 20 to 28 per cent. (in guinea pigs). In man and also in animals, even with the strongest doses, only a trace can be found in the urine.

There is no information upon the effects of acetanilide in industry. However, it can be said that it is a virulent poison for the eyes and that it can even cause methaemoglobinemia.

Acetic Acid

Acetic acid, the chemical symbol of which is CH₃.CO.OH, is, when pure, a colourless liquid with a penetrating odour; it solidifies about 16.7° C. in brilliant transparent laminae as glacial acetic acid. It melts at 17° C. and boils at 118° C. Its specific gravity is 1.0553 at 15° C. Its fumes burn with a bluish flame. It combines with water or alcohol in any proportion.

Acetic acid is industrially obtained, either by oxidation under the action of micro-organisms in dilute alcoholic liquors (wine, beer, etc.), the liquid obtained being vinegar, or by dry distillation of wood (see article "Timber Industry"). The acetic acid thus obtained is purified by distillation through bichromate or permanganate of potassium. Synthetic acetic acid is obtained by using as basis acetylene (hydration of acetylene and oxidation of the aldehyde formed).

Acetic acid is used in the textile industry (printing and dyeing of wool and silk; dyeing with alizarine colouring agents: concentration of 35-40 per
ducts, injury from which is compensated.

Acids have been frequently noted by swelling and phlyctena. on contact with the skin lesions characterised by swelling and phlyctena.

Acids are used to dissolve certain acetic ethers and of acetyl-cellulose, and of certain aniline colouring agents; in the preparation of vinegar essence and table vinegar, etc.

Acetic acid is absorbed by animals in the proportion of 65.85 per cent; absorption by human beings seems to be equally easy, especially in small doses. According to Lehmann 47.87 mg. of acetic acid fumes per litre of air inhaled during half an hour do not give rise to serious disorders amongst animals. These fumes exercise, however, an irritant action on the mucous membrane, especially of the eye. Even the concentrated acid only exercises a slight action on the skin, especially if the part affected be washed immediately after.

The action of acetic acid involves no certain risk beyond that of conjunctivitis. The mucous membrane of the throat and nose is, as a rule, but slightly affected. Acetic acid produces on contact with the skin lesions characterised by swelling and phlyctena.

Cases of dermatitis due to acetic acid were reported in Switzerland in 1919; acid burns have been frequently noted amongst hat makers and workers engaged in cleaning bottles and bronze objects. Cases of mercury poisoning have been reported in acetic acid factories where the product is obtained by utilising acetylene in the presence of mercury (as catalyst).

Closed recipients should be used to prevent the escape of fumes.

Acetic acid (anhydrous and concentrated) is included in the list of products, injury from which is compensated as an accident in Switzerland. In Spain girls under twenty-one and boys under sixteen are excluded from work in establishments where acetic acid fumes are given off.

Acetic Aldehyde

Acetic aldehyde, the formula of which is CH₃CHO, is produced by the oxidation of ethyl alcohol by means of potassium bichromate and sulphuric acid. It is a very volatile colourless liquid with a penetrating and suffocating smell. Its specific gravity is 0.795 at 10° C.; its boiling point 21-22° C. It is easily soluble in water, alcohol and ether; it burns with a pale flame; on exposure to the air it becomes oxidised into acetic acid; it easily becomes changed into paraldehyde and metaldehyde.

Preparation. — Aldehyde is prepared by slowly pouring three parts of alcohol (at 50°) and four parts of concentrated sulphuric acid into a solution of three parts of potassium bichromate dissolved in twelve parts of water, and cooling the mixture.

Manganese dioxide can be used instead of potassium bichromate. Industrially, aldehyde is either obtained as a first product in alcohol distilleries, being separated from the alcohol by fractional distillation, or starting from acetylene (see article “Acetic Acid”).

Use. — It is used in the preparation of numerous chemical products, of celluloid, of dyes, of aniline colours (aniline green), of varnishes and of vinegar. It is used also in the manufacture of explosives, silvering mirrors, etc.

Iwanoff found that 0.5 mg. of aldehyde did not produce any injurious effects after five hours; that 2 mg. caused symptoms of marked irritation; these symptoms are very violent with a dose of 3-7 mg., which also produces narcotic effects. A dose of 20 mg. kills an animal in the space of one to two hours. Together with signs of cerebral paralysis are seen oedema and irritation of the lungs. Traces of aldehyde are found in the expired air and a slightly greater quantity in the urine.

Poisoning. — Poisoning produced by inhaling the vapours causes irritation of the mucous membranes of the nose, larynx, bronchi and eyes. The stronger vapours cause a sensation of suffocation and coughing, acceleration of the heart, profuse night sweats, narcotic effects and methaemoglobinuria, etc. Kunkel states that workers suffering from
chronic aldehydism have thickening of the inner lining of the vessels.
Aldehyde is included in the Swiss list of substances liable to produce illness classed with accidents for the purpose of compensation. ***

**Acetone**

Acetone, of which the formula is C₃H₆O (CH₃ CO. CH₃), is a colourless, volatile and inflammable liquid with a smell of ether and a burning taste. Its density is about 0.79 at 18° C. and 0.812 at 0° C. It boils at +56° C., burns with a clear flame and is soluble in water, alcohol, chloroform, and ether.

**Preparation.** — Acetone is obtained by

(a) **Dry distillation of wood**: this method is little used, for the acetone is mixed with methylic alcohol from which it is difficult to separate it. The crude product is treated by bisulphite of soda; it then forms a complex crystal, which is separated by the centrifuge and then decomposed by an alkali (soda). The crude product is purified by distillation.

(b) **Decomposition of acetates**: starting from pyroligneous acid which becomes transformed into dry acetate of lime free of tarry substances. Acetate of lime is given off when dry distillation is carried on at about 300° C.

(c) **Catalytic decomposition of the vapour of acetic acid in the presence of coke containing alumina**.

Acetone can also be obtained from acetylene in the presence of mercury (acting as a catalyst).

**Use.** — Acetone is used at factories for making electric batteries in the manufacture of celluloid boxes (it is in this industry that the greatest risk of poisoning occurs); but it is chiefly used as a solvent in the trades connected with varnishes, paints, resins, metallic colours (bronze powders), india-rubber, chemical products (acetate cellulose, nitrocellulose, celluloid, fatty substances, camphor, etc. usually mixed with amyl acetate, benzol, methylic alcohol, etc.). It is also used in the preparation of chloroform, ketones and certain blue shades, of iodoform and sulphonial; in the preparation of some glues or cements, of zapon lacquer, etc.; in the manufacture of explosives, the preparation of smokeless powder; and in its pure form for burning in the same way as denatured alcohol. As regards the toxic action, the recent experiments of Kagan (1924) show that acetone given to cats by inhalation causes acute poisoning of which the clinical features are the same for all animals and characterised by the following three successive phases: loss of equilibrium, slight and then deep narcosis. The smaller the dose the slower will be the appearance of the symptoms. The personal factor, however, must be taken into account. Small doses given during a long period of time will act in a much more marked manner than strong doses given during a short time.

As regards chronic poisoning (19 experiments upon three cats), Kagan found that the inhalation of 3 to 5 mg. of acetone per litre of air was borne without any injury by the cats and that they became accustomed to acetone. Acetone was found in the urine the day after the experiment, but not at all on the following days even with the strongest concentrations of the poison. Acetone is often rapidly eliminated by the lungs. The toxicity of its vapour (according to Kohn-Abrest) is negligible compared to that of benzene and chloroform: 0.590 grm. of acetone per litre of air does not produce upon the guinea pig even at the end of an hour any symptoms except slight stimulation of the lacrymal glands.

Numerous cases of illness have been noticed among persons occupied in trades using lacquers, varnishes, cements, colours, etc. in which the solvent contains acetone; in the manufacture of india-rubber, of boots, of aeroplane wings, of metal articles (process of painting), etc. In these same trades cases of eczema and conjunctivitis caused by acetone vapour are also noticed fairly frequently.

It should be mentioned that in the manufacture of acetone from acetylene the use of mercury may cause cases of poisoning. In 1914 several workmen were poisoned by mercury in a German acetone factory.

According to Lehmann, acetone causes the same clinical effect as amyl acetate: a hot feeling with vertigo, slight fainting attacks, irritation of the throat, attacks of coughing, etc. Roth considers that the signs of irritation are of primary importance.

Suitable hygienic measures are required to prevent the dispersion of the vapour.
DETECTION OF ACETONE

Transform the acetone into iodoform by the action of a decinormal solution of iodine and of one-fifth normal ammonia. This reaction is not specific.

LEGISLATION

None. (See article "Painting Industry ".)

### Acetylene

**French: Acétylène (Éthane). — German: Äthylen. — Italian and Spanish: Acetilene.**

**PROPERTIES**

Acetylene, obtained impure by Davy in 1829 and pure by Berthelot in 1859, is a colourless gas with a specially sharp garlic-like smell, unpleasant because of the impurities it may contain, and with a sweetish sugarlike taste, pleasant enough if purified. Its formula is C2H2; its density 0.9056; a litre weighs 1.65 grm.

Acetylene is liquefied easily, in which form it appears as a mobile colourless liquid. It is very refractive (specific gravity 0.451 at 0° C.), which when rapidly evaporated partly solidifies in the form of snow and then melts at —81° C. One kilo of liquid acetylene yields 800 litres of gas at ordinary pressure and 20° C.

During its formation acetylene absorbs 61,000 calories, but being an endothermic compound, only slightly stable, it decomposes readily at a temperature of 750° C., yielding a carbon of the greatest fineness (fine acetylene black). Mixed with air it burns at 480° C.; it explodes violently on contact with a flame or an electric spark, or on detonation with a cap of fulminate of mercury. The risk of explosion occurs more readily and is more dangerous with compressed acetylene (already dangerous at a pressure of 2 atmospheres) and still more so with liquid acetylene. The latter is in a very convenient form, were it not more so with liquid acetylene. The latter is in a very convenient form, were it not more so with liquid acetylene. ally the yield should not fall below 250 litres. The reaction requires to be carried out at a temperature below 50° C. as, under the influence of heat, acetylene polymerises with formation of benzene, which gives a smoky flame to acetylene. On the other hand, there is advantage in keeping the temperature of the generators low in order to avoid evaporation of water. This would make the gas moist, which is unsuitable for blowpipe work.

Crude acetylene contains from 10 to 14 per cent. of impurities, including phosphoretted hydrogen (0.8-1 per cent.), carbon bisulphide, hydrogen sulphide (1.5 per cent.), siliciuretted hydrogen (0.8-2 per cent.), arseniuretted hydrogen, as well as other gases such as ammonia, carbon monoxide (1-2 per cent.), hydrogen, nitrogen, oxygen, and hydrocarbons. All the impurities may cause easy or spontaneous combustion of the acetylene, especially the phosphoretted and siliciuretted hydrogen which are auto-inflammable.

As has been already said, these dangers are greatest in the case of acetylene when under a pressure of more than 2 atmospheres. Apart from the unpleasant smell, these impurities account for the poisonousness of acetylene when inhaled for a long time. They are derived from the raw materials (lime, coal, etc.) containing phosphorus, arsenic, sulphur, and silicon, and also from the methods of manufacture (reaction of the carbide on water, influence of local temperatures of heating, etc.). These latter factors notably affect the nature of the impurities (organic sulphur compounds are very complex even in the same carbide) and are present in greater quantity when the gas is produced by means of a dropping apparatus.

Among the impurities, phosphoretted hydrogen plays the most important role. It occurs in impure carbides containing phosphates of calcium (von Jaksch) and causes the spontaneous combustion of acetylene because it favours the formation of explosive metallic acetylenes. According to Jokote and Ichle, American calcium carbides yield an acetylene containing 0.04 per cent. phosphoretted hydrogen. In Swiss acetylene 0.02 per cent. has been found, but Lunge and Cedernkreutz have found up to 0.06 per cent. These quantities would suffice to bring about poisoning, and Dietz has reported a case. According to Hayhurst, acetylene derived from carbides manufactured from lean coal might contain up to 0.01 per cent. of phosphoretted hydrogen as well as hydrogen sulphide, compounds of tellurium, ferrosilicon, etc. The content in phosphoretted hydrogen should not, it is held, exceed 1 grm. per cubic metre.

Purification. — The washed, and in most cases, dried acetylene is next purified by passage through a special mixture or various substances which absorb from 90 to 99 per cent. of the impurities (Zangger).

As absorbent materials, oolitic iron and analogous pulverised minerals are used, milk of lime, hypochlorite, chloride of lime (mixed with sawdust — Lunge and Cedernkreutz), a mixture of chloride of lime and bichromate (Wolff's method), copper chloride (Frank's method); when it is a question of small quantities of gas, with a view to analysis, chromic acid or chrome salts may be used, concentrated sulphuric acid (with arsenious anhydride) or even nitric acid, which, however, cannot be used for large-scale work because the mixture of acetylene with the nitrous fumes would be too dangerous.

Purification by means of chloride of lime is the least costly, gives the best results, and presents the least risk of accident.

In operations in which chlorine gas is evolved very careful absorption should be assured, because a mixture of acetylene and chlorine readily explodes in the light.

Purifying preparations are on the market: "Purethylene" (a mixture of chloride of lime, quick lime and chloride of calcium in granules) a kilo of which can purify 30 cm. of acetylene; "Frankolina" which is a concentrated solution of chloride of copper and other salts. A fossilised earth impregnated with metallic salts is also used.

Zangger reports the heating of the gas until the arseniuretted, phosphoretted and siliciuretted hydrogen are decomposed. In large establishments after purification the acetylene is led into gasometers.

Use — Sources of Poisoning

In the course of purification, effected by oolitic iron and analogous pulverised minerals (see above), the workmen, in drawing the charges, in recharging, in cleaning and repairing, are often the only workmen in the factory in contact with acetylene.

In industry and domestic installations the uses of acetylene are as follows:

(a) Lighting. — Acetylene ignites at a temperature of 480° C. and burns
from an ordinary jet with a reddish, smoky flame, which, however, becomes luminous and very brilliant if the acetylene is made to emerge from a special tap with a narrow slit through a fine opening under a moderate pressure of 7 to 8 cm. of water, or if it is mixed with a little air or inert gas. The best proportions of acetylene and air for maximum luminosity are 3 volumes acetylene and 2 of air. The luminous intensity of acetylene is, at equal volume, fifteen to twenty times that of gas from an ordinary jet, and three and a half to four times that from a jet with an Auer mantle. As a matter of fact special incandescent mantles of rare earths are actually made.

Special mention should be made of the oxy-acetylene lamp with a lime pastille carried to a white heat and used in lanterns, cinematography, etc. First the acetylene flame is lighted and then only is the oxygen added. For signals on railway lines use is also made of dissolved acetylene, which gives the most steady, unchangeable signal, and the one requiring the least attention.

It is also used for lighting purposes in the construction of tunnels, mine shafts, galleries, etc.

(b) For obtaining high temperatures.

The heating power of acetylene is 14,350 grand calories per cubic metre, or 12,300 grand calories per kilo. Burnt in a Bunsen burner a temperature of 2,000° C. can be obtained higher than that from coal gas. This is why the oxy-acetylene blowpipe, giving a temperature of 3,000° C. is used for autogenous soldering in the case of iron and steel. In autogenous cutting of iron or steel the metal to be cut is heated to bright redness in an oxy-acetylene flame; escape of acetylene is then shut off; the oxygen burns the iron, converting it into oxide, which is got rid of by blowing from above. A mixture of acetylene and petrol vapour under the name of "Thermoline" also yields high temperatures.

The use of the blowpipe may produce explosive mixtures which require the adoption of certain technical precautions. The greatest danger comes from the incomplete combustion of the gas. In welding the proportions of acetylene and oxygen ought to be constant, with an optimum amount of the former of 7.3 per cent. With higher amounts combustion is incomplete and hydrogen, water, carbon monoxide, and dioxide are formed. Further, incomplete combustion causes sulphuretted, arseniu-retted, phosphoretted, and silicuretted hydrogen to escape into the atmosphere, as these substances are contained in crude acetylene. When acetylene gas is burnt in the air much nitric oxide is produced, which does not happen with any other flame (Zangger).

An acetylene burner was reported (1919, United States) to have succumbed after having welded for half an hour the interior of a large boiler. Hayhurst believes that this operation exposes the worker to a sixfold risk of poisoning: from acetylene, carbon dioxide, and monoxide (produced by imperfect combustion), sulphuretted hydrogen (from the phosphorus in the coal), and arseniu-retted hydrogen (arising from the hydrogen formed). Acetylene is also used to replace ordinary coal gas for furnace work (glass work, manufacture of incandescent electric lamps, etc.).

(c) As a means of motive force.

New openings have recently been demonstrated for utilising acetylene in internal-combustion engines to replace other hydrocarbons. Acetylene was further used during the war as a carburetted agent.

(d) Its use as an explosive (especially in the liquid form).— Copper, however, gives with acetylene an acetylide of copper which is too explosive to use.

Quite recently, from acetylene as the starting point, a fine resin has been manufactured which, used in combination with pure liquid oxygen, is a very powerful explosive having a speed of propagation of 6,000 to 9,500 metres a second.

(e) Use as a reagent and point of departure in the chemical industry.

In analysis it is used, e.g., to separate copper from its solutions as well as in a series of organic chemical syntheses. Acetylene, by catalytic hydration, in presence of salts of mercury is converted into acetaldehyde, which on oxidation yields acetic acid, and on reduction alcohol (this is more rarely carried out). Acetone can be similarly obtained, crotonic aldehyde with its salts and the acids corresponding to all these bodies.

In the course of these operations the greatest risk is represented by acetaldehyde — a very volatile substance which does not irritate the mucous membranes, but nevertheless impedes the action of the respiratory centre even in low concentrations of 1 in 10,000 up to 1 in 1,000, and thus acts in the same
way as do the fumes of hydrobromic and hydrochloric acids (Zangger).

While it is true that acetaldehyde is converted in the organism by oxidation and fractionation of the acetic acid and carbon dioxide into a series of products which are not poisonous, its action, before oxidation, is of great importance because functional disturbance with a tendency to catarrhal and various digestive disturbances, etc., arise in consequence of the presence of additive compounds. In any case acetaldehyde acts on the nervous system like paraldehyde (product of condensation used as a hypnotic) and on the circulatory system (although in a manner little understood); experiment shows, however, that it may favour the development of the early stages of arteriosclerotic processes.

In addition to acetaldehyde, accessory substances are produced in these operations, notably saturated and unsaturated bodies of which the principal is crotonic acid. Its toxicity is well recognised, because in small doses acting for a period of some months it brings about cardiac irregularity and particularly tachycardia on exertion. These troubles are sometimes excruciatingly painful, especially in young persons. Convalescence takes several months.

The risks to the health of the persons employed in this part of the process can be summed up as follows:

1. Action of volatile aldehydes (acetaldehyde, crotonic aldehyde and allied substances) on the mucous membranes, the digestive tract, the circulatory and nervous systems.

2. Action of the impurities in acetylene.

3. Action of the catalysts (mercury, mercuric oxide, mercurial vapour) in the course of the distillation and recovery of mercury. Further, production of volatile, organic mercurial compounds.

The preparation of acetylene is the starting point for numerous syntheses, and in these the impurities, which give rise to the poisonous character of acetylene, have equally a deleterious effect on the reactions and on the chemical agents present, notably the metallic catalysts. It is thus that in the electrolytic oxidation by means of mercury large quantities of phosphoretted and sulphuretted hydrogen may be produced; and this reaction renders an explosion liable to occur. At the same time a large part of the mercury is precipitated with the phosphorus and the sulphur in the residue in the vat.

When it becomes possible to lower the price of the original product a large number of syntheses will be able to be put on the market, such as those from the manufacture of various chlorinated compounds (ethyl chloride, dichloracetic acid, etc.), the synthesis of indigo, thiophene, and rubber, the preparation of movilith (on condensation from acetylene and monochloracetic acid, chloracetate of vinyl is obtained which, on polymerisation, yields a plastic substance, movilith).

Acetylene is used to make lamp black, of a pure and very fine kind obtained by decomposing acetylene by electrical discharge.

Finally mention should be made of the organic additive compounds — tetrachlorethene, hexachlorothene, tri-chlorethylene — which are to-day the principal substitutes for carbon tetrachloride and carbon bisulphide, while the latter are explosive the former are not. They exert a narcotic action and are powerful solvents of fats and of substances soluble in fats (lacquers, colours, medicinal intermediate products).

Recently (1925) acetylene has been employed to colour lemons yellow (the effect of this gas in artificially giving a lemon a yellow colour is already evident in a proportion of one part in a thousand parts of air; a mixture of acetylene in a proportion of 1 to 5,000 parts of air is used.

Acetylene may also be a by-product in the incomplete combustion of a certain number of carbon compounds, various hydrocarbons (ethane, methane, ether, alcohol, lighting gas into the composition of which it enters to a small extent); in the course of the manufacture of calcium carbide (because of the humidity constantly present in the air, smell of acetylene in carbide factories) mixed with other impurities in the liberation of calcium cyanamide, with calcium carbide in excess as the starting point; in the utilisation of calcium cyanamide, which is often impure and sometimes contains much carbide, in the preparation of chemical products (and more recently for the manufacture of derivatives of urea — Zangger).

Zangger, instancing two cases personally known to him, states that the carbide, rich in phosphorus and nickel, often gives off acetylene containing more phosphoretted hydrogen than the urban by-laws allow in the case of calcium cyanamide.

Mention similarly should be made of the fact that acetylene is produced in
the electrolysis of solutions of alkaline salts and of fumaric and malic acids during the action of silver, copper and zinc on iodoform or of a copper zinc couple on bromoform.

**Danger from Explosion**

The great danger of acetylene lies in the risk of explosion due, on the one hand, to the presence of air or of impurities in the gas and, on the other, to the numerous uses to which it is put. It should be remarked, however, that most accidents are the result of defective apparatus or of faults in handling and use.

Technical details would here be out of place, except to say that it is especially at the moment of purification that the greatest precautions require to be taken because of the presence of phosphoretted hydrogen.

The use of dissolved acetylene is unattended with risk provided certain technical precautions are rigorously observed, especially in the manufacture and recharging of the cylinders. These ought to be of extra soft steel and should be tested at a pressure double that of the charge. They should only contain two-thirds of their capacity of liquid acetylene because the coefficient of expansion is very high. Further, in order to avoid explosion from dissolved acetylene, it is important that pure acetone and pure acetylene should be used. At any rate these are the conclusions come to after recent experimental study in Germany (1922). (See also article "Air (Liquid)").

**Statistics**

Statistics in literature bearing on poisoning by acetylene are very rare. S. Pontopidian (1921) describes one case affecting a young workman using an oxyacetylene blowpipe, but other authorities regard the symptoms and circumstances as indicating rather poisoning by phosphoretted hydrogen. Nicol, quoted by Lehmann, reported two cases of poisoning with symptoms especially of narcosis (see above).

**Toxic Action**

The channel of absorption is by the way of the respiratory tract.

The toxicity may be due to two factors: either the gas itself or the impurities contained in it.

**Toxicity of Acetylene Itself**

It was thought for a long time that this gas acted as a poison like carbon monoxide, but later experience has shown it to be practically non-poisonous, as it is not more toxic than other gaseous carbides like methane, propylene, etc., but it is irrespirable like nitrogen and hydrogen. Really, no simple case of poisoning can be attributed to pure acetylene. Animals do not die in an atmosphere containing 9 per cent. of acetylene, and even in certain cases of 20 per cent. (Kohn-Abrest). Lehmann states that dogs support an atmosphere of 20 per cent. for 60 minutes without showing any signs. Brociner made animals breath gaseous mixtures of acetylene and air or acetylene and oxygen renewed constantly of from 25, 30, and 55 per cent. without poisoning resulting. Malvoz and Crismer had similar results.

Gréhant, however, from quite recent experiments believes that acetylene has a certain toxicity of its own, but only in a very high proportion like that of carbonic acid gas. Asphyxia is very unlikely to result from gaseous mixtures containing proportions of, e.g., 35-40 per cent. Rosemann thinks, however, that 40 per cent. would have a narcotic action.

The most recent researches of Haldane appear to show similarly as one might expect, acetylene being an unsaturated body — that acetylene accumulates in the body, is eliminated with difficulty, and does bring about ill-effects (Zangger). Whatever be the case, blood charged with acetylene shows no particular bad when examined spectroscopically but looks like normal blood (Brociner). If acetylene does combine with haemoglobin, the combination is eminently unstable (Kohn-Abrest).

On the other hand acetylene has anaesthetic properties which have only been medically applied recently.

Acetylene, if used as an anaesthetic, ought to be freed of all such impurities as are likely to make it smell unpleasantly. Mixed with oxygen it is administered in special masks applied over the nose and mouth. The patient loses consciousness in one or two minutes. When administration is stopped consciousness quickly returns: the ill-effects of anaesthesia (nausea, vomiting, and headache) are not completely eliminated, but disappear quickly.

The anaesthetic properties of acetylene appear to be due to an alteration in the absorption of oxygen by the nerve cells. When, however, there is sufficient oxygen present (partial pressure above 16 per cent. of oxygen) acetylene, even if present to the extent of 10 to 20 per cent., produces no narcosis and in many persons causes no malaise — only a
marked degree of reduction in working efficiency (Zangger).

Toxic Action of the Impurities

Numerous authorities (Rambousek, Zangger, Hayhurst, Floret, etc.) admit that the toxicity of industrial acetylene is due principally to the toxic gases which it may contain as impurities (see above).

Recently (1925) Floret insisted afresh on the importance of the impurities contained in the calcium carbide, used in the preparation of acetylene, the organic compounds of sulphur and phosphorus especially ranking first.

Floret emphasises again the fact that the majority of the poisonings attributed to acetylene are in reality due to phosphoretted hydrogen.

Symptoms

The symptomatology relating to acetylene, if it exists, is very obscure. So far as acute poisoning is concerned there is nothing to say. As regards chronic poisoning, Hayhurst describes an acetylene lamp cleaner who suffered for a long time at his work, especially when the lamps were not fit and gave off acetylene gas. The principal symptoms noted were — headache,-nausea, general malaise, feeling of suffocation, and pain over the liver.

According to Floret, effects on respiration may be very serious; often there is loss of consciousness, vomiting, vertigo, headache, and sub-normal temperature in less severe cases. The patient complains of a feeling of cold, which, in the opinion of Lewin and Floret, would appear to be a symptom of poisoning by phosphoretted hydrogen.

As sequelae of acetylene poisoning there have been noted bronchitic symptoms, nervous affections (excitability, trembling of the hands, muscular cramps, exaggerated superficial and deep reflexes, nystagmus, atrhymic action of the heart, tachycardia, etc.).

In acute and sub-acute cases irritation of the mucous membranes and particularly of the conjunctiva have been reported (see articles "Occupational Diseases (Eyes)" and "Welding (Autogenous)").

Diagnosis

This must be based especially on the history and knowledge of the occupation of the patient.

Demonstration

The presence of acetylene in an atmosphere is an indication of incomplete combustion capable of giving rise to other more dangerous substances such as carbon monoxide, phosphoretted hydrogen, etc. The characteristic garlic-like odour of acetylene may sometimes reveal the presence of the gas.

Traces of acetylene in a gaseous mixture are demonstrated by passing a current of the air to be analysed into a solution of ammoniacal cuprous chloride, which gives rise to a reddish brown precipitate of copper acetylide. This reaction is very sensitive and shows 1/200ths of a milligram of acetylene.

Another reagent for acetylene is the sulphate of ammoniacal chromium prot-oxygen which changes it gradually into ethylene (Berthelot).

Bromine absorbs it rather irregularly; ordinary sulphuric acid slowly.

Hygiene

Preventive measures are directed against the risks of explosion and fire: use of relatively small gasometers connected up in lighting installations by iron pipes directly leading to the jets. At every part of the gasometer and pipe connections care must be taken to avoid all use of bronze or copper in order to prevent explosion.

The regulations for unhealthy and dangerous trades lay down measures concerning the industrial manufacture of acetylene, acetylene lighting, storage and manufacture of liquid or compressed acetylene (over or under 1.5 atmospheres), use of apparatus for private individuals, or portable acetylene generators.

Among the conditions to be laid down for factories or storage of liquid and compressed acetylene, it will suffice to state here that they should be away from occupied premises; their construction should be of light incombustible materials; there should be good ventilation, the floor should be of impermeable material; the carbide should be kept in receptacles impermeable to moisture, it should be used as it is wanted; breaking up the pieces of carbide should be done without the creation of dust; lighting by daylight only should be allowed; boiler hearths, if they exist, must be quite away from the workrooms; the solid residues should be collected in a watertight metal reservoir, the milk of lime may be carried into the sewer after dilution with water; the generating apparatus should never be installed in cellars or in underground rooms or parts of inhabited houses; all rubber connections should be rejected; every
precaution should be taken to prevent the freezing of the water in winter, and only hot water should be used for thawing purposes, etc.

**Legislation**

Employment of women and young persons is usually regulated by law excluding them from all processes bringing them into contact with toxic or explosive gases. Most associations for the prevention of industrial accidents, several associations of the chemical industries, as well as State departments of different countries have issued Regulations or Orders regarding safe working in the manufacture or use of acetylene. The recent memorandum issued by the Factory Department of the Home Office, London (Dangers from the Use of Acetylene Gas and in Oxy-Acetylene Welding in Factories, dated November 1922, form 1704), may be cited as an example.

Acetylene is included in the Swiss list of substances for which compensation is accorded as in cases of accidents.

**Prof. H. Zangger**

(Zurich).

**Acids**

The object of this article is merely to assemble general data concerning liquids with an acid reaction, leaving in consequence all detail to be dealt with in the special articles such as "Acetic Acid", "Hydrochloric Acid", "Nitric Acid", etc., "Diseases of the Eye", "Skin Diseases", "Diseases of the Mouth and Teeth", "Gas and Fumes", "Waste Water", etc.

Acids exercise a local action the gravity of which increases with increasing concentration.

In concentrated form these liquids coagulate the protean substance of the tissues and cause lesions which are, however, not so deep-seated or so extensive as those caused by alkalis. Acid burns closely resemble burns caused by fire. In dilute state acids cause dermatitis, chiefly eczematous forms, often noted amongst workers coming in contact with acids. They exercise further a harmful action on nails and teeth and, in the acute form, on the kidneys.

When the skin presents scratches and contusions, which is frequently the case with workers, the acid liquids find a mode of entry through these and then set up very painful and persistent ulcers. The eyes are often attacked by acids, the effect in this case being made more serious than in the case of skin lesions. With dilute acid the lesion is confined to slight causticisation with oedema and hyperemia of the conjunctivae, photophobia, etc.; when in concentrated form, lymphatic circulation of the cornea is caused, with softening, perforation, hypophonia, followed by panophthalmy and blindness.

Poisoning by acids, especially when massive doses are in question, produces a special clinical picture designated by von Jakob "acidity". Apart from the well-known local action there is said to be an indirect action (very, rare in human beings, however) characterised by nervous disorders and due to poverty of the system in alkalis.

Acid fumes are given off in a whole series of industrial operations. It is sufficient to recall in this connection casting of brass, making of storage batteries, manufacture of rubber and of explosives, galvanoplastic processes, the chemical industries, etc.

Acid fumes have been regarded by certain experts as one of the causes responsible for Paget's disease, while certain authorities hold that acid poisoning among certain categories of workers is much more responsible than lead, for instance, in causing this disease— noted by Oettinger and Agasse-Lafont as affecting 15 workers in a total of 31 engaged on work in an acid atmosphere.

**Statistics**

Statistical data will be found in the article "Chemical Trades", since data relating to workers handling acids are often included in total figures for those industries. In Germany, Leymann assembled the following figures for workers in the acid sections of the chemical industries (1881-1904):

<table>

Cases of acid burns reached 70 in 1881, 103 in 1890, and 80 in 1900, while eye injuries due to acids numbered 23 from 1881-1890, and 30 from 1890-1900. The last period however bears a higher figure (111) for burns caused by various products. Twenty cases were reported for the period 1900-1904.
Burns accounted in 1907 for a percentage of 11.92 (per 100 accidents) in the chemical industry as against 2.80 for all other workers. They affected various parts of the body in 4.80 per cent.; one single part (exclusive of the eye) in 4.42 per cent.; and eyes only in 2.70 per cent. of the workers in the chemical industry. For all other workers the percentages are as follows: 1.77, 0.57, and 0.53.

Hygienic conditions in the great chemical industry are certainly improved to-day as compared with the past, but the mistake of generalising unduly and imagining that favourable health conditions found in certain countries or met with in certain factories present a true picture of conditions in all factories of this kind must be avoided.

The figures for instance collected by Brückner (1925) for workers engaged in the acid departments of the great chemical works in Germany (Badische Anilin und Soda Fabrik) during 1921 are favourable:

**HYGIENE**

In the case of acid burns, immediate treatment is of first importance. The first thing to be done is to dilute the acid (with water) and to apply compresses of a bicarbonate of soda solution to the part affected. Where the eye is affected, it should be douchèd with water, holding the eyelid well back; such treatment should of course be applied by a competent person (factory nurse). The doctor should be called in immediately. In the English Government factory at Gretna already referred to, the following instructions were distributed to foremen:

Get rid of surface acid by the application of clean water to the part; this may be done by immersing the part in a tub of water, by playing a hose on it, or by leaving the water on it if it is the face or head. Neutralise the acid in the part by applying the alkaline solution and allowing it to act for ten minutes. Gently dry with cotton wool and apply moist picric acid gauze. Cover the surface with a layer of cotton wool and keep in position with a bandage lightly applied. The person who is burned should not be allowed to move the affected part. If the arm is burned a sling should be applied; if the legs are burned, a stretcher should be used. The patient should be seen by the doctor as soon as possible. When the part affected is the eyes or the mouth, it should be washed with alkaline solution and oil applied over the surface.

The manipulation of acid liquids, especially where these are concentrated, should be effected by suitable means so that during transport, pouring, emptying, etc., the worker is not obliged to enter into contact with the liquid, its fumes, or with drops thrown off.

In certain cases it may be advisable to use mask respirators, but it is
always advisable to insist on the wearing of protective glasses.

Precautions should be taken in regard to waste waters with a strong acid reaction (see article "Waste Waters").

Industrial operations involving the use of acids, especially when these are in strong concentration, should be effected in closed apparatus or under ventilation hoods closed by a curtain which can be let down as far as the plane on which the operation is carried out.

Joints of piping should be rendered airtight by applying an acid-proof cement.

Fumes given off, if not recuperated, should be condensed, neutralised, etc., effectively in such a way as to prevent the escape by way of the chimney of all but a minimum quantity of non-condensable acid fumes.

When acids are in basins, vats, tanks or chambers the latter should have an interior lining and should be closed in such a manner as to prevent all escape of fumes. The entry of workers for the purpose of cleaning, repairing, etc., should not be permitted except after adequate measures have been taken to prevent all danger of poisoning or risk to the health.

Inspection services have often drawn up notices to be posted in the workrooms. Similarly associations for accident prevention in the different countries publish a whole series of documents on safety measures appropriate to the use and manipulation of acids. For health precautions in regard to the workrooms, see article "Air of the Workroom."

LEGISLATION

Women are excluded from work involving the use of acid in Argentina (see also articles relating to the various acids). Young persons under 16 years of age are excluded from work involving the use of toxic acids in the United States (Alabama, Arizona, Arkansas, California, Colorado, Connecticut, Florida, Illinois, Kentucky, Maryland, Minnesota, Missouri, Nevada, New Jersey, New York, North Dakota, Ohio, Oklahoma, Pennsylvania, Utah, Vermont, Wisconsin); young persons under 15 years of age are excluded in Greece from the same industries.

Several legislatures have enforced measures of protection for workers handling acids. Thus, for example, English law provides, by section 10 of the Regulations of 11 July 1922 relating to chemical factories, that in all places where strong acids or dangerous corroding liquids are used there shall be provided for recourse in case of extreme urgency: (a) an apparatus for facilitating douching with cold water persons who have received acid splashings; (b) a sufficient number of collyrium bottles filled with distilled water or another appropriate liquid; (c) gloves and protective glasses, or other suitable means of protecting hands and eyes shall be provided for workers required to manipulate acids and corrosive liquids, except in workrooms where manipulation of the said acids or liquids is effected in such a way as to exclude the risk of accident by splashing or by any other means. Gloves shall be collected, examined and cleaned at the end of each working day; they shall be repaired or renewed each time that this is necessary; (d) official notices relating to burning and the risk of asphyxias by gas shall be posted up. For details of the regulations provided by the Alkali, etc., Works Regulations Act of 1901, see article "Gas and Fumes".

Italian legislation excludes women and children from operations enumerated in Table A appended to the Act on the work of women and children (see articles concerning the various acids).

In Norway a Decree dated 29 June 1923 provides for stricter regulation in regard to cleanliness of acid factories and enforces measures in regard thereto (cloakrooms, lavatories, baths, special canteens, exclusion of children, prohibition of the employment of young persons in departments for continuous processes, etc.).

In Russia the Regulations dated 10 April 1922 cover all establishments engaged in the production of mineral salts (exclusive of chloride of lime and chrome salts) as well as the production of chemically pure hydrofluoric and sulphuric acids. These Regulations exclude for instance women and young persons from work in connection with reaction vats (nitric acid factories), from Lorenz vats in decomposition of phosphates by sulphuric acid, from work connected with the recovery of gases liberated during decomposition of phosphates; in the production of hydrochloric, sulphuric and nitric acid, as well as during transport, decanting and bottling and in the production of hydrofluoric acid, etc.: it restricts the length of the working day, deals with hygiene of workrooms, including lighting, heating and ventilation, provision of protective apparatus, medicaments, first-aid boxes, cloakrooms, lavatories, and regulates means of accident prevention, etc.

The Regulations giving effect to the Swiss Federal Law provide by sections 183-189 bis for measures of hygiene in relation to the manipulation and use of acids.

Compensation for occupational disease caused by acids is provided for by English law and by that of the State of Missouri. Japanese legislation provides compensation for ulcers due to mineral acids. In Queensland work involving contact with acid liquids is included in the list of operations to be regarded as entitling the worker to compensation analogous to that provided in the case of accidents.

Acridine

CHEMICAL PROPERTIES

Acridine, the chemical formula of which is C₁₃H₁₄N₂, is one of the principal basic constituents of crude anthracene. Pure anthracene crystallises in the form of colourless (yellowish white) needles, melting at 107°-111° C. It is soluble in cold water, more readily soluble in boiling water, alcohol, ether, carbon disulphide, and hydrocarbons. With acids it gives crystallisable salts with a fine greenish blue fluorescence. Heated with nitric acid it gives nitric derivatives; with alcohols and phenols it gives such derivatives as methylacridine, phenylacridine, naphthoacridine, etc.

INDUSTRIAL PREPARATION

Acridine is got from heavy coal tar oils boiling at 300-360° C., by boiling them with sulphuric acid diluted with four times its volume of water. The aqueous solution is then filtered and treated with an alkaline chromate which precipitates the acridine chromate in crystal form. It is thereafter decomposed with ammonia. To obtain absolutely pure acridine, the salt is decomposed several times by heating with ammonia. Synthetic acridine may be prepared in several ways, of which the following is most currently applied. A mixture of diphenylamine, chloroform, chloride of zinc and zinc oxide is heated in an autoclave at 200° C. for seven or eight hours. The resulting mass is dissolved in hydrochloric acid at 22° Be., then plunged into ten times its volume of water and filtered to separate the diphenylamine, and the acridine is thereafter precipitated by means of soda or ammonia. It is then purified by crystallisation in boiling water.

INDUSTRIAL USES

Acridine is used in the preparation of a series of organic colouring matters (animated derivatives) very frequently applied in dyeing textile fibres and leather and especially cotton. Such colouring matters include orange acridine prepared from amido dimethyl-aniline and formic aldehyde, benzoflavine, acridine yellow got from formic aldehyde and meta-toluylenediamine, chrysazline formed in small quantities in the preparation of fuchsine, phosphine or leather yellow, naphthoacrindine, amidoacridine, etc.

SYMPTOMS

Acridine, whether solid or liquid, irritates the skin and the mucous membrane, causing burning and itching. It gives rise to inflammation and twitching of the skin and to violent sneezing. Its salts cause salivation and lachrymation; in grave cases irritation of the skin and mucous membrane is very marked and the rate of respiration and the blood pressure is increased. Derangement of the central and peripheral vascular systems follows. Internally the action of acridine affects primarily the nervous system. It was noted in 1913 that in course of handling coal tar pitch many of the workers developed itching on those parts of the body exposed to light: face, hands, arms, and neck. Such symptoms were found to favour to an extraordinary degree (86 per cent.) fair-haired workers. Lewin ascribes the malady to the absorption of the poisonous substance and the accident of parts exposed to light being affected he attributes to photodynamic action. Amido phenylacridine or phosphine (leather yellow) also exercises an irritant action more marked than that of acridine. (See article "Anthracene".)

LEGISLATION

Injury due to acridine is compensated in Switzerland, which country also excludes young persons under 18 years of age from all processes where risk of exposure to this product is incurred.
Acrolein
(Acrylic Aldehyde or Allylic Aldehyde)
French: Acrélène. — German: Akrolein. —
Italian and Spanish: Akroleña.

CHEMICAL PROPERTIES

Acrolein — formula CH$_2$: CH. CHO or
$\text{C}_3\text{H}_4\text{O}_2$ — is a colourless liquid, soluble
in 40 times its weight of water and in
alcohol, having a disagreeable, acrid,
penetrating and irritating odour (well
known as the odour felt when a tallow
 candle or an oil lamp is extinguished by
blowing). Pure acrolein is an ethereal
substance with a penetrating odour, got by
oxidation of allyl alcohol or dehydration
of glycerine by means of phosphoric
trioxide and potassium bisulphate and a
small amount of neutral potassium sul-
phate.

SOURCES OF POISONING

Apart from such methods of pre-
paration followed in laboratories, the
product is formed in course of several
industrial operations as, for instance,
when fats are burnt and carried to a
high temperature (soap factories, boil-
ing of linseed oil, manufacture of
stearic acid), in the manufacture of
glue from bones, of tallow (refineries),
of lard, in the manufacture of linoleum
and varnishes, in galvanisation and
inning. When the latter operations
are not effected by the galvano tech-
nical process, the metals to be heated are
first corroded in an acid bath, then
placed in melted fat and finally dipped
in the molten metal. Tinning
is generally carried out in a horizontal
tinning machine. The sheet to be
tinned passes through a layer of
molten zinc chloride and subsequently
through a grease pot containing me-
ted palm oil. Acrolein may also be present
during smelting of alloys used for type
in printing, during cleaning of type-
setting machines, in melting down old
greasy type, in the electrical Industry
being used there for insulation pur-
poses, and in the manufacture of cellu-
loid, etc.

SYMPTOMS

Acrolein fumes produce excessive
irritation in the mucous membrane of
the eyes, nose, respiratory passages,
mouth, and throat, causing severe
itching, headache, and nausea. It
gives rise to bronchial catarrh and
more rarely bronchitis. The smallest
dose proved by experiment to set up
symptoms of irritation and gradually
induce slight necrosis is 0.025 mg. per
litre, while 0.01 mg. causes more
marked irritation and recovery there-
from takes several days; 0.2 mg. causes
more deep-seated lesions, and death
was found to occur among animals
about 18 hours after a 24 hours' ex-
posure to 1.6 mg. Post-mortem
examination revealed deterioration of
the lungs and cauterisation of the
mucous of the respiratory organs.
Symptoms similar to the above
have been met with in industry
amongst galvanisers, tinmen, varnish
makers, etc., including workers in all
the processes enumerated above.
Effects experienced include coryza,
dryness of the throat, chest oppres-
sion, loss of appetite due to acrolein fumes
escaping from the pots. From 1912 to
1923 the Factory Inspection Department
in Holland reported 8 cases of poison-
ing.

HYGIENE

Hygiene consists in the provision of
effective localised exhaust ventilation to
draw off fumes at the source of their production. (See articles "Fatty
Substances" and "Soap Industry ".)

LEGISLATION

Compulsory notification of lesions set up
by acrolein is demanded in the Nether-
lands.

***

Actinomycosis — Streptotrichosis

French: Actinomyose. — German: Aktino-
mykose. — Italian: Actinomicosi. —
Spanish: Actinomycosis.

These 'two parasitic' affections are
grouped together in one article as their
causes have much in common. Accord-
ing to some authorities, notably Lieske,
they are the same species, endowed
with a power of variability sufficient
to explain the differences ordinarily
noted between actinomycoses and strep-
tothrix. There is no doubt, however,
that on this point, as on the epidemi-
ology generally of the maladies, much
still requires elucidation. One must
confine oneself therefore to matters of
a practical nature in the absence of
assured facts.

AETIOLOGY

The actinomycoses and streptothrix are
imperfect fungi (hypomycetes), compris-
ing forms characterised by slender fla-
ments (0.5 to 1.2 microm.), immobiles, not cellular, ramifying but not by dichotomy, and multiplying by sporulation. The spores of actinomyces are characterised by the tendency to metastases and generalisation of the process. It is characterised by suppurative lesions (abscesses, broncho-pneumonia, pleurisy, pericarditis, pyelonephritis, typhus, etc.), or by neoplasms tending readily to caseate (a pseudo-tubercular process). The spit or pus appears homogeneous and contains the specific germ — generally aerobic — which can be easily cultivated and is pathogenic for laboratory animals (guinea-pigs, rabbits on intraperitoneal inoculation). Ordinary the site of the affection is in the lungs: but it has been reported in the brain, following on meningitis of otic origin. Streptothrix is the cause of certain peculiar mycetomas localised in the feet (madura foot), with formation of nodules in the skin, swelling and infiltration of the soft tissues, followed by atrophy of the muscles and enormous hyperplasia of the conjunctival tissue and formation of markedly pigmented granulation tissue. It is often localised in the lacrymal sac and on the conjunctiva.

**Actinomycosis**

This lesion is characterised by the formation of nodules made up of agglomerations of elementary actinomycotic granulations, surrounded by granulation tissue (hyperplasia). These nodules undergo fatty degeneration and go on to form characteristic abscesses, the pus being yellowish in colour, thin and containing bramble-like yellow grains. These are made up of a central mass of tangled filaments, clubbed at the extremities, which form a peripheral zone to the grain. Union of all these cavities constitutes larger and larger pockets in size (abscesses) and as the process spreads by direct extension from place to place fistulous openings are created which produce the formation of new foci and of metastatic abscesses in different parts of the body. The most frequent seat of election is in the soft tissues near the lower jaw and neck (the masticatory organs, generally of a hard, woody tumour); in the centre of the tongue with hard and diffuse swelling; in the lungs where they are situated in the lower lobes and may be associated with pleural thickening and necrosis of the ribs and vertebrae — by extension of the process along the psoas muscle in the pelvis and even into the muscles and enormous hyperplasia of the conjunctival tissue and formation of markedly pigmented granulation tissue. It is often localised in the lacrymal sac and on the conjunctiva.

**Sources of Infection**

The diffusion of actinomyces and streptothrix in nature is very wide. These parasites may be met with in all kinds of vegetation in the earth, water, air, in dust, in certain foodstuffs (butter, cheese, etc.), and as hosts, apparently inoffensive in the intestine, the mouth, on the tonsils (probably following on ingestion of contaminated foodstuffs) of man or animals. Natural infection of man is rather rare if regard is had to the wide distribution of these moulds. It must be admitted that it does not occur except under certain favourable conditions, such as lesions of the skin or mucous membranes, produced, for example, by the ears of grasses, especially corn, seeds or straw or vegetable debris ordinarily contaminated by moulds. Klinger is of opinion that the pathogenic actinomyces are all anaerobic and incapable of development at temperatures below +30° C.; they are, therefore, of necessity parasites on man and domestic animals, acting perhaps as habitual hosts in the mouth, for example, but only in certain circumstances (presence of bacteria, inflammatory processes, etc.) can they develop pathogenic properties. The fact is that dental caries, with its rich microbial flora, seems to constitute a condition sufficiently favourable for the development of these infections. In view of the prevailing uncertainty on these points it is not possible, at present at any rate, to determine
exactly the occupational risk from these infections. The idea that actinomyces from transpiration to man from cattle, which are frequently victims to the disease, has not yet received any decisive proof in its favour, nor again that it is transmitted from man to man, or that it is the direct action of vegetable debris, ears of corn, etc., chewed or inhaled or acting as a cause of traumatism.

Statistics

According to Delépine 75 per cent. of the cases of actinomyces are occupational in origin. Unfortunately, the published accounts too often do not specify the occupation of the persons attacked: when it has been specified a very large proportion of the cases (about 50 per cent.) have been found to affect agricultural labourers. The malady is common, and Poncet is even of the opinion that "actinomyces is only sought in districts where it is not looked for". The period of year during which infection is most frequent is from July to October, i.e. the harvest times. Of 27 cases treated in 1901 by Rieger at the Surgical Clinic of Jena, 18 occurred among agricultural labourers.

According to Bergenheim the number of cases of actinomyces affecting human beings, treated in the hospitals of the different provinces of Sweden is inversely proportionate to the number of cases reported as affecting cattle.

All workpeople handling straw or grain are particularly subject to risk of contracting the disease: agricultural labourers, packers, those tending cattle or cutting and pressing straw (1 case); those manufacturing articles of straw, straw for bottles, mats; those employed in "basket making", using tresses of straw; those making straw hats, or rush mats (1 case), remaking the bottoms of chairs, etc.

Ulmann in Austria has described a certain number of cases amongst shoemakers and explains their frequency by the multiple punctures made in the tongue and lips by these workers holding the awl in their mouths.

Contagion from vegetable dusts is especially to be feared during the threshing of the grain (actinomyces of the hands: Bertha, of Vienna) and is likely to affect people engaged in commercial handling, storing and especially cleansing of grain (grain distilleries, flour mills, grain crushing, breweries and malting houses, starch factories). In malting houses the danger is especially great when the barley is undergoing dust removal, because owing to the special structure of the grains, in the course of this operation, much fine debris is produced. When African barley is handled the amount of dust produced is well-nigh unbelievable (France).

The most frequent channels of entry are the mucous membrane of the mouth, of the tongue, of the pharynx, the tonsils and even the nose — more rarely of the digestive and respiratory tracts (inhalation of the dust of corn and hay). Sometimes infection takes place through the skin.

Diagnosis

The diagnosis of actinomyces is based on the clinical characteristics of the malady, the peculiar aspect of the lesions, the extreme hardness of the tissues affected, and above all on microscopical examination of the grains in the sanguinolent serum, and better still in value of flowing from the actinomycotic nodules. These grains ordinarily have a diameter varying from between 0.01 and 1 mm.; they are visible when the pus is spread out on a slide placed on a black surface. Microscopical examination is aided by the action of hydrochloric or acetic acid, which dissolves the mass of albumen and the pus globules enclosing the grains, or, again, by the action of hydrochloric or acetic acid, which dissolves the calcareous salts present. Generally speaking, the grains are not very hard and simple pressure of the coverslips crushes them, exposing a granular mass surmounted by a crown of club-shaped filaments or a tangled mass of filament. These peculiarities are well brought out by staining with Gram or Kühne-Weigert.

Direct examination of streptotrichosis without previous fixing and after staining (Gram and basic aniline colours) generally suffices. If the parasite is not readily visible, one can try and dissolve a little pus in a physiological solution, which enables small membranes, generally very rich in parasites and serving very well for cultures, to be obtained (Ciani). These can be prepared by the usual means at ordinary temperature and in the thermostat both aerobically and anaerobically. There are no data as to the practical value of immunisation reaction on diagnosis.

Prophylaxis

In the matter of prophylaxis, in view of the uncertainty of pathogenesis, it suffices to call attention to the danger presented by dental caries, by traumaticisms set up by vegetable products, and generally by wounds soiled by straw, hay and other vegetable débris, espe-
cially at harvest time and from threshing, and to bear in mind also the possibility, although only hypothetical, of the transmission of the disease from animal to man.

Vegetable dust being the usual and most dangerous vehicle, measures of prevention should be directed to its capture at the point of origin and removal outside the workrooms. Difficulty is greater in the matter of threshing and cleaning the grain in agricultural undertakings. The development, however, of mechanical appliances in agriculture promises better protection in the future for the agricultural labourer in these operations. Lastly, personal cleanliness of workpeople employed in dusty atmospheres and maintenance of a proper hygiene of the mouth, which is the most frequent channel of entry for the parasite, should be aimed at. Every excoriation of the skin and every inflammation of the mucous membrane of the mouth should be attended to. The putting of grain, spikes and bits of straw into the mouth should be avoided.

LEGISLATION

Actinomyces is compulsorily notifiable in New Zealand and Dominica. It does not appear in any list of occupational diseases for which compensation should be paid. At the same time, Decaillly, in establishing a parallel between anthrax and occupational actinomyces, regarded as industrial accidents, considers that if the establishment in question comes within the French law of 9 April 1898, reported cases of actinomyces employed in such establishments should be considered as accidents and treated as such under that law.

The Industrial Committee of California has awarded compensation as an accident in one case of actinomyces affecting a workman engaged in putting corn into sacks. Such compensation might also be given under the formula of the legislation in the State of Ohio which recognises compensation for "infection due to dust".

BIBLIOGRAPHY

Prof. D. Ottolenghi (Bologna).

Agricultural Labourers

(Occupational Diseases of)

The hygiene and pathology of agricultural labourers (both general and occupational) varies markedly from one country to another and even from one district of a country to another, for the reason that so many different classes of peasants are to be found. Further, different systems of engaging workers, conditions of living, education and housing, the existence of over population or under population, and consequently of immigration and emigration, all exercise considerable influence on the sanitary conditions of the agricultural labouring class. The peasant on his own little farm or on one he rents, or the small proprietor, the shepherd, the market gardener, or the agricultural labourer engaged by the year or seasonally (e.g. clearing olives, beet, corn, tea, etc.) are all types living under different economical conditions and exposed to various occupational maladies.

If, in general, living conditions are not quite comparable with those of pre-war times, it can be said that they have not been bettered, because to-day very often the agricultural labourer especially prefers quantity to quality in what he eats. Under these conditions the food deficit may not be noticed, but although the stomach may be filled the body is not properly nourished. An improvement in nourishment will not be possible until the time arrives when the indifference and ignorance of the masses has been overcome.

Again, housing is still frequently very defective; dwellings are overcrowded, damp and badly ventilated; too often the stable and the house are one and the same. Under such circumstances the labourer evidently cannot feel encouraged to keep clean a house which affords him no comfort.

Lastly, his hours of work, especially during times of pressure, as in harvest and haymaking times, are themselves a cause of fatigue and overstrain.

As an occupation agriculture certainly presents hygienic advantages in comparison especially with industrial employment, carried on as it is in the open air and under the open sky in sunlight. But there are serious disadvantages such as exposure to rapid changes of temperature and weather, the risk of illness contracted from cold (pneumonia, pleurisy, rheumatism, acute nephritis, sunstroke, heat and cold) to quite a series of accidents (wood cutting, agricultural machinery, tending cattle) and infections, diseases and poisoning; to stings of bees, wasps, snakes, etc. Certain kinds of work such as those in connection with rice fields, flax, hemp,
jute, etc., have particular dangers of their own, e.g. initial fever, similar to hay fever, during the time of ripening of certain plants and vegetables. The skin takes on an icteric tinge, there is headache, fever and general pains, etc. In most cases the attack is benign and incapacity does not last for more than a few days.

A great number of agricultural labourers have to look after cattle and have to spend many hours in stables and cow-sheds which are not always models of cleanliness. In several countries the peasants are known to pass the whole of the winter in the cowhouse to escape the extreme cold.

Except in modern farms and in very advanced centres, the byres are deficient in regard to cubic space, ventilation and cleanliness. The air is vitiated by the products of animal respiration (both from man and beast) and emanation from the litter; it is warm and moist, heavy and nauseating. Children and debilitated persons who go from the cowhouse to the cold, outer air often catch bronchial troubles.

The agricultural labourer looks after the cattle, tends and feeds and doctors them when ill, etc. According to the country, this class works on the land or in the farm buildings. Then, for example, the stockman spends the whole day in the open air, as do also the lads and less skilled labourers who look after the cattle in the fields. In the cowhouse the dairymen are especially occupied with milking operations. They have to get up early in the morning (3 o'clock) and can only sleep from 6 o'clock in the morning until noon when they again resume work. These men are the faithful companions of the animals and interpret their needs: they are their breeders, their nurses and their midwives.

**Sources of Risk**

The special pathology of the agricultural labourer is in strict relation to his various occupations, which can be described as follows: (a) various field operations—meadows, vegetables, beet, potatoes, vineyards, fruit growing, gardening; (b) stock raising and care of cattle; (c) wood working; (d) special work such as rice growing, flax, hemp, etc.

The general view taken is that agriculture has no specific occupational diseases: such maladies as there are being due to long hours and fatigue due to carrying on the head and back heavy loads, especially in the case of children and women, which sometimes cause very serious lesions.

Among the operations in the first group mowing, harvesting, digging and threshing, etc., are certainly arduous, and are accompanied fairly frequently by acute morbid symptoms, the result of fatigue, characterised by fever (39-40° C.) headache, pains in the joints, intense thirst and drowsiness. The attack lasts for one or two days and ceases by crises accompanied by excessive perspiration. Sometimes the attack is mild; some observers believe it to be the result of fatigue and circulatory troubles. Digging is without doubt the most arduous work—especially when carried out in full summer sunlight. Frequent in youthful labourers is an acute inflammation in the tendon sheaths of the flexor muscles of the fingers. The forefinger becomes swollen and the palm of the hand oedematous; flexion of the fingers and especially of the thumb becomes very painful. It is an acute inflammation of the serous tendon sheaths due chiefly to excessive fatigue. The condition is quickly cured by rest. Forced flexion of the trunk produces the result of long continued work also sets up circulatory abdominal disturbance and fairly frequently localised inflammation of certain muscles in the lumbar region recalling the clinical picture of sciatica.

Agricultural labourers engaged in stock-raising and the care of cattle are exposed to the risk of accident and infectious maladies: anthrax, tetanus, glanders, foot and mouth disease, actinomycosis, the bacillus of abortion, etc. Labourers employed in applying copper sulphate in solution in vineyards exhibit pathological anatomical changes in the vertebral column, which, however, are not permanent, as Mori thought, but last during the season (Mazzi). The lateral curvature produced results from carrying the pump on the back and the awkward attitude of the body necessitated by the work.

The question requires more detailed study and is still _sub judice_. These workers may also suffer from poisoning after the use of explosives or from products containing arsenic compounds or carbon bisulphide used to destroy parasites.

Forestry often entails accidents in felling trees which may fall on the woodcutters, or falls of the men themselves when climbing; the agricultural machines and particularly mechanical threshers are a frequent cause of serious accidents (especially evulsion of the arms); the effort to control hail by means of cannon firing exposes the workers to burns and explosions, etc. In field work the labourers' tools—scythes, forks, etc.—may cause very serious damage especially to the lower extremities. Similarly, the processes of vintage wine making, etc., may provoke severe accidents. Further, the
spreading of artificial manures by hand may cause serious inflammation of the mucous membranes of the eyes, and throat, as well as set up pulmonary lesions.

In certain operations also the workers may fall from trees, especially when engaged in gathering fruit or mulberries.

Cases of psychic traumatism among women and children have been reported as a result of attacks from animals, cases which have been complicated with neurasthenia or even insanity, especially in the case of attacks of bulls.

Pellagra, beri-beri, etc., have been known to follow receipt of wages in the form of food where this leads to an insufficient or one-sided nutrition.

Women and children are not infrequently made to carry loads too heavy for them, especially on the head or back, in mountainous districts or at the docks. In this way they carry wood, stones, hay, and vegetables, placing them on their backs or carrying them for long stretches in sacks or baskets. Children of from 8 to 10 years old have been known to carry on their heads weights of 70 kg.: cases have also been reported among women of loss of hair, flattening of the bones of the skull, marked lateral curvature of the spine, displacement of internal organs, cramp of the lateral neck muscles, pulmonary emphysema, "heart weakness," and compensatory curvature of the spinal column, which are not without effect on the female pelvis, rendering childbirth more difficult. This work of weight-carrying for long hours exerts a pressure on the posterior part of the thorax making inspiration more difficult, increasing the predisposition to pulmonary diseases, diminishing oxygenation of the blood and setting up a state of chronic anaemia difficult to cure (Repaci, Bernstein). Among women miscarriages are said to be fairly frequent; at any rate some authorities maintain that they are as frequent as in towns. The medical attendants account for this frequency by the heavy work required of young girls and especially of pregnant women. The sexual organs do not develop physiologically as they should and fail to function normally when desired. The young mother does not rest sufficiently long after childbirth; frequently she is seen walking about the day after. Such conditions easily explain the defective growth of the newly born, their lessened resistance, and reduced chance of survival. Further, they explain also the frequency of maladies of the generative organs (prolapse of the uterus, chronic inflammations, etc.).

Work at too early an age, fatigue, household cases combined with work in the field often require the mother to stop breast feeding; the child is then subjected to irrational feeding, often even insufficient and liable to cause digestive troubles, anaemia, debility and grave nutritional defects which develop slowly but fatally.

Children outside their school hours are occupied in different kinds of work on the field or farm. Sometimes they are even kept from school especially for the more pressing seasonal work.

**STATISTICS**

Statistical data collected by Gherardi (1924) from Italian sources show that for the period 1908-1917 the average mortality rate for agricultural labourers (per 1,000 deaths from all causes) is less than that for all occupations (28.1). In this occupation the various causes of violent death are examined, the following facts are brought out:

<table>

</tbody>
</table>

The yearly curve of accidents exhibits a peak in March, followed in April by a drop, and another high peak in July (the time of harvest and of the most arduous work in the open), followed by a fall lasting till November.

According to the Prudential Insurance Company, the mean age at death for the period 1911-1913 is 47.9 for all occupations, and 58.5 for agricultural labourers, as compared with only 36.5 for office clerks, etc.

The statistics of the United States for 1910 show an average mortality of 13.8 per 1,000, and of 2.8 for *tuberculosis*. But while there are 18.8 from phthisis out of every 100 deaths from all causes, clerks, accountants, and office employees show a proportion of 22.5, domestic servants 27.4, agricultural labourers only show 17.6 per cent.

As regards cancer, the statistics of the Prudential Insurance Company show for gardeners a value of 8.43 for every 100 deaths, for agricultural labourers of 6.94, and for all classes of the population 5.49 per cent. The statistics of the United States for the period 1911-1913 is 47.9 for all occupations.

The daily action of the sun, wind and light sets up generally in time an erythema, and sometimes an eczema of the skin. The early degeneration of the skin of the face seen in old peasants (acne, naevus and even skin cancer) has been known for a long time. This last-named affection is sometimes situated on the lips and can be induced by pipe smoking. Of 182 cancers on the face collected by Marassovich, 149 affected agricultural labourers and sailors.

Demanyssus arivm among poultry farmers, tricophyton, favus of domestic animals, Ixodes ricinus, Argas reflexus of pigeons, etc.

Regarding diseases of the eyes or eyelids among agricultural labourers, it will suffice to mention the following: conjunctivitis due to dust raised in the work of grain threshing and packing in sacks, etc.; hay fever set up not only by the pollen of certain flowering plants, but also by the extremely fine hairs found on the surface of leaves and fruits which may be set free in the air (e.g. on the grape leaves when the fruit is ripe: case cited by Villard); lachrymation and erythema of the eyelids occurring among florists. At the same time Zeper, from microscopical examination of the dust of the bulbs of hyacinths, is reported as saying that though they contain none in June and July they do, on the contrary, in August and September contain living acari and their larvae especially Leptus autumnalis. Probably, therefore, these animal agents are the cause of the conjunctival inflammation and erythema, which, according to others, are said to be due to exalate of lime present in remarkable quantity in the bulbs. The dust from crocuses and primroses also sets up analogous affections.

The severe ophthalmia occurring among persons working in flower shops, etc. (Topolanski) and among hop-pickers (Adam) must be attributed to the hairs of flowers and of hops. Persons living in contact with the latter especially may suffer from lesions on the cornea so severe as to lead at times to necrosis of the cornea.

Those who do forest work, and more rarely workers in the fields, show a characteristic eye lesion due to penetration of caterpillar hairs (One-thocampa processionae, Aretis caja, Bombyx rubi). The green and smooth-bodied caterpillars do not set up this affection. A fair number of cases has been described by Elsching and D. Gunn (India).

This malady may even present itself in endemic form among those who collect and destroy caterpillars (Stoermann). At certain times (some days before moulting) the caterpillars appear to lose their hairs more readily, and these set up in persons coming into contact with them catarrhal ophthalmia and dermatitis. The irritating action on the eyes and skin is certainly due to a chemical substance (formic acid?) present in the hair, because mere mechanical action could never set up the clinical picture of nodular ophthal-mia. The loss of tissue which allows the poison to enter the conjunctiva or cornea is provoked by the rigid, cutting part of the hairs themselves. Whatever it be, the researches carried out hitherto seem to exclude action due to microorganisms.

The severest cases, which may last even for years, may be complicated by involvement of the iris. The hairs that have penetrated the sclerotic and anterior chamber reach the choroid (Reis) and set up nodules in it resembling those due to tubercle. Analogous inflammatory conditions often result from the action of the secretion of other insects (aphis, for example), from the stings of wasps and bees, etc. They set up very severe symptoms, especially when the cornea is involved, or inflammatory changes take place in the iris with formation of hypopyon.

Serpiginous ulceration of the cornea is said to be fairly frequent in Germany and to be accountable for two-thirds of the cases of blindness.

Retinitis with opacities in the vitreous have been reported among agricultural labourers after long duration of work in summer without protecting the eyes from the action of the sun's rays.

Antonelli has described a specific disease, vibrio-gangrene of the pupils, which is met with among persons employed in carrying and using manure. There is swelling of the upper eyelid with phlyctenular ulcers which rapidly pass on to a moist gangrene. The chest, face and neck become oedematosus accompanied by high fever, etc. At the end of four, or five days the fever comes down, the necrotic tissues slough off and the patient recovers. Serious deformity of the eyelids (ectropion, etc.) always results. This malady closely resembles malignant pustule due to attenuated anthrax bacilli; it differs, however, in its course and aetiology, as it is due to an anaerobic septic vibrio found in the dung — an ideal culture ground. Soelbrig considers this disease characteristic of southern countries, while Bernstein thinks it can occur also in northern.

A particular conjunctivitis has been described by Gifford in Nebraska. characterised by a painful swelling of the pupils, ulceration of the palpebral conjunctiva and infiltration of the cornea (7 cases in 1922-1923 and 1 in 1924).

Keratomycosis of special type described by Bietti is benign in form; only some dozen cases have been
AGRICULTURAL LABOURERS

described. The first described by Uthhoff and and Axenfeld in 1897 was set up by Aspergillus fumigatus. Bietti has isolated a mould which Saccardi has called Mucor cornealis; in another case Aspergillus flavus and in a third Sporodesmium punctas.

Ophthalmomyiasis localised in the conjunctiva or sometimes in the eyeball (anterior or posterior chamber) is found in Europe more frequently than elsewhere. About 50 cases are known in Europe — 10 in Italy. The causal agent is found in different larvae deposited generally by insects which have flown into the eye, the eggs of which are incubated in the conjunctival sac.

Pterygion and pinguecula are the ocular lesions most frequently found in labourers exposed to dust, particularly those working in the open air and exposed to weather changes (Fuchs, Landsheere, etc.).

Ocular accidents among agricultural labourers are set up primarily by injury, the result of foreign bodies (vegetable and mineral) penetrating the conjunctival mucous membrane readily and coming in contact with the cornea. It will suffice to mention here the injury inflicted by Aspergillus fumigatus, which is carried into the eye by fragments of straw, etc., the small spikes of the husks of chestnut, the small wings of insects, and the husk of grain. All these bodies very often set up keratohypopion, the gravity of which has been recognised, involving, as it often does, loss of an eye.

Labourers in the field are also exposed to more serious accidents to the eyes, the result of blows from the horns of animals (cows, goats, etc.). According to Bertram and Muller's statistics they are more frequent in the left eye, which is explained by the fact that they occur mostly at milking time, the milkman being placed to the left of the animal; other statistics (Eversheim and Hartmann) support the opposite view. As to their frequency it may be recalled that at the ophthalmic clinics of Giessen and Halle they form 8.5 per cent, of all eye accidents. Other statistics state the proportions as 1.8 per cent. Prognosis in these cases depends on whether or not the sclerotic is ruptured. Rupture occurs in about 50 per cent. and is generally situated in the anterior portion, most often above the horizontal midline. Where rupture occurs loss of the eye follows in almost one-half of the cases. Eversheim's statistics show enucleation in 35 per cent. Sometimes the eye lesions are set up by the animal's tail (especially of the ox), flicks from the whip, work tools, etc.

A number of eye injuries are also reported from lightning, which often strikes the labourers when in summer they are surprised by a storm in the open fields and attract the lightning through their wet tools or as a result of the unfortunate habit they have of seeking shelter under the trees.

The development of tuberculosis can be explained by considering the agricultural labouring class as constituting virgin soil unfavourable to resistance against infection. Emigration, forsaking the land for factory life, entry of young girls from the country into towns to take up domestic service, unsanitary conditions, even when the family is in a good economic condition, life in common with children and the aged, work of women in the field even after marriage and during pregnancy, consumption of milk of tuberculous animals, etc., are all factors which play a very important role in the spread of tuberculosis among the agricultural class.

As regards the danger of infection, from bovine tuberculosis, stable boys are admittedly only rarely attacked. Enquiries by Loriga, Maggiora and Gosio, and Terni, etc., bring out the fact that workers of this class, although sensitive to tuberculosis, are not more exposed to risk from bovine tuberculosis than others.

They are, on the other hand, frequently the victims of typhoid fever, of intestinal infections due to the Bacillus coli of oxen and of vaccines. Milkers especially suffer from the last named, but curiously enough infection is frequently conveyed to animals by children who have been recently vaccinated, and then to the cowman or milkman by the animal. Cases of Lichtheimiiasis italic, ondulant fever (especially among goat herds), etc., have also been reported. (See article “Occupational Diseases”.)

Lastly, the frequency among agricultural labourers of diseases of the circulatory organs (heart, blood-vessels, arteriosclerosis, etc.), the digestive organs, and of the peripheral nervous system (neuritis, especially of the fatigued muscles from work such as potato-digging, milking, pressure from tools, carrying sacks of corn, etc.) is noted. In Germany, Coxa vara (Bauerheim) is said to be less frequent now than formerly, although, according to statistics of Bernhardt, 49 were found among agricultural labourers. In old men lordosis of the spine and Coxa vara are frequently seen (Lehmann).
HYGIENE

Agricultural workers require quite a series of legislative measures to improve their lot: housing, water supply, drainage, washing accommodation, and education (even elementary) to demonstrate that women and children should not be subjected to over-arduous and tiring work, and that the workers should not be treated like machines but (like machines in one respect) should be cared for as a good investment.

Quite an education is needed in regard to individual hygiene, proper feeding, antenatal and infant welfare.

Cowsheds should be carefully built so as to secure good ventilation, good natural lighting, adequate water supply for cleaning purposes, etc. There should also be isolation stalls for sick animals. The floor and walls should be easily washed down, windows and indeed all openings should be protected by sackcloth where there is question of infectious diseases like anthrax, glanders, etc. Instruction through leaflets, etc., should be practised; there should be compensation for occupational diseases, accidents, etc.

LEGISLATION

In Holland compulsory notification applies to synovitis of the knee joint, dermatitis and eczema, ulceration of the cornea and conjunctiva in agricultural labourers, as well as to inflammation of joints and cellulitis in gardeners. For both classes of workers, similarly, notification is required of purulent inflammation of the synovial lining of the knee joint and of tetanus.

In Hungary the diseases compensated are enumerated in the Order issued by the Ministry of Agriculture, dated 19 August 1926: anthrax, glanders, infectious diseases, and poisoning by chemical products.

In Brazil the following maladies are treated for compensation purposes like occupational diseases: sunstroke, glanders, tetanus, snake bite, anthracosis, malaria, and Chagas' disease.

New South Wales by special provisions dated 1901 requires, for persons employed in sheep shearing, sleeping accommodation, mess-room and washing accommodation, a sufficient supply of drinking water, sanitary accommodation, etc., maintained in a cleanly condition. Similar provisions apply in other Australian States which (as in the case of Queensland) have extended them to building construction.

The protection of agricultural labourers comes under the regulations of 27 April 1923 applying to factories in Detroit.

In Russia the Compulsory Order of 30 June 1922 deals with protection of agricultural labourers.

From an international point of view, several questions affecting agriculture have been the subject of discussion and resolutions in the course of the Third Session of the International Labour Conference (Geneva, 1921). This Conference made various recommendations, including notably, means of prevention of unemployment; protection of women before and after childbirth (every Member of the International Labour Organisation should take such measures to secure for women employed in agriculture protection similar to that adopted at the First Conference in Washington (1919) for women engaged in industry and commerce; period of absence before and after confinement with compensation during the said period either from public funds or by a system of insurance); as regards night work of women, provision of a rest period suitable to their physique not less than 9 hours on end if possible; age of admission to work (children under 14 years of age ought not to be employed or to work in public or private agricultural concerns or their depots except outside school hours and such work if allowed should not interfere with regular attendance at school; Art. 1). With a vocational object school hours should be arranged so as to allow children to be employed in light agricultural work and particularly at harvest time. The total yearly period of school attendance ought not to be less than 8 months (Art. 2); night work of children and young persons (governed by the requirements of night work for children under 14 years of age, with a rest period suitable to the needs of their physique, etc., not less than 10 consecutive hours); improvement in technical education in agriculture; housing and sleeping accommodation for agricultural labourers (regulations as to conditions of housing and sleeping accommodation bearing in mind special circumstances, climatic and other, affecting work in the field, after consultation with the employers and workers' organisations concerned: this regulation to apply to all places assigned by the employers to the workers, whether single or in groups or with their families, or in the houses of the employer or in buildings placed at their disposal by the employers).

Dwellings intended for families of the working class, etc., should contain rooms capable of being warmed, unless the climatic conditions render that unnecessary.

The rooms should be provided with a bed for each occupant, and so placed as to allow of adequate personal cleanliness. Separate rooms should be assigned to persons of opposite sex. In rooms occupied by families, suitable arrangements should be made for children.

Stables and barns should not be utilised as places for workpeople to sleep in.

Draft Conventions as to rights of association and combination, compensation for accidents and social insurance have also been approved by the Conference.

By 31 March 1926, the Recommendation as to the minimum age for admission had
been ratified by Austria, Bulgaria, Czechoslovakia, Estonia, Ireland, Italy, Japan, Poland, and Sweden. Ratification was also taken into account, especially in Argentina, Chile, Denmark, Spain, and Uruguay. A law applying it has been passed in Bulgaria, Germany, and Hungary.

The Recommendation concerning right of association has been ratified by Austria, Bulgaria, Chile, Czechoslovakia, Estonia, Finland, Germany, Great Britain, India, Ireland, Italy, Latvia, Poland, and Sweden. Ratification was recommended in Argentina, Belgium, Denmark, France, the Netherlands, Spain, and Uruguay.

A Draft Convention concerning compensation for accidents has been ratified by Bulgaria, Chile, Denmark, Estonia, Germany, Great Britain, Ireland, Poland, and Sweden. Ratification was authorised in Hungary, and recommended in Argentina, France, Italy, the Netherlands, Spain, and Uruguay.

Air: Diminished Pressure

(Rarefied Air)

The chief factors causing troubles reported among persons who spend some time in rarefied air are lowering of atmospheric pressure and of the partial pressure of oxygen, together with alterations in temperature and humidity. Increase in intensity of the solar rays, as well as altered electric conditions of the atmosphere, must also be taken into account, especially when the effect of a stay on high mountains is being studied. In that case the troubles and functional modifications do not depend entirely on the action of rarefied air, but also on the effect of meteorological conditions.

If a stay is made on glaciers or on snowfields, the reflection of the sun and even of mere daylight must be taken into account.

It is known that respiratory exchanges are incompatible with a reduced tension of oxygen when it falls to 3 per cent. of the atmosphere (22.8 mm. of Hg.), for at this tension, at 37° C., almost complete dissociation of oxyhaemoglobin occurs. The result of the formation of this substance in the lungs is a lack of oxygen in the tissues.

Laboratory experiments have shown that if the reduced tension of oxygen descends below two-thirds of the normal strength (20.9 per cent.: 159 mm. of Hg.), the exchange of oxygen between the air and the blood becomes insufficient, and mammals begin to experience symptoms of mountain sickness.

The increase of respiration which occurs at high altitudes is related to diminution in the alveolar tension of carbonic acid, which diminishes according to a rather complicated curve studied by Agatzid. It descends, below a barometric pressure of 500 mm. of Hg., in proportion to it.

In high mountains and especially in the glacier regions, very serious dermatitis sometimes occurs. The mucous membranes of the eyes, nose and upper respiratory passages may also be affected by the action of wind, by ultra-violet radiations from sunlight, by dryness of the air, or by glare from the snow.

The inhabitants as well as animals at high altitudes show a very large number of red blood corpuscles. This phenomenon is also found among persons who reach high altitudes and stay there for a fortnight to six months, according to different writers; they become acclimatised by means of this compensatory mechanism — the increased formation of corpuscles peculiar to high altitudes. Physiologists have not, however, been in agreement as to the origin of this phenomenon, and whereas some of them have considered it arose from an actual increase in number necessary to counterbalance the diminution in the pressure of oxygen in the lungs (the larger number of red blood corpuscles serving to increase the respiratory surface), others have held the opinion that it arose simply from an apparent increase. This would be explained either by an unequal distribution of the red blood corpuscles, or by a thickening of the blood. Some writers, however, have emphasised the complexity of the
phenomenon: Ehrlich and Langlois, among others, have admitted that this phenomenon perhaps includes two phases: a peripheral increase of corpuscles with central scarcity, due to the effect of vasoconstriction and associated with a real increase of corpuscles.

There is now no further doubt that it is a case of real increase in the corpuscles. The haemoglobin also shows an increase with a curve parallel to that of the red blood corpuscles.

The quantitative modifications of red blood corpuscles seem to be less clearly shown in the case of airmen. Research into modifications of white cells and platelets in rarefied air have, up to the present, not given results.

As soon as a man reaches above a certain height (2,000-3,000 metres on the mountains or 4,000 metres in a balloon), he experiences symptoms of varying gravity, although training enables him to overcome this trouble to some extent.

Mountain sickness has been described by climbers of all times. It is chiefly above 3,000 metres, between that altitude and 5,000 metres, that symptoms appear: increasing muscular fatigue making it necessary to breathe often; acute thirst; nausea; vertigo; cephalgia; marked tendency to sleepiness, requiring a strong effort of will to continue climbing. Dyspnœa is noted with increase of pulmonary action, acceleration of pulse and sometimes even palpitations. The pulse rate increases gradually up to a height of 5,000 metres; beyond that the acceleration is still more rapid. If a stay is made at the same level for some time, the pulse tends to become slower.

The arterial pressure does not, however, seem to be noticeably modified. Some writers have noted a slight increase of from 10 to 15 mm. of Hg in cases with good compensation.

The minimum pressure keeps level at 5,000 metres and then shows a fall of 8 to 10 mm. In cases with defective compensation the maximum and minimum pressures may be uncertain and cause faintings. Cyanosis of the lips and face, with a sensation of congestion of the face, have also been noted. These symptoms are more pronounced under certain conditions, as when ascending steep inclines, or in a strong wind. Haemorrhagic complications are rare, as is also syncope. But occasional haemorrhages of the nose and mucous membranes may occur, especially with persons not accustomed to a rarefied atmosphere between 2,500 and 3,000 metres, and these haemorrhages are due to dryness of the mucous membranes.

According to some experts, mountain sickness shows itself under two forms: a toxic form, which is indicated by a sudden prostration, more or less serious, with torpor, an overwhelming feeling of cold, cold sweats, cephalgia, vomiting, oliguria and even anuria, all leading up to coma and death if the subject is not brought down to a lower altitude; and an asphyxia form, characterized by anhæmia, cyanosis, tachycardia, and mental excitement, all of which are generally easily and success-fully treated simply by rest, or the use of oxygen. Some subjects actually show simultaneously signs of poisoning and manifestations of asphyxia.

During decompression there is a rise in the blood urea, which is well demonstrated by keeping an animal for some hours at a reduced atmosphere corresponding to an altitude of from 4,000 to 6,000 metres (R. Wolff).

The prognosis is good, and return to lower regions removes the trouble. This is not the case, however, if the climber persists in continuing his ascent, if he stays too long at high altitudes or if, caught in a snow-storm, he becomes seriously chilled. The death of Dr. Jacottet on Mont Blanc in 1900 from acute oedema of the lungs is an instance in point. He did not wish to descend in spite of the onset of serious symptoms.

In addition to this acute form there exists a subacute and slow form described by Régnier. The journey up is made without incident, but there is no acclimatisation to the stay at a high altitude. Sickness comes on during rest, and results from a series of modifications in nutrition and secretions (Guillemard and Moog, Régnier).

The difficulties which have prevented climbers conquering Mount Everest are too well known to make it necessary to dwell on them here (see Bibliography) 1.

In balloon ascents there is an absence of muscular fatigue; but on the contrary, the system is subjected to a rapid change of atmospheric pressure and to the effects of cold and wind.

1 The English expedition to Mount Everest (1924) found that it was necessary to breathe 7 to 10 times for each step at 8,500 metres. The pulse was 160-180 a minute, regular, rhythmic, and normal in volume: above 8,000 metres dilatation of the heart was found, which required 1 to 3 weeks to disappear. No mental trouble was noted, but at the very great altitudes (8,500 metres) the slightest movements were very fatiguing. The rate of respiration diminished and this diminution was explained by the small proportion of carbonic acid in the alveolar air, due to the great aeration: 56 respirations a minute. This rate at 6,000 metres was less by 3 per cent. than that at 4,550 metres.
In the absence of physical exertion, troubles are rarely noticed among airmen — except in the case of predisposed subjects — below 5,000 metres (Pitard, Von Schroetter). Respiratory troubles do not occur up to this height, even if the ascent is rapid. But pulmonary aeration is increased in consequence of an increase in the depth of respiratory movements. Above 5,000 metres the pulse, rapid at first, becomes small and irregular (at 5,000 metres Crocé-Spinelli had a pulse rate of 155). There occur sensations of cardiac distress, sometimes buzzing in the ears, abdominal distension often accompanied with diarrhoea, nausea and even violent vomiting, which may occur at any height.

Above 6,000 metres the face becomes flushed and the cyanosis pronounced; a state of syncope, mental depression and faintings follow on the least muscular effort (for example, emptying a bag of ballast). Haemorrhages are frequent. Crocé-Spinelli and Sivel, who were killed in the catastrophe of Zenith (15 April 1875), were found with their mouths and noses filled with blood.

At high altitudes (Flemming and Steyrer) a diminution of cardiac and respiratory activity is observed, an almost imperceptible pulse, cramps and tremors of the muscles, sometimes paralysis of the legs and arms, reduction in the central and peripheral sensibility, then troubles of hearing and vision, blindness and deafness, followed by loss of consciousness. Dr. Flemming attributed this to the combined action of cold, flatulent distension of the intestines and passive congestion. All these symptoms call for the administration of oxygen, or better still, a mixture of oxygen and carbonic acid, to prevent a fatal issue.

Although not directly concerned with the subject, there may be noted, with regard to the pathology of aeronauts, other occupational dangers. They are: first and foremost, danger of poisoning from the gases: by carbon monoxide at the time of filling and deflating, or of balloon collisions (several cases are reported by Von Schroetter), by arseniureted hydrogen, 16 cases have been reported by Glaister (Glasgow) in the course of filling or deflating, or during flights. A certain number of cases have been reported in the French army by Maljean, and in the German army by Crone. The ordinary symptoms are malaise, nausea, jaundice, dark and albuminous urine.

In dirigible balloons fresh dangers arise from explosion of spirit, from poisoning by carbon monoxide or hydrocarbons, and from breaking of propellers.

Mountain sickness is analogous to the altitude sickness which affects airmen (see that article), although the two are not absolutely identical.

Mountain sickness described for the first time by Alf. Borelli (1671) after the ascent of Etna has been studied for a long time by physiologists and especially by Mosso.

The pathogenesis of conditions caused by rarefied air seems to indicate several factors.

Whereas P. Bert attributed it to deficiency of oxygen in the blood (anoxaemia), caused in its turn by diminution in the partial pressure of oxygen in the rarefied air, Mosso has advanced the hypothesis of acclimatisation; the reason for this is that mountain sickness is not due to want of oxygen, or at least not exclusively to that fact, but also to diminution in the proportion of carbonic acid in the blood.

The lower limit of partial pressure of oxygen at which it is considered that it is possible to live is ordinarily about 30 mm. of Hg., that is to say, the pressure of half an atmosphere corresponding almost to the maximum altitude at which some races live.

As a matter of fact the acclimatisation of individuals living habitually at high altitude must be borne in mind. Thus in the mines of Cerro del Pasco (4,700 metres) it has been noticed that it is possible to live at an altitude of about 3,000 metres, which is not due to want of oxygen, or at least not exclusively to that fact, but also to diminution in the proportion of carbonic acid in the blood.

As a matter of fact the acclimatisation of individuals living habitually at high altitude must be borne in mind. Thus in the mines of Cerro del Pasco (4,700 metres) it has been noticed that it is possible to live at an altitude of about 3,000 metres, which is not due to want of oxygen, or at least not exclusively to that fact, but also to diminution in the proportion of carbonic acid in the blood.

As a matter of fact the acclimatisation of individuals living habitually at high altitude must be borne in mind. Thus in the mines of Cerro del Pasco (4,700 metres) it has been noticed that it is possible to live at an altitude of about 3,000 metres, which is not due to want of oxygen, or at least not exclusively to that fact, but also to diminution in the proportion of carbonic acid in the blood.

As a matter of fact the acclimatisation of individuals living habitually at high altitude must be borne in mind. Thus in the mines of Cerro del Pasco (4,700 metres) it has been noticed that it is possible to live at an altitude of about 3,000 metres, which is not due to want of oxygen, or at least not exclusively to that fact, but also to diminution in the proportion of carbonic acid in the blood.
The researches of Mosso, Agazzotti, etc., make it possible to affirm that not only oxygen, but also carbonic acid diminishes in the blood of persons staying at high altitudes; and also that the potential alkalinity, that is to say, resistance to displacement of the reaction, diminishes from 36 to 44 per cent. at 4,500 metres and that this diminution of alkalinity of the blood is in proportion to the diminution of carbonic acid. But the acidosis is not due to lactic acid, which only appears when a height of about 5,000 cent. is reached, nor to amino-acids, nor acetone bodies.

Recently some American physiologists (Y. Henderson, Haggar) have advanced the theory that, in rarefied air there is not an acidosis, but an alkalosis, and that the succession of changes takes place as follows: lowering of the tension of oxygen in the inspired air; stimulation of the respiratory centre by a substance X of unknown nature, which is not a fixed acid; increase of the pulmonary aeration with strong elimination of carbonic acid; diminution of the ratio $\frac{NaHCO_3}{CO_2}$ in the blood; from which alkalosis arises from lowering the concentration of hydrogen ions, and thus alkal disapperes from the blood.

The existence, however, of alkalosis has not up to the present been confirmed by other experts. On the contrary, a loss of alkali by the urine has been proved, which may explain the acidosis (Viale).

There are arguments of clinical and experimental nature to support both theories, and it seems that it may be necessary to adopt an eclectic theory and attribute the conditions partly to auto-intoxication and partly to acapnia.

A third theory has, however, been put forward. According to Raphael Dubois, mountain sickness, distinct from the sickness of aeronauts, resembles seasickness and is due to defective aeration caused by jolting while climbing, which strains the diaphragm; to this is added a low oxygen tension and an increased formation of CO$_2$ due to muscular exertion. The result is an auto-intoxication from uneliminated respiratory waste products, and these troubles are somewhat similar to those caused by confined air.

But other factors may be added to these: flatulent distension of the intestines with pressure on the diaphragm, which interferences with the vital capacity of the lungs (Zuntz), especially in rapid ascents in balloons and aeroplanes; muscular exertion and the products of fatigue (Zuntz, Regnard), which is chiefly true for mountain sickness or for labour in mines, or construction work at high altitudes. For a long time observers (Saussure, Jacquemont, Regnard, Mosso) have noticed this injurious influence, which will explain why alarming symptoms appear much more quickly in mountain sickness than in the sickness of aeronauts. In a hard climb the fatigue is increased because the thorax is overtaxed and also because the products of organic combustion increase; their circulation in the system is also a cause of fatigue. These toxic products clearly explain the insomnia, anorexia and chronic fatigue observed among miners at high altitudes. Among the same workmen the output of work is diminished; for example, in the copper mines of Cerro del Pasco workers can only work in shifts of eight hours for a few months and are then obliged to return to their farms.

Efforts have also been made to explain mountain sickness by vasomotor conditions of the pulmonary circulation.

**Prophylaxis**

Persons suffering from cardiac, pulmonary or renal lesions should abstain from ascending mountains, or making balloon flights.

Healthy individuals should only enter upon great ascents after a methodical training, so as to reduce muscular fatigue as far as possible. Training, by staying at medium altitudes, has the further advantage of encouraging the production of a compensatory increase of blood corpuscles.

The symptomatic treatment of mountain sickness consists in inhaling oxygen. But it is well known that this is not sufficient to keep up the cerebral functions, when there is a deep barometric depression. Whilst acknowledging that oxygen is capable of reviving the depressed functions of the system, when haematoisis becomes insufficient at high altitudes, Mosso, in 1903, tried upon some suffering alpinists, who arrived at the Marguerite Cabin (Monta Rosa), a mixture of oxygen and carbonic acid. Most of them felt the greatest benefit from the mixture (0+13 per cent. of CO$_2$). It is on these lines that work at high altitudes should now be approached.

This efficient remedy is impracticable on the mountains, but can be used in balloon ascents if a face-piece is used to insure automatic breathing of the gaseous mixture, especially in case of loss of consciousness, which would
prevent recourse to this remedy if a face-piece were not used (Croce-Spinelli, Sivel). Rest and warmth are indicated. In case of syncope, as soon as consciousness returns descent must be insisted on. In case of delayed sickness, acclimatisation to lowered pressure may be facilitated by rest in bed, hot and abundant drinks with a diet, of low toxicity, of milk and vegetables.

**Air: Hot and Humid Atmospheres**

**GENERAL**

The temperature and relative humidity of the air in workplaces should be considered as a matter of fundamental importance on account of the influence which they exercise upon the very delicate human heat-regulating apparatus.

As a matter of fact, these physical properties of the air have a value which appears greater as time goes on.

The quantity of aqueous vapour present in the air is in proportion to the quantity of water evaporated and the surrounding temperature; it increases with a rise of temperature. But for each temperature a cubic metre of air can only contain a definitely fixed maximum weight of water. A cubic metre of saturated air contains:

- at — 20° C. 0.8 grm. of water
- — 10° . . . 9
- — 0° . . . 5
- + 10° . . . 33
- + 20° . . . 17.12
- + 30° . . . 30.04

**Absolute humidity** expressed as a percentage is the weight of aqueous vapour contained in a fixed volume of air at a given temperature.

**Relative humidity** is the relation between this weight and that which it would contain if it was saturated at the same temperature.

Example: at 17° C. a cubic metre of air contains 10.1 grm. of water. If it was saturated at the same temperature it would contain 14.43 grm. The relation

$$\frac{10.1}{14.43} = \frac{70}{100}$$

is the hygrometric state of the air tested.

**Deficit of saturation** is the quantity of water expressed in grammes which a cubic meter of air can absorb at the same temperature to cause complete saturation.

**Relative dryness** is the difference between 100 and the value for relative humidity.

In industrial life there is a temperature and humidity which are necessary to efficiency and a temperature and humidity which are inefficient.

**SOURCES OF DANGER**

Furnaces, steam pipes, and chimneys, insufficiently protected against distributing heat and steam, are in certain industries frequent causes of useless rises in temperature and in the degree of humidity of the surrounding atmosphere.

As regards humidity, this depends chiefly on two factors: human exhalations from the lungs and skin, and natural (hygrometric state of the air) or artificial causes.

With respect to this it should be stated that the use of steam or of hot or cold water may be an industrial necessity, as in the textile trades, when a certain hygrometric state of the surrounding air is required.

The industries in which workers are inconvenienced by an excess of moisture are in particular dyeing and bleaching factories, humid cotton mills, wool combing, natural silk spinning, and often factories for colouring materials, the manufacture of potash salts by means of potash from molasses, sugar refineries, and distilleries. Again, certain places should be noted, such as mines, tunnels, submarines, etc. In mines the temperature increases with the depth, 2.5° for about every 100 metres; in submarines it is possible to
reach 26°C or even 28°C with a relative humidity of 100.

It is a common practice for the textile trades to ensure good production by maintaining special conditions of humidity. The fibres work best when the air is warm and humid; that condition prevents the threads from becoming electrified. The parallelism of the fibres and their smoothness are less perfect when the air is not damp and moist.

It is always difficult to fix an optimum temperature and humidity for various trades; the thickness of the fibre in question, the thread to be obtained, and the subsequent processes to be carried out, all requiring to be taken into consideration. The following figures may however be accepted:

In weaving mills more humidity is needed than is spinning mills.

In other trades on the contrary, humidity is useless and does not help any industrial process, e.g. dye works and laundries of the old type.

Steam rises in bleach and dye works, in cleaning factories from two kinds of apparatus: from vats in which objects are treated by a hot process in a suitable liquid at temperatures from 10°C to 150°C (this applies in particular to circulating vats, boat-shaped vessels, tubs, fullers' tanks, etc.), and from apparatus for drying exposed surfaces, used to cause evaporation of moisture from articles to be dried.

In the first case, the surface of the bath emits steam, the amount of which is in proportion to the true surface of the liquid and its temperature and to the movement of the air at the evaporating surface. The surrounding atmospheric pressure must not be forgotten.

It has been calculated, for example, for dyeing vats by A. Turin that, with the liquid at temperature 50°C, evaporation amounts to 2 kg. of water an hour per square metre of evaporating surface, at atmospheric pressure, and a surrounding temperature of 18°C. Under the same external conditions a bath at 95°C gives off 18 kg., and at 100°C it may give off 35 kg. of aqueous vapour per square metre per hour.

The temperature of the combination of air and aqueous vapour causes a rapid ascending current; the cooler layers of air come in contact with the air loaded with aqueous vapour, which will condense according to the principle: "at the same pressure, air absorbs less aqueous vapour in proportion as its temperature is lower."

The air in workshops moves from a cold region to a warm region, that is to say, as a rule it ascends; damp vapour, on the contrary, moves from a warm region to a cold. If the air of the workshop is not agitated, a state of equilibrium can occur, when the vapour remains at a certain level without descending.

In the second case, evaporation is produced by the contact of drying articles with heated cylinders at temperatures well above 100°C. The air above the drying apparatus is at a high temperature and, if the quantity of moisture to be evaporated is not too great, it may remain below its point of saturation. When the apparatus is surmounted by an efficient ventilating hood and the external atmosphere is favourable, a more rapid ascending current is caused; vapour then only forms outside, after contact with cold external air. The fairly high temperature caused by the frame favours the disappearance of vapour from the workroom.

Vapour can always be accidentally formed by a sudden diminution of temperature in the workroom at any point. It is known that if an opening is made in the vertical side of a wall near the floor, a rush of outside air towards the interior of the workroom is observed; if the opening is made high up on the wall near the ceiling, the current is directed in the opposite way. But there is an intermediate height at which the opening made in the vertical wall will neither give entrance to the external air nor act as an exit for the internal air. The plane at this point is called the neutral zone. This plane is at a fixed height for a certain permeability of the walls and always occurs close to the most permeable parts of the walls. If an additional opening is made, the neutral zone tends to approach this opening, which

Now, if a door is opened (naturally at the bottom of the wall under consideration) the equilibrium is broken, the neutral zone tends to fall and cold external air enters the workroom when aqueous vapour condenses and an
opaque mist forms. If, on the contrary, a skylight or a window is opened in the roof, there is logically an exit of hot internal air. But the phenomenon is more complex than one would think, the speed of the wind which opposes this movement outwards playing an important part (A. Turin).

Mist leads to several inconveniences; it causes the workers to remain in a warm and moist atmosphere; and it interferes with the technique of work by obstructing visibility and favouring the causation of accidents from falls and collisions. Then, again, the abundant condensation of steam upon the lining of the roof and walls falls in drops of more or less dirty water and damages merchandise, the walls, and woodwork.

**Physio-Pathology**

As pointed out elsewhere (see article "Air of the Workroom"), excessive atmospheric humidity is harmful to health both at high and at low temperatures. In cool air the body loses heat chiefly by conduction, and moisture in the clothing increases conduction; hence high humidity makes cold air feel colder. In hot air the body loses heat chiefly by evaporation of sweat, and moisture in the atmosphere checks evaporation; hence high humidity makes hot air feel hotter. The combination of high atmospheric temperature and high humidity is peculiarly detrimental both to health and to efficiency.

All the organic functions and biochemical reactions, which are going on without ceasing in the body, are intimately bound up with the heat-regulating function.

Height, age, sex, food, external temperature, and atmospheric pressure exert well-known influences on the respiratory exchanges. Respiratory activity is greater in man than in woman. But, first and foremost, muscular exertion exerts most effect on these exchanges, for it may make the value of these exchanges three or four times greater than when in the resting state.

The system protects itself against surrounding heat by increasing the cutaneous circulation and by increasing evaporation of moisture either from the surface of the skin, or from the lungs. The physical principle upon which this phenomenon is based is the passage to a gaseous state of a certain quantity of water, a change of state which absorbs heat.

It is calculated that to pass from the liquid state (at 37° C.) to the gaseous state 1 kg. of water absorbs 582 calories. Now, an adult man produces an average of 100 calories per hour, that is, 2,400 calories in 24 hours. The evaporation of a litre can then remove all the heat produced in six hours. The quantity of sweat is taken on an average for 24 hours at from 600 to 900 c.c.; in violent exercises it may even reach 400 c.c. per hour.

Through its interference with this evaporative process, atmospheric humidity greatly complicates the influence of atmospheric temperature upon the body. With a relative humidity of 100 per cent. air at 17.2° is as comfortable as air at 20.3 with only 20 per cent. relative humidity and as we proceed to higher temperatures the influence of humidity becomes still more marked.

The Chicago Commission on Ventilation has designed a diagram which shows the comparison existing between temperature and humidity. This diagram gives thus the zone of comfort for the hygrometric degree at a given temperature:

![Relative Humidity Diagram](image_url)

The dotted line shows the optimum zone.

- **Very hot.**

In the article "Air of the Workroom" is reviewed the work of the New York State Commission on Ventilation, which showed a reduction of 15 per cent. in physical work performed at 24°, and of 28 per cent. at 30° as compared with 20° C.

McConnell and Yagloglou, at Pittsburg, have studied productive efficiency under more extreme conditions. Taking a temperature of 32° C. with 30-50 per cent. relative humidity as a base line, they found that production was cut in half by an increase in humidity to the saturation point and a rise in temperature of 1°; or by an increase to 43° with 60 per cent. relative humidity, or to 52° with 50 per cent. relative humidity. Production was reduced to one-quarter at 38° with saturated air, at 48° with 60 per cent. relative humidity, and at 57° with 30 per cent. relative humidity.

Lee has stated that an animal which was submitted for six hours to the influence of hot moist air lost a quarter of its muscular force. Loriga has received the evidence of a director of silk-spinning mills who could foretell the influence of hot moist air on the efficiency of his workers. It was found that the production of silk at 32° C. with 30-50 per cent. humidity was half as much as at 24° C. with 20-30 per cent. humidity, and that production was reduced to one-quarter at 38° with saturated air, at 48° with 60 per cent. humidity, and at 57° with 30 per cent. humidity.

In consequence, the heart uses up a valuable supply of energy; and the nerve centre which regulates and controls the distribution of blood is brought also to a condition of exhaustion.

The experiments made in this field by Wolpert, Haldane, and Langlois are of great interest. By 1907 Haldane had already drawn particular attention to the fact that it is not necessary to measure the loss of water from the body during a fixed period, but that it is better to judge by variations of rectal temperature. If the air is not moving and the subject is at rest and unclad as far as the waist, the temperature of the wet-bulb thermometer, which can bear for several hours, without there being a definite rise of rectal temperature, is from 31° to 32° C. The determining factor will then probably be the temperature as indicated by the wet-bulb thermometer. If this temperature passes beyond the limit just mentioned, the rectal temperature begins to rise regularly, and once the rise has begun it continues until the height of the internal temperature is reached, which occurs, firstly, when the temperature becomes more and more unbearable, with, at last, serious and even fatal results, unless the worker is withdrawn soon enough from the heat and moisture.

If the worker is subjected to muscular exercise, the temperature shown on the wet-bulb thermometer — which is called "the critical temperature" — must be lowered. In this case the rectal temperature begins its rise sooner. And, if the worker wears ordinary clothes, the rise of the internal temperature shows itself sooner — of course an atmosphere at rest is referred to.

There is then some analogy between the wet-bulb thermometer and the bodily system. One might say that the system is "a wet-bulb thermometer which possesses the faculty of automatically accommodating itself to various conditions".

But this faculty of accommodation is not elastic without limit and does not apply to every condition. It happens, under certain conditions, that the rise of the internal temperature is fatal and that continued accommodation to an abnormal condition of things cannot go on without causing trouble. A certain group of factors must still be borne in mind: the constant degree of the individual temperature; the nature of the exertions made; the quantity of heat generated in the interior of the body; the kind, shape, etc., of clothes which cover the body.
the state of saturation of the surrounding air, its movement, etc. It is notorious that in the same place with an identical hygrometric state, two persons are differently affected by a warm and humid atmosphere.

The investigations of Rübner, revised by Benedict, Carpenter, and especially by Langlois, who introduced into the experiments the factor "work", have shown the great importance of muscular exercise and of ventilation on cutaneous or pulmonary evaporation on the one hand, and upon internal temperature and blood pressure on the other. A person placed in an atmosphere saturated with humidity and not ventilated, subjected to work requiring a certain effort, secretes sweat at a rate which, feeble at first, increases after thirty minutes, and reaches a maximum at the end of an hour. This secretion declines from its maximum, but recrudesces a little later to another maximum less accentuated than the first, and so on. It is the fatigue curve of the means of defence of the organism.

According to these tests, it follows that in a saturated and unventilated atmosphere not only does the elimination of sweat take place, following the above-mentioned curve, but that a certain "deficit of saturation" has some influence upon this elimination of sweat, especially in an atmosphere where the movement of air is from two metres a second, and that under the influence of currents of air pulmonary evaporation does not undergo the important changes which are noticed in cutaneous evaporation.

It is necessary then to take into account to a certain extent, the deficit of saturation." But Haldane says that "when the air is constantly hot and moist, and when the factors which contribute to the establishment of a critical temperature are well defined, the temperature is better determined by the wet-bulb thermometer than by any other means.

The factors of import for the fixation of a critical temperature vary according to the industry under consideration — it can even be said according to each individual. It is necessary then to take an average figure and to indicate to what industry this average figure applies.

Thus, for example, a temperature of 25° C. by the wet-bulb thermometer has been considered in France as the critical temperature in mines. In Great Britain the Act of 1911 on cotton weaving prohibits any artificial humidity above 73° F. (29.3° C.) wet bulb.

It is evident that for workers occupied in cotton weaving and wearing ordinary clothes it is desirable that their clothes should not get wet by perspiration. But the situation is different for miners who can work with their clothes off, or stop work when it is too hot. When there is no movement of the air and the wet bulb exceeds 21.1° C., work causes disagreeable sweating if the worker wears clothes similar to those of the weavers, and any temperature above that indicated increases the bad effects pointed out. If the clothes are lighter, the critical point may then be raised some degrees (34° F.).

It should be further added that while it is possible to ventilate mines by means of a sufficiently powerful air current, it is impossible to do so in the same measure in the textile industry, for any rate sufficiently low has a considerable effect upon the critical temperature (see articles "Cotton Industry", "Textile Industry", "Woollen Industry", and "Ventilation").

Though it is generally estimated that a temperature of 23° or 24° C. may be borne, whilst at 20° C. it becomes troublesome, and that at this temperature it is necessary to reduce the humidity to 50 per cent. Nevertheless, some French manufacturers have asserted that a prolonged stay in an atmosphere charged with steam at 20° C. is not at all inconvenient and that a temperature of 23° C. has a troublesome effect (Heim).

Boulin has fixed as a limit a wet-bulb temperature of 24° C. According to this expert, a temperature of 24° C. is almost that admitted by English legislation for cotton weaving, and it represents an average which must not be passed; for at a higher temperature, if the air is stagnant, the workers will be placed under conditions which in the long run will damage their health.

These general conclusions have been fully confirmed by specific practical experience, such as that obtained by Carozzi in the Italian silk mills and by Glibert, of Brussels, in the textile factories of Belgium. Before the British Departmental Committee on Humidity in Cotton Weaving Sheds, experts testified that the workers in mines subjected to a high wet-bulb temperature exhibit a marked degree
of lassitude and exhaustion. According to Professor Cadman, exertion begins to be accompanied with depression from a wet-bulb temperature of about 25° C. At 28° wet bulb "if clothes be removed and maximum body surface exposed, work can be done providing a current of air is available." At 29° "only light work is possible" and at 32° work becomes out of the question (all wet-bulb Centigrade temperatures).

Haldane, in the same enquiry, says that at 31° C. wet bulb a marked rise of body temperature is noted with muscular exercise, and hard and continuous work is impracticable even when the subject is stripped to the waist; while above 31° wet bulb "in fairly still air the body temperature begins to rise, even in the case of persons stripped to the waist and doing no work; and when once started this rise continues until symptoms of heat stroke arise, unless the person leaves the warm air.”

**PATHOLOGY**

**Acute troubles caused by warm and humid air are various.**

They affect the nervous system with violent headache, supra-orbital pain, most varied reflex troubles with syncope, coma, and death in the most serious cases. As regards the circulatory system there occur small pulse, lowered tension, cardiac weakness, reflex congestion of the organs of the body, such as the lungs and intestines.

Troubles connected with thermogenesis manifest themselves sometimes by high and sometimes by low temperature. As regards the excretory, there have been observed oliguria, sometimes dysuria, with urinary hypertoxicity and haemoglobinuria. The blood shows signs of alterations in the red cells.

Finally, more serious phenomena develop, appearing at the same time as, or a little later than, these other troubles, either combined or separate (see later).

But the acute phenomenon of much the greatest importance, and which has been specially studied by medical officers on ships, is **heat stroke**.

In the first degree, the person affected shows weakness and fatigue, a heaviness in the limbs, a kind of asphyxia with early intense dyspnoea, painful congestion of the face and syncope with sudden onset, followed after the acute stage by somnolence and sleep during several hours.

In the second and more severe degree, Jacksonian convulsions (convulsions of stokers) are seen, varying in duration and character, with intention tremors, nystagmus, tetanic crises, clenched hands, hysterical forms with nervous symptoms of the emotional kind, psychoses, heat delirium (mental confusion, hallucinations, illusions, restlessness, sometimes encephalitis) and troubles caused by dilatation of the heart. Heat stroke terminates in sleep and return to complete consciousness and lucid mind, but cases of coma and death are not rare.

In the third degree, death comes with terrible suddenness.

The internal temperature may rise very high, 43°-44° C. A case has been reported where it reached 47.3° C.; and a temperature of 40.5° C. generally causes heat stroke. But it may also occur at a lower temperature when the physical conditions of the surrounding air are very unfavourable.

Heat stroke is accompanied by hyperaemia of the brain and meninges, polynucleosis and hypertension of the sub-arachnoid fluid, various kinds of degeneration of the nerve cells, contraction and sometimes flaccidity of the heart, haemorrhages of the endocardium and pericardium, and pulmonary congestion.

Fiske has reported that heat stroke on ships shows a special clinical picture, characterised by heat syncope which is peculiar to the engineers. The heat-regulating centres are not affected as in sunstroke: fever is moderate and hypopyrexia is quite common. Cold sweats occur, troubles of the circulation and respiration, stupor, muscular phenomena, abdominal pains, muscular contractions due to dehydration of muscular tissues, and diminution in the alkalinity of the blood due to retention of organic acids of malassimilation.

As regards the blood, it has been observed that if the air reaches saturation point, there is hyperglycemia which experts attribute, on the one hand, to troubles of the peripheral circulation, and, on the other hand, to a concentration of the blood mass, as well as to the reaction of the individual to a diminished oxygen supply.

Continued exposure to hot and humid air can, without bringing on the serious troubles described above, cause chronic troubles. Then are observed dyspnoea on effort, nervous irritability, fatigue, lassitude, oppression and torpor. Layet has already described a relaxation of the tissues, a diminution of functional activity with slowing down of the general nutrition, and lymphatism. This organic breakdown is particularly
progressive, and important pathological troubles only show themselves little by little. The difficulties of pulmonary hematomas, digestive troubles with all their consequences, and weakness of nutrition, lead to chronic auto-intoxication with all its reactions, among which may be mentioned anaemia (Layet, Arlidge, Gilbert), which, for example, is the rule in the humid weaving mills. Together with diminution of appetite, digestive troubles, constipation or diarrhoea, especially during high temperatures (the bilious cholera of weavers).

Investigations made by experts of various countries have brought into prominence diseases of the skin favoured by maceration of the corneal layer following on the local action of moisture, some cases of oedema of various parts of the skin — even of those which are not exposed directly to the action of moist air — some rheumatic symptoms, and painful cramps of certain muscles, or muscle groups.

The same investigations have emphasised high sickness and death rates from respiratory diseases and notably from tuberculosis, high infantile death rate, and, among women, frequency of abortions and miscarriages (see articles "Textile Industry", "Cotton Industry", "Silk Industry", etc.).

**CONTROL OF WARM AND HUMID ATMOSPHERES**

Temperature is measured directly by thermometers. Experts estimate that the temperature should not exceed 20-21.50° C. for active workers, 18-20° C. for semi-active workers, and 19° C. for those employed in hard work.

Humidity is measured in various ways:

1. By *hygrometers*: (a) which act by condensation, based on the temperature of the dew point — too delicate for industrial purposes; (b) which act by absorption, not very exact, but able to be used as an indicating apparatus; and (c) which act by compensation. A good hygrometer should be easy to handle and within the reach of all; it should rapidly give the degree of saturation of the air or the temperature of the dew point and give the indication as approximately as possible.

2. By *psychrometers*: a psychrometer is made of an ordinary or dry-bulb thermometer, and another called "the wet bulb" because the bulb is surrounded by muslin dipping into a reservoir of water which keeps it moist and maintains at the surface a constant evaporation. The heat from the evaporation of the water is taken up by the reservoir of the thermometer, so that the wet bulb shows a temperature (t₁) lower than the other (t). The difference t₁ — t is so much the greater as the evaporation is the more rapid, which occurs when the air is dry, that is to say, more removed from saturation point. It is nil when the air is saturated.

The tension (F) of aqueous vapour is calculated in mm. of mercury, according to psychrometric observations by means of the formula:

\[
F = F₁ = h \left( T₁ - T \right)
\]

where:

- \( h \) = the barometric pressure
- \( T₁ \) = the temperature of the wet bulb
- \( F₁ \) = the maximum tension of aqueous vapour corresponding to the temperature \( T₁ \).

The use of the wet bulb naturally requires precautions. Two thermometers differently placed and supported in different ways will give different readings. The proximity of a pillar or a wall, the composition of the materials used to make such a pillar or wall, the nature of the water used for moistening the muslin, the position of the psychrometer in a small or large room where the relative humidity is however the same, the movement or stagnation of the air, are all factors capable of varying the reading.

Some ordinary psychrometers will not generally yield accurate results since in still air the wet bulb becomes surrounded by a layer of moisture which prevents the evaporation which would naturally be caused by the air of the room as a whole. A more satisfactory type consists of an ordinary psychrometer usually mounted on a handle which permits it to be swung back and forth for a minute or so before a reading is taken so as to expose the bulbs to a representative atmosphere. The silk envelope of the wet bulb is freshly moistened just before each reading. Such a device is known as a sling psychrometer.

The results of psychrometric readings are usually expressed in terms of relative humidity. Since \( T₂ \) is the relative humidity, it is the absolute amount of water vapour which determines the drying influence of the atmosphere upon the human body.

In order to do away with the chief cause of error in the use of the psychrometric formula, "psychrometry by aspiration" has been proposed (W. Lambrecht). It indicates in less than a minute the exact temperatures, allowing, by the use of the tables drawn up by Jellinek, the degree of saturation of the air to be obtained within less than a hundredth of a degree.

The instrument is contrived so that by one turn of a crank each second the air is displaced against the bulb of the thermometer at a rate of about 0.50 metres per second.

The same maker has produced a psychrometrograph which enables one to read with the greatest possible exactness the readings of the psychrometer. Lambrecht has made as well "an indicator of the dew point". Into a sort of capsule containing ether, of which one of the faces forms a mirror of polished
metal, is plunged the bulb of a very sensitive control thermometer. By means of an india-rubber bulb, air is blown into the capsule causing in this way rapid evaporation of ether, that is to say, a progressive cooling extending to the thermometer and to the metal mirror and surrounding atmosphere. When the point of saturation of this atmosphere has been reached, the metal mirror a slight cloud standing out distinctly from the edge of the mirror, which remains bright. At this precise moment the temperature is read, which is none other than the temperature of saturation point of the air in the confined atmosphere and in the external atmosphere. If at the same time a thermometer is arranged to record the temperature, upon the air, it is easy to calculate the relative humidity.

Bellon, moreover, formulates this rule, of great importance in the domain of general hygiene, of ventilation: *If, in a closed place, where persons are required to stay, the ventilation is carried on in such a manner that it ensures a maximum of pure air, there should only be found a difference at the temperature of the saturation point of the air in the confined atmosphere, and in the external atmosphere.*

Proved that certain precautions are taken, the readings of a psychrometer have a certain physiological value, although they have only a relative value from the physical view, properly so called.

In practice each apparatus is supplied with tables of psychrometric readings, more or less exact. It is then possible to determine with sufficient accuracy the hygrometric state of a sample of air and its temperature, and to know, upon the basis of the difference between the two thermometers, the number of grammes of water per cubic metre of air.

(3) By the katathermometer: Leonard Hill some years ago suggested a spirit thermometer ranging from 100° F. (37° C.) to 95° F. (35° C.) which can be used as a dry-bulb or a wet-bulb thermometer. In this way an apparatus is provided which records not only the degree of humidity of the surrounding air, but also the movement of the air.

Instead of noting the temperature at which the spirit becomes steady in the two cases, the rate of cooling is registered, that is to say, the time which the spirit takes to descend from 100° to 95° F. With this object the apparatus is warmed by immersion in hot water at well over 100° F., the apparatus being used either with or without a covering of muslin according to whether it is used as a dry-bulb or a wet-bulb thermometer. It is hung in the air to be examined and the time of cooling is noted. The dry kata cools by radiation and convection, whilst the wet kata cools by radiation, convection, and evaporation—the evaporation depending on the hygrometric state of the air and its movement. When simultaneous observations are made with the dry and wet kata, formulas permit the hygrometric state of the air and its rapidity of movement to be calculated. As a matter of fact the total quantity of heat lost in cooling from 100° to 95° F., expressed in microlcalories, divided by the surface of the katathermometer, gives the loss of heat in microlcalories per square centimetres—characteristic for each instrument which constitutes its coefficient and is engraved thereon.

Provided the systematic experiments of P. Weiss (1925) show that each temperature is closely associated with a most favourable rate of air movement, which permits the body at rest to experience in these conditions a loss of heat almost equal to that which it experiences in motionless air at 18° C. An analogous connection exists between the temperature of the air and the kata index, for there exists for each temperature of the air a kata index which corresponds to the most favourable conditions for heat-loss.

Investigations made by Weiss to determine the existence of an analogous connection for humid air have not led to results, for, while the wet kata reacts to variations in humidity, the temperature of the skin does not react within limits that can be accurately measured.

Computations of the various combinations of temperature, humidity and air movement which produce an equivalent sensation of comfort, based on the experiments of the U.S. Bureau of Mines at Pittsburg, Pa., are cited in another place (see article "Air of the Workroom").

**HYGIENE**

Prophylactic measures naturally vary according to whether a warm humid atmosphere is necessary for the process or not.

In this latter case all radiation of heat must be avoided by employing coverings for boilers, non-heat-conducting lagging, furnaces with a double lining with circulation of water, protection by screens, curtains of asbestos canvas, ventilation in front of fires, humidification or ventilation with...
humidification; while all escape of aqueous vapour and steam must be avoided.

Aqueous vapour exists in the latent state in the atmosphere on account of its high temperature.

But when the temperature is lowered, moisture condenses on the walls and roof of the workroom creating a mist which sometimes goes so far as to pervade the whole room. This also happens when steam cools as it escapes from hot water vats into an atmosphere already saturated. The mists are naturally more frequent in winter than in summer.

In order to disperse mist, two methods may be used: first, by rewarming the atmosphere of the workroom to a temperature at which the quantity of aqueous vapour set free cannot saturate the air, or, secondly, by sending into the workroom a volume of warm air which remains under the saturation point.

The first method should not be adopted, for it will bring the surrounding air to an inadmissibly high temperature.

As the temperature of a workroom should be a fixed datum of the problem to be solved (from 20° to 23° C. maximum), the second method should henceforth be put into practice.

Nevertheless, for several reasons, ventilation more than is strictly necessary for desaturating the air should be provided. And air drawn in from the outside must be warmed to a suitable temperature so that it disperses into the room the calories lost by the walls, roof, and floor, and so that it maintains in the workroom a temperature of 20° C.

In order to prevent the re-entry of outside air, causing the accidental formation of mist, it will be necessary to lower the "neutral zone" as far as the level of the floor and below the plane of formation of the mist. To this end it is enough to create in the workshop an increased pressure, so that it can oppose the external pressure which tends to arise naturally.

Condensation can be theoretically avoided by suitably changing the air in order to keep it at a degree of humidity sufficiently distant from its point of saturation, so that when it cools, through contact with cold walls and roof, it does not reach saturation point. This problem is, however, complex, the construction of the building coming under consideration.

Elimination of mist from a workroom can be obtained by sending in a current of warm air of fixed temperature, of calculated amount, and at a suitable height, but this installation should be made as economical as possible. As far as possible the use of live steam should be avoided for heating air, and the greatest possible use should be made of waste heat, that is to say, to recover unused calories. It is a technical problem which a skilled expert should be able to solve easily.

Without passing in review the principal means of heating the air, it will be enough to stress that apparatus should be placed judiciously in the workroom or outside, and combined with artificial ventilation (see article "Ventilation").

When warmth and humidity are necessary, the problem of maintaining a healthy atmosphere is certainly serious and complex, all the more so as factory owners take the opportunity of exceeding the limits which experts have fixed.

To solve the problem of desaturation of the atmosphere, it is necessary to take into account certain secondary difficulties, such for example as: the process carried on in the workshop, determining as exactly as possible the quantity of aqueous vapour produced; the length of time that hot and moist objects remain in the workshop, which is especially important when the manipulations are slow; the temperature of vats; the external surface of vats and its nature; the construction of the building; the kind of roof, whether of reinforced concrete, without insulation by paper or air, or special tiles; the number of doors; the surroundings, which are important from the point of view of warming and also of removing moist air.

In order to prevent sickness, certain conditions of temperature and humidity must, according to Haldane, be maintained. This writer has been able to determine that in still air the rectal temperature of workers begins to rise as soon as the wet bulb marks 31-32° C., the subject being half dressed and not doing any work. If the thermometer keeps at this degree in a humid atmosphere, the rectal temperature continues to rise until trouble ensues.

If the subject is doing only a moderate amount of work in a still atmosphere, the rectal temperature commences to rise when the wet bulb only registers 26° C.

This is why this English expert asks for no rise of the wet bulb above 24° C. for textile weaving, as work that is only slightly laborious becomes impossible in a place where the wet bulb registers more than 25° C.
Fleicher, of Gottingen, is of opinion that the criterion of the injuriousness of the air is given by the dew point, that is to say, by the temperature to which the air should be brought in order that the aqueous vapour may be held in the air at maximum tension. This dew point lies between 12° and 13° C. and should never exceed 19° C., which corresponds to 85 per cent. of humidity at a temperature of about 21° C.

The experiments of Haldane have been confirmed by the English Cotton Cloth Factory Act of 1909, under this clause:

Between the reading of the dry and wet bulbs there shall always be maintained at least the following differences:

<table>
<thead>
<tr>
<th>Dry bulb</th>
<th>Difference between the dry and wet bulbs</th>
</tr>
</thead>
<tbody>
<tr>
<td>Up to 29° C.</td>
<td>1°</td>
</tr>
<tr>
<td>From 21 to 25° C.</td>
<td>2°</td>
</tr>
<tr>
<td>Above 25° C.</td>
<td>3°</td>
</tr>
</tbody>
</table>

The temperature of the wet bulb shall never exceed 28° C.

Boulin considered that the best temperature is 24° C., which is not too low for the needs of the industry. In spinning and in certain weaving, for example, humid conditions are of more importance than anything. A prudent factory owner tries to maintain the same percentage of humidity whatever may be the temperature. It is, therefore, necessary in practice to deal with the temperature, technical conditions being opposed to any diminution of the necessary humidity.

In conclusion, in order to improve the hygienic conditions of a workshop, it is necessary to arrange for the critical temperature not to be exceeded or, if that is impossible, to modify one of the factors which assist in fixing that temperature in such a way as to make it rise only slightly.

Boulin has remarked that to reach the end sought for, it is not possible for technical reasons to make a variation in the deficit of saturation, a fixed deficit of saturation being necessary for each thread and for each manipulation. If then the hygrometer is useful from the technical point of view, it is in the case in question at least superfluous in the matter of hygiene.

In the case where the critical temperature is reached or passed, it may be inopportune to cease work or to cease artificial humidification. In certain places, especially in summer, when the outside temperature exceeds 30° C., it is impossible not to exceed 24° C. wet bulb if the relative humidity must be raised inside. It is, then, very rare that the ventilation or the humidifying system adopted will enable the temperature of the workroom to be lowered more than 3°. Under these conditions Boulin makes the following two recommendations:

(a) In workrooms of the textile industry where artificial humidification is carried out, when the thermometer rises to 24° C., a system by which the air is renewed at least twice an hour must be established. The air should be drawn from the outside, or, if technical considerations do not allow it, then either wholly or partially from the interior.

(b) In the same workrooms and under the same circumstances as in the combing of wool, and workrooms adjoining, where heat and moisture arise from the manipulations which are carried on there, arrangements must be made in summer to prevent the entrance of solar heat rays. Pipes which convey steam should be coated throughout with efficient non-conducting material wherever it is not indispensable that they should be left uncovered.

As regards mist, this must, according to A. Turin, be removed by heat combined with ventilation, which, except in special cases, should be mechanical. The amount of air sent in will be important and must be calculated by taking into account all the considerations examined. Mechanical ventilation should be by propulsion. The current of air should be suitably introduced at a height of 2.50 metres so as not to inconvenience the workers. It can be carried out by using open fans, or by a shaft—which should, however, be avoided as much as possible. The temperature of the atmosphere must not exceed 20° C.

Utilisable heat, save in exceptional cases, is that contained in steam allowed to escape, or from a high-pressure boiler, and better still from a specially constructed low-pressure boiler. The heating apparatus should be capable of being regulated; it should for preference be placed outside the workroom or at its entrance, and groups of heating radiators should be constructed by which the air can advantageously be heated.

The withdrawal of humid air must be effected by aspiration, or by free openings specially constructed and of a calculated capacity.

It may be said that a test of the efficiency of an installation for desaturation is to be able, under the most unfavourable conditions, to see 20 metres ahead in the workroom.

Atmospheric humidification should be carried out in such a manner that the phenomena reported among persons
remaining in hot and moist places are not to be feared. It is also essential to maintain the necessary hygroscopic degree whilst renewing the air.

An exhaustive study has been made of the problem, with special consideration for the case of industries which require at the same time a fairly high temperature.

The reasons for which most of the fibre textiles require a moist atmosphere are known. But in certain processes, as, for example, work with the yarn of flax, hemp, and cotton, in preparation for the weaving process, a moist atmosphere is required without the need of a high temperature.

It is not necessary to build to-day, as in the past, workrooms with limited apertures, thick walls, and low ceilings.

At the beginning the means taken to ensure the removal of excess of moisture were the same as for steam; large workrooms, well aired, supplied with louvred ventilators in the upper part, or with hoods linked up to collecting ducts, or the two systems conjointly.

But it was soon found that these costly means were not only inoperable, but actually encouraged the formation of mist, for the arrival of saturated air at a lower temperature into air already saturated at a fixed temperature favoured the formation of the mist, just as when a saturated atmosphere is cooled.

It is clear that in these workrooms with louvred ventilators and a large roof surface difficult to warm, the walls and ceilings are, especially in winter, always colder than the saturated air above the vats, and cause in consequence the formation of mist which they should have prevented.

The results are better when the removal is effected by shafts placed above the vessels containing the hot water. But this means is also insufficient, for the moist air leaving by the shaft causes a strong back draught of outside air which is generally colder. This air comes in contact with the saturated air at the level of the water and causes the formation of fresh mist, while the walls run with moisture.

The value of a ventilating shaft is increased by placing above it a chimpey set so that its action does not depend on outside conditions.

A method employed by certain factory owners, which consists in shutting off completely the space between the vat and the hood, presents several disadvantages; the workman is liable to leave open any sliding shutter, which only ought to be open during actual work in connection with the vat; further, work goes on without any supervision; and, finally, it is not possible to apply this scheme to movable tanks, or to those of small size, or when the work is carried out with two.

Elevation of temperature, in order to prevent condensation of aqueous vapour, is only a makeshift. That scheme can only act for a very short period, for, if removal of moist air is not assured and if the heat is distributed uniformly in the workroom, the air will very quickly become saturated at the new temperature. Next, the new temperature must be raised, when after a short time a saturated atmosphere at great heat is established, which is more harmful to the workers than the mist at a low temperature.

It is necessary, then, to insure the entry of fresh air which will not cause new condensation of mist, and this is effected by admitting air which is far from its point of saturation and capable of dissolving a fresh quantity of condensed moisture. The effect obtained is so obvious that English workers say, "the steam is eaten by the hot air".

In conclusion the problem may be solved theoretically by two methods: (a) by warming the air admitted into the workrooms, which is the method most employed; (b) by first drying the air by passing it over hygroscopic substances. In certain cases the air can also be admitted at a low temperature.

A third method consists in preventing the formation of mist by ensuring that the air never becomes saturated. In this case warm air is admitted, which replaces that removed by the hoods arranged over the hot water tanks.

Only by mechanical ventilation can renewal of air be calculated with any accuracy, the temperature in the workshop be fixed with certainty, and the entry of fresh cold air be prevented.

The exhaust system, which produces in the workroom a slight negative pressure, can be useful if the workroom is well closed and if the windows are few. Exhaust fans are placed at the ceiling of the place, causing an oblique current of air, which enters through openings placed at the bottom of the wall opposite the fans. The air, passing over radiating surfaces heated by steam, is warmed to the desired temperature; it then passes into the room where it meets the saturated air,
causes a desaturation and is removed by the exhaust fans.

In certain particular cases, for example, dyeing vats, direct exhaust over the vats has been tried, but this system has many disadvantages.

The plenum system has on the contrary several advantages: it creates a slight pressure which opposes the entry of cold air, at least at the upper and middle zones. The warmed air should be introduced into the workrooms at a suitable height, which has been carefully studied and may be between 2.50 and 3 metres. Ventilation which is not annoying to the staff can be easily obtained, amounting to six to eight times the volume of the workroom.

Air may be introduced immediately into the workroom, or directed at a desired height and distributed by sliding panels or special fittings. These last must be as simple as possible, and be capable of being regulated, the object being to distribute the warm air in the desired amount at each place. Moreover, the area allotted to each air-distributing duct or tube should be calculated exactly.

The ducts have fallen into disfavour as the result of experience, and some factory owners have tried to introduce warm air directly into the workroom by constructing groups of air-heating ventilators, a certain number of which are distributed in the workroom and pass in the hot air direct (noticeable even at 15 metres) with the ventilators only open a few millimetres at an angle of little more than 15 degrees.

Finally, plenum and exhaust can be used at the same time, so that the warm air follows a horizontal movement. The result may be exact that if the volume of air dealt with by the exhaust fans is sensibly less than that allowed for by the ventilators and if the building is well closed up in the vicinity of the exhaust fans.

Turin recommends putting in the system without fixing definitely the removal of air, so as to reserve the possibility of modifications, e.g. by opening the window sashes. He further holds that it is better to allow the moist air to escape by openings of sufficient size in places determined beforehand and rectified afterwards, if required, after trial, and without exhaust.

In the particular case of mist forming in great quantity at a well-defined point, Turin suggests avoiding its extraction, but dispersing it by heat supplied by a coil of galvanised pipes placed above the centre of its formation.

It has been seen that, in a moist atmosphere, electricity produced by textile fibres rubbing against the parts of the loom disappears in a conducting atmosphere with advantage to technique.

In practice efforts have been made to replace the necessary warm humidity by currents of high frequency. The first applications were made about 1911 by Ducretet upon looms for weaving wool in region of Fourmies, France. These currents discharge the electricity from the textile fibres and allow good weaving without excess of heat or moisture. But the trial period cannot be considered as closed.

In the same way the fight against excess of steam in the atmosphere, which condenses in a mist when the point of saturation is reached, can be carried on by the help of air heated by an electric heater. It is not too much to hope in the future, as Bar- geron says, for electrical dispersion of mist and perhaps dehumidification of atmospheres charged with mist.

LEGISLATION

Legislation provides for the prohibition of work in places which are too moist, especially if underground work is concerned. Measures have been enacted for preventing the escape of steam into the atmosphere of a workroom when humidity is not necessary. When, on the contrary, humidity is necessary, regulations provide that processes shall be carried on without too much injury to the health of the workers. Hence legislators have laid down very detailed regulations for unhealthy trades, such as the textile industry, paper works, and laundries (see the relative articles).

BIBLIOGRAPHY

Air (Liquid)

Air is a mixture of oxygen (23 per cent. by weight) and nitrogen (77 per cent. by weight) containing very small quantities of argon, neon, helium, krypton and xenon. These elements are also found in liquid air.

Liquid air is colourless, but with a bluish reflection, and has a density of about 1; its boiling point is between $-19.5^\circ$ C, the boiling point of nitrogen, and $-182.5^\circ$ C, the boiling point of oxygen. To be preserved, liquid air must be protected against heat and for this purpose silver vessels with double sides within which a vacuum is created are used (Dewar vessels, similar to "thermos" flasks).

In spite of its very low temperature, liquid air only rarely causes lesions of the skin. As a matter of fact the hand can be dipped into liquid air without harm. This immunity is due to the formation of an insulating gaseous layer; it is the phenomenon of calefaction.

Liquid air is excellent for supporting combustion owing to its high concentration of oxygen.

Air cannot be liquefied by compression, its critical temperature being $-140^\circ$ C. But the lowering of the temperature caused by the expansion of compressed air is used.

Linde's machine, which is used for the liquefaction of air, is constructed as follows: (a) a triple compressor which compresses air to 200 atmospheres; (b) a purifier containing lime and potash, which removes from the air the moisture and carbonic acid which it contains; (c) a freezing chamber constructed of concentric coils. Compressed air circulates downwards in the interior coil, then it cools itself by expanding. The expanded air rises in the annular space created between two coils. Thus it abstracts heat from the compressed air, which is within the interior coil and is cooled before expansion. In this way a number of successive coolings are obtained, which enables a sufficiently low temperature to be rapidly reached. The liquid air is gathered together in a collector situated at the lower part of the freezing chamber.

The machines of Hampson and of Heylandt are based on the same principle as that of Linde. In the machine of Claude the air when expanding is made to do work. The cooling is thus greater. This machine possesses much the same parts as that of Linde, but it includes in addition a cylinder furnished with a piston. It is true that the expansion of the air occurs, which then passes through the tubes of the freezing chamber. The cylinder and its sliding valve are lubricated by liquid air.

Uses

Liquid air is used for the preparation of explosives of the type "oxylignite", frequently used for piercing tunnels. A cartridge of liquid air, or, better still, of liquid oxygen, is made up of a paper tube enclosing absorbent materials: soot, sawdust from wood, wood dust, etc., combined or not with metallic powders, such, for example, as aluminium. This cartridge is perfectly inert and only acquires its explosive properties after being dipped in liquid air. The oxygen evaporates fairly rapidly and the cartridge becomes again completely inert at the end of about half an hour. In practice, the explosive cannot be utilised for such a long period. The explosion should occur when the quantity of oxygen and the combustible material of the cartridge are in such proportions that combustion of this material can occur without setting free carbon monoxide which would be injurious in the atmosphere of a mine. Cartridges of 38 mm. diameter by 300 mm. in length should be used with a delay of ten to fifteen minutes. The metallic powders are intended to increase the explosive force.

Liquid air is further used for respiration apparatus, life-saving apparatus used in mines, respiration apparatus for balloons and aeroplanes, and in scientific laboratories where liquefied gases are manipulated.

Most of the liquid air produced industrially is distilled in apparatus comprising columns in tiers similar to
those used for the rectification of alcohol.

Thus oxygen is obtained, the uses of which are numerous; nitrogen, which is used in the manufacture of ammonia (see that article) and calcium cyanamide (see that article); argon, used for filling incandescent electric lamps (see that article) and neon, used for making red-coloured luminous tubes with rarefied gas.

Montlaur (Paris) reported in 1926 that a jet of liquid air received on the back of the hand by him set up erythema followed by numerous phlyctenae. He considers that liquid air is not without danger when coming in contact with the bare skin.

Another accident occurred in the course of evaporation of large quantities of liquid air to obtain crypton and xenon present in the last stages, the reservoir exploding and killing the engineering chemist in charge of the operation (1926).

Claude considers that the accident was due to the presence of impurities and particularly to traces of acetylene and ozone.

An apparatus for production of liquid air transforms 1,000 cub. m. of air per hour; should the air, as a result of the liberal use of acetylene for soldering and lighting, contain one part per million at the end of the month, there would be a kilo of liquid acetylene in the apparatus, which would form with the liquid oxygen a very powerful explosive mixture. Claude is therefore of opinion that only very high layers of the atmosphere should be liquefied in order to ensure that no traces of acetylene are included.

***

Air of the Workroom
(Close Air, Vitiated Air)

In many factory workrooms there are special hygienic hazards of the first importance created by the presence of toxic fumes or of siliceous dust. These problems are discussed elsewhere under various headings — see articles "Gas and Fumes", "Stone Industry", "Dust", "Tuberculosis", etc. — and this article is confined to changes in the atmosphere due to human occupancy and to the combustion of illuminants, that is, to the conditions which obtain in the ordinary workroom where no special poisons or industrial dusts are generated.

Composition of Air

Normal outdoor air is composed of approximately 78.1 per cent. of nitrogen by volume, 20.9 per cent. of oxygen, 0.9 per cent. of argon, 0.03 per cent. of carbon dioxide, and small proportions of other gases such as neon, helium, krypton, and xenon. In addition to these substances, which are relatively constant in their proportions, there is present a variable amount of water vapour. The maximum amount of moisture which the air can retain in gaseous form varies widely with the temperature. Thus air at 0° C. will hold only 4.8 grm. of water vapour per cubic metre; at 20° C., 17.0 grm.; and at 30°, 29.9 grm. In view of this fact, the amount of moisture present is commonly expressed not in terms of absolute volume, but in terms of relative humidity — the ratio of the water vapour actually present to the amount which the air could hold at its actual temperature if saturated.

Factors of Vitiation

As a result of the vital processes of the human body or of the combustion of ordinary illuminants (both processes being essentially similar oxidations of organic matter), five changes are effected in the air of an occupied room. The oxygen is decreased, the carbon dioxide is increased, the temperature and moisture are increased, and there are added to the atmosphere certain incompletely oxidised substances, often of an odorous nature. In the case of the human body the latter type of materials includes the products of organic decomposition discharged upon the skin by the sweat glands and the sebaceous glands (valeric, butyric and caproic acids, methylamine, trimethylamine, etc.) : the results of putrefaction of organic substances accumulated through lack of cleanliness of the surfaces of the body and the clothing or arising from the mouth and teeth, and products originating in the digestive canal (intestinal gases, ammonia, hydrogen sulphide, indole, skatol, fatty acids, etc.). It is such products which give to the air of an unventilated room its characteristic "body odour:"

Former Theory

Taking up, one by one, these five changes in the atmosphere produced by human occupancy, the decrease in oxygen which takes place in an ordinary unventilated room was shown by Lavoisier in 1777 to be without
practical significance; and in 1868 Pettenkofer showed that the increase in carbon dioxide was equally unimportant. In the deep parts of mines where carbon dioxide has largely replaced oxygen, or at high altitudes where the partial pressure of oxygen has been reduced in similar degree, men actually suffer from oxygen starvation. In the worst ventilated rooms on the earth’s surface, however, the natural ventilation through cracks and diffusion through the actual substance of walls and ceiling is so great that oxygen never falls below 20 per cent. and carbon dioxide rarely rises above 0.5 per cent. Such changes as this are far below the threshold of physiological significance.

Pettenkofer himself believed that the effect of bad air was due to hypothetical organic poisons associated with the products of decomposition which give rise to the body odour, and that the object of ventilation was the removal of these poisons by dilution with fresh air. To Pettenkofer, carbon dioxide was of significance as an indirect measure of the presence of morbific matter, and it is to him that is owed the assumption that air containing less than a certain amount of carbon dioxide is good and air containing more than a certain amount is bad. Brown-Séguard and, in later years, Weichardt, Trillat, and Henriet have been the chief exponents of the theory of atmospheric “morbific matter” in various forms.

Modern Theories

The great majority of physiologists, however, now accept the view that the harmful effects of bad ventilation (apart from the presence of industrial poisons and industrial dusts) are no more the result of hypothetical organic poisons than of changes in concentration of oxygen and carbon dioxide. They are due to the other two effects of human occupancy, increase in temperature and moisture, combined with lack of air movement — conditions which, in combination, produce a serious interference with the heat-regulating mechanism of the body. As far back as 1833, Hermans of Amsterdam, arrived at the conclusion that the harmful effects of bad air were due not to its chemical but to its physical properties, and in 1905 Flogge and his associates at Breslau definitely and clearly formulated the modern conception of ventilation — a conception expressed by Professor F. S. Lee in the succinct formula that the problem is essentially physical, not chemical, cutaneous, not respiratory. The conclusions of Flugge have been amply and universally confirmed by Hill and Haldane in England and by Benedict and the New York State Commission on Ventilation in the United States.

In one form or another these various investigators have shown that a group of subjects enclosed in an experimental chamber and suffering from the familiar effects of bad ventilation can in no way be relieved by permitting them to breathe fresh outside air admitted through a tube, but can be completely relieved by cooling the vitiated air of the chamber in which they are imprisoned. The only effects which can be definitely traced to chemical vitiation are slight interference with appetite and with the inclination to physical work, due to the psychic effect of body odours. These latter effects, however, only appear, with a concentration of some 20 parts per 10,000 of carbon dioxide, equivalent to an air change of some 11 cubic metres per person per hour, and are entirely subsidiary to the thermal influences which constitute the major problem of ventilation.

Effect of Increased Temperature and Relative Humidity

On the other hand, all recent work has tended to emphasise the very serious effects of even slight degrees of overheating upon the physiological state. The human body produces by its vital activities from 100 to 400 calories of heat per hour, depending upon the extent of physical exertion. This heat is given off to the surrounding air at a rate which would normally vary very widely with the temperature of the atmosphere. Yet, by one of the most complex regulative mechanisms of the human body, these processes are so beautifully balanced that the actual body temperature does not vary in health more than a degree on either side of the normal (36.5° C.).

At low temperatures this regulation is in part, but only in small part, accomplished by an increase in heat production; at high atmospheric temperature there is no such adaptation, the heat production within the body being actually though slightly increased. It is, then, the rate of heat loss which varies and which is the chief factor in maintaining the body temperature at a fixed level. When in a hot room, the tiny blood vessels of the skin expand (as is the face becomes flushed) said, and bring a large
amount of blood to the surface of the body to be cooled off. On passing into cold outside air, the skin blood vessels contract, the blood is sent into the inner organs, and the cooling effect of the air upon it is thus correspondingly reduced. This is the chief regulatory process which operates at atmospheric temperature below 10°. As the temperature of the air rises a new factor enters: the increased production of sweat, which is evaporated (if the air be not too humid), with the absorption of heat which always accompanies the change of a liquid to a gaseous form.

The primary effect of high atmospheric temperature is, then, to dilate the tiny blood vessels of the skin and thus concentrate the blood flow in them at the expense of the inner parts of the body. In part, the feeling of discomfort and lassitude experienced is probably due directly to anaemia of the brain and other internal organs caused by a reduced flow of the blood in the capillaries. Furthermore, as will be pointed out below, habitual exposure to such conditions leads to a lowered tone of the whole heat-regulating mechanism and an inability to respond to the demands which may be put on it, and in this way exerts a profound and important influence upon susceptibility to respiratory infections. With only slightly excessive atmospheric temperature, the body temperature of the subject rises, the heart rate and the respiration increase, and the Crampton index—a measure of the efficiency of the vapor motor system—falls to a significant degree. The performance of physical work is markedly affected. In the New York State Commission studies, 28 per cent. less work was accomplished at 30° C. as compared with 20° C. even under conditions of maximum effort, and in a test where the subjects were influenced only by a small bonus, a temperature of 24° C. showed 15 per cent. less work performed than was accomplished at 20° C., a conclusion of the most far-reaching importance as an argument for the regulation of temperature in the workshop and factory.

Finally, the work of Hill in England and of the New York State Commission in America has indicated profound effects of only slight degrees of overheating upon the prevalence of respiratory disease. In the studies conducted by the New York State Commission on 2,500-3,000 school children during two successive winters, it appeared that a room temperature averaging 20.3° C., as compared with a room temperature averaging 19.1° C., showed an 18 per cent. excess of absence due to respiratory disease and a 70 per cent. excess of respiratory disease among pupils in attendance. Both English and American observers find the explanation of this effect in observable changes in the membranes of the nose and throat due to overheating and in consequent inability to resist the change from heat to cold on passing into the outdoor air.

At still higher temperatures symptoms of course become much more acute. The United States Bureau of Mines, in an extensive series of studies recently carried out at Pittsburg, Pa., equipped a carefully controlled experimental chamber in which subjects, variously clothed, under a very wide range of temperatures, humidities, and degrees of air movement and prolonged exposure to high temperature to the point at which a longer stay appeared definitely dangerous. Restlessness, irritability, headache, and palpitation of the heart, soreness of the eyes, a sensation of oppression on the chest, dizziness, and confusion were the chief symptoms experienced; and weakness and a dragged-out feeling persisted for some time after such experiments had closed. The extreme dry-bulb temperature which could be endured was 69° C. (wet-bulb temperature 38° C., relative humidity, 15 per cent.) for forty-five minutes while the extreme wet-bulb temperature was 44° C. for thirty-five minutes. The body temperature under such conditions rose several degrees. The pulse rate seemed to be the best measure of discomfort, 135 beats per minute corresponding to marked discomfort, and conditions becoming almost unbearable when the pulse rate exceeded 150 beats. With moderate overheating, both systolic and diastolic blood pressures fall; under more extreme conditions systolic blood pressure increases while the diastolic pressure continues to decrease.

Curiously enough, the increase in respiration rate observed by the New York State Commission and by Vernon in England was not noted at Pittsburh. Marked rise in body temperature and pulse rate were, however, apparent above 32° C. in saturated air. One of the most important contributions of these investigators is the recent report that basal metabolism (the rate of oxidation within the body) decreases with increasing temperature up to about 26° C. (with 100 per cent. relative humidity) and then increases, the rise becoming very rapid when the atmos-
phic temperature is higher than that of the body. Such a temperature of 26° C. with 100 per cent. relative humidity (corresponding in its physiological effects to about 31° C. with 50 per cent. relative humidity in still air or 34° C. with 20 per cent. relative humidity in still air) is clearly a critical temperature beyond which serious harmful results may be expected. Ideal conditions were found to lie between 17° and 21° C.

**VENTILATION STANDARDS**

Official administrative standards of ventilation are still generally based on the older chemical theory rather than the newer thermal one. According to the Pettenkofer conception, a concentration of carbon dioxide in excess of 6 parts per 10,000 was supposed to be associated with a dangerous proportion of poisons in the air; and standards advocated by more recent authorities vary from 6 to 10 parts.

On the assumption of such a carbon dioxide standard it is course very simple to calculate a standard of per capita air supply. Since it is known how much carbon dioxide is eliminated by an average individual per hour, the dilution of this carbon dioxide by outside air containing 3 parts per 10,000 so as to keep the room air below a given concentration is merely a matter of arithmetic.

In addition to Pettenkofer's standard there should be mentioned the "anthracometric standard", which has for its aim to stress the importance of renewal of air in confined spaces and which measures such renewal by charging the atmosphere with artificially produced CO₂ and determining the content at stated intervals. The system is as follows: CO₂ is liberated in a confined space till a given percentage (approximately) of the gas is present—the percentage in question being a fairly high one. The liberation of the gas having ceased, after a lapse of time the CO₂ content is taken in order to provide an estimate of the rate of renewal due to ventilation.

Another method consists in liberating carbon dioxide at a constant rate throughout the whole experiment and by taking the content, on two successive occasions separated by a given lapse of time, to ascertain the variation in the percentage present in the air (P. Bellon).

Leclerc de Pulligny and Boulin have studied a formula for calculating the vitiation and the cubic capacity of rooms:

* If an individual exhaling 0.02 cubic metres of carbon dioxide per hour is placed in a room the cubic capacity of which is C cubic metres while the renewal rate of air per hour is V cubic metres, the outer air containing 1/10,000 of carbon dioxide, the time at the end of which the content of the room in CO₂ will reach N is expressed in hours by the following formula (1):

\[
t = \frac{200}{V} \log \left( \frac{C}{200} - \frac{N - n}{V} \right)
\]

(1)

* This content has moreover an upper limit 10,000/10,000 which it approaches indefinitely without however attaining it and which is expressed by the formula (2):

\[
t = \frac{200}{V} \log \left( \frac{C}{200} - \frac{N - n}{V} \right) = 0
\]

(2)

* On the other hand the CO₂ content rapidly reaches the value N which it approaches indefinitely which differs from the maximum only by 1/10,000 and the time t, at the end of which this content is attained is expressed by the formula (3):

\[
t = \frac{200}{V} \log \left( \frac{C}{200} - \frac{N - n}{V} \right)
\]

(3)

In practice, these experts state, "it is equation (2) which is used for calculating the renewal of air V independent of the cubic capacity per person, required, to maintain the vitiation below a given limit N, and when it is desired to ascertain the length of time after which vitiation has reached approximately 1/10,000 recourse will be had to equation (3). If it is desired that, without renewal or with slight renewals V, the maximum vitiation tolerated 1/10,000 (N = 10) should not be attained after a period of four hours, the values of C which should correspond to each value of V will be got from equation (1). Taking N = 3 (3/10,000 carbon dioxide present in the outer air), there is found:

<table>
<thead>
<tr>
<th>Cubic capacity per person (in cubic metres)</th>
<th>Cubic capacity per hour in cubic metres</th>
</tr>
</thead>
<tbody>
<tr>
<td>Cubic m.</td>
<td>Cubic m.</td>
</tr>
<tr>
<td>15</td>
<td>80</td>

</tr>
<tr>
<td>3</td>
<td>114</td>
</tr>
</tbody>
</table>

which rate is considerably higher than the minimum cubic capacity per head of 7 metres provided by legislation, and which in certain cases is judged as difficult of attainment.

* For a renewal of 28.5 cub. m. the vitiation of 10/10,000 is precisely the limit which is never attained. For a cubic
capacity of 7 metres that of 9/10,000 is reached after 28 minutes. 48 seconds.
A renewal of 28.5 cub.m. is that which must be considered as normal. Further, it is essential that the fresh air introduced should be well distributed throughout the workroom.
The time at the end of which vitiation reaches 10/10,000 is calculated by applying equation (1) and the values will be as follows:

### The Standards Adopted

From an ideal point of view, each worker should be accorded a surface space of 2 metres and a cubic capacity of 5 metres with an hourly exchange per capita varying according to the nature of the work effected, but never falling short of six times per hour for a sedentary worker and ten times for a worker engaged in active physical exertion.

Though formerly health experts demanded a renewal of air which varied between 6-10 cub.m. per capita per hour (Leblanc), 8-12 (Peclet), 10 m. (Arago) and 38 m. (Offermann) or 54 (Parkes), to-day the average value demanded is 30 per capita per hour (see article "Ventilation").

### Legislation

All legislative systems in the industrial countries contain regulations the purport of which is to prevent workers from being allowed to follow their occupation in unduly close air. It is however important not only to set limits as to cubic capacity, but at the same time to regulate the surface space and the hourly renewal of air per head.

Though in a minority of legislative provisions a vague and indefinite formula is still used, such for instance as "adequate cubic capacity proportionate to the number of workers and in accordance with hygienic requirements", most legislative provisions now cite a minimum value for cubic capacity and even for air renewal. Thus, for example, Austria demands a cubic capacity of 10 cub.m. and a surface space of 2 metres which are subject to increase should certain circumstances render it necessary (dust, fumes, etc.); Belgium also demands 10 cub.m. per worker and a renewal of 30 cub.m. at least per hour and of 60 cub.m. in specially unhealthy workshops; Canada requires 11 cub.m. per worker; Denmark 8 cub.m. (which the Factory Inspection Department may increase to 12); France demands 7 cub.m. at least and 10 cub.m. in certain industries (laboratories, kitchens, stores, shops, and public offices). The air must be renewed in such a way as to maintain the standard of purity essential to the health of the workers (Decree of 10 July 1913), and the general ventilation for any enclosed space shall be such as to prevent an undue increase of temperature.

In Great Britain 7 cub.m. is demanded as a minimum: further the Cotton Factory Act and other Orders impose a maximum of 9/10,000 of CO₂ for the textile industries with a cubic capacity of 11 metres when overtime is worked unless electric light is installed. In Italy the draft regulations for industrial hygiene provide for a uniform cubic capacity of not less than 10 m. per person as well as a minimum surface space of 2.50 metres. Air in closed workrooms shall be frequently renewed so that the CO₂ rate produced by exhalation shall not exceed 10 in 10,000. Where this rate is exceeded factory inspectors shall have authority to demand that natural ventilation be completed by artificial ventilation. Whatever the system of ventilation, all draughts liable to inconvenience workers must be avoided. The air of workshops must be renewed at a fixed point and exceeding a rate of 0.50 per second must be avoided. In Holland, good natural ventilation must be provided where mechanical ventilation is not installed. Natural ventilation is deemed insufficient where the local surface of aperatures communicating directly with the outer air is not at least 5 cub.decametres exclusive of doors. The third part at least of the surface of such apertures must be situated at a minimum of 1.80 m. above the ground and it ought to be open independently of all other apertures demanded by legal requirements. Sweden demands 10 cub.m., and Switzerland likewise with a minimum height for workrooms of 3 metres, etc.

A whole series of values are provided for the various industrial operations more especially as regards the work of women and young persons. (See also article "Workrooms").

### Criticism and Suggestions

All of these legislative standards in the light of more modern views as to the objectives of ventilation now appear to be more or less obsolete, or at least very incomplete. Ventilation is to-day primarily conceived as a means for removing the excess heat produced by the human body and replacing it by fresh air that is cool but not too cold. The amount of air needed for this purpose will obviously bear no necessary and direct relation to the number of persons in a given confined space unless the opportunity for direct heat loss through windows, walls, and ceiling be also taken into account.
Under certain conditions, as for example in an interior auditorium with no appreciable heat loss, the standard of 70 cub. m. per hour (legally required for schools in many American States) will prove substantially correct. An average adult gives off approximately 100 calories of heat per hour, and this is almost exactly the amount of heat necessary to raise the temperature of 70 cub. m. of air from 16° to 21° C. In factory workrooms where there are special heat sources such as forges, furnaces and annealing ovens, the amount of air necessary to maintain good ventilation may be materially more than this. In certain annealing shops for example, 30 changes of air per hour have been effected with notably successful results. On the other hand, where the room is relatively small and has one or more outside walls the necessary air change may be materially less.

The standards cited above, of 30 to 50 cub. m. of air supply per hour are, however, very moderate even on the basis of thermal considerations, corresponding roughly, as they do, to 10.5 parts and 8 parts per 100,000 of CO₂ respectively. An air change of this extent will generally be needed in order to remove the heat produced by the human body and to avoid the accumulation of body odours which are offensive, even if not dangerous to health. It is by no means sufficient, however, to supply a given volume of air to the factory workroom. The main essential is temperature control, and a room with only 30 cub. m. of air supply per person per hour at a temperature of 19° C. is far better than one with 100 cub. m. at 22° C.

The temperature is of course only one of the conditions affecting heat loss from the body. Humidity and air movement must always be kept in mind as two factors in the problem.

The influence of atmospheric humidity upon heat loss from the body is quite different at different temperatures. If the air temperature be low, there will be little or no discharge of perspiration and the body will lose heat chiefly by direct conduction and radiation to the surrounding atmosphere. Moisture in the air tends to produce a deposit of moisture on the clothing, and moist clothing conducts heat more readily than dry clothing. Hence, very moist cold air seems chillier than dry cold air. This condition obtains up to a dry-bulb temperature of about 4° to 10° C. Above 10° C. the secretion of sweat begins and the cooling effect of the evaporation of this sweat becomes more and more important as a factor in heat loss the higher the temperature. Under these conditions the cooling influence of conducting moisture is outbalanced by the fact that moisture in the air interferes with the evaporation of perspiration. Because of this interference with evaporation, moist, warm air is far more uncomfortable than dry air at the same temperature.

Air containing only 20 per cent. relative humidity at 21° C. is about as comfortable (according to the Pittsburg figures) as saturated air at 18° C.

The third factor in determining the physiological effect of a given atmospheric condition is the extent to which conduction, or evaporation, or both, are favoured by the movement of the air. In a still atmosphere the body is surrounded by a layer of air which has been rendered hot and moist by the heat and moisture given off by it and it is this hot moist air to which the surface of the body is actually exposed.

The Pittsburg studies indicate that the conditions tabulated below are roughly equivalent to each other from the standpoint of human health and comfort.

Relative humidity is measured by the wet-bulb thermometer and the cooling effect of air movement is estimated by the katathermometer (see article “Air: Hot and Humid”). Except where humidity is produced by special industrial processes or where air movement is greatly increased by artificial ventilation, the ordinary thermometer is a reasonably close measure of indoor atmospheric conditions.

The thermometer should be an essential part of the equipment of every workroom, and whenever the temperature rises above 20° C. steps should be taken to remedy the condition by turning off heat sources or opening windows or by the installation of the secretion of artificial systems of ventilation. That such attention to temperature regulation will bring
sample results in diminishing absenteeism due to illness and in increasing working efficiency is amply demonstrated by the New York State experiments cited above and by practical industrial experience reviewed in another place (see article "Ventilation").

Air: Testing in Workrooms
French: Air des ateliers (Contrôle de l'). — German: Luftuntersuchung der Arbeitsräume. — Italian: Analisi dell'aria dei locali di lavoro. — Spanish: Control del aire de los talleres.

Medical men are often called upon to decide, during claims for compensation, the responsibility for casualties caused by the escape of noxious gases, poisonous dust, and the like. The question of the healthiness of the air of workrooms is important, but it is also most complex. It is expedient to act promptly and whenever possible to carry out an analysis of the air on the spot by methods which, even though sometimes empirical, are none the less useful. It is even essential from the hygienic point of view, without waiting for a casually to occur, to carry out periodical analyses of the atmosphere in places where unhealthy processes are carried on. Slow poisoning by carbon monoxide, or by an atmosphere strongly charged with various impurities, often remains unrecognized, or is only found out when serious symptoms have already developed. Troubles of nutrition, anaemia, neuritis, jaundice and other serious symptoms are too often among working workers without definite cause, when in reality the condition should be attributed to the unhealthy atmosphere.

A definition of normal air is required. Its average composition is: from 20.50 to 20.80 volumes of oxygen per 100 volumes of dry air, from 79.47 to 79.17 of nitrogen, and from 0.03 to 0.07 of carbonic acid, argon and neon, etc.

Normal air is odourless and has a humidity of from 60 to 150 (in volume) per 100 (0.005-0.010 per litre) and 1 to 100 of pollution.

The quantity of carbonic acid must be determined and also the reducing power (degree of pollution); but in reality the degree of pollution and the quantity of carbonic acid are two independent variables, and the quantity of carbonic acid has been claimed as sufficient by itself for giving precise indications of the degree of closeness and even of the injurious nature of the atmosphere. The requisite measures for ventilation or aeration required to bring the strength of carbonic acid within the generally admitted limit, which for workplaces is 6 parts per 10,000, can be rapidly estimated.

Ventilation and aeration must not be confused: to aerate is to ensure a sufficient cubic capacity; to ventilate is to remove by appropriate means foul and injurious vapours and prevent any risk from their inhalation. Gases of poisoning by gas occur even in the open air, for want of suitable ventilation.

ESTIMATION OF CARBONIC ACID

The method of Pettenkofer may be here recalled. Into a five-litre flask containing the air to be analysed there is poured 100 cub. cm. of a baryta solution (1 litre of water, 5 grm. of pure barium hydroxide, 0.2 grm. of barium chloride). After shaking for half an hour, it is allowed to settle and 25 cub. cm. of the clear liquid floating on the top is withdrawn, made alkaline and titrated with a titrated solution of oxalic acid (1.12 grm. of oxalic acid and a sufficient quantity of distilled water to bring the solution up to a litre). The diminution in alkalinity gives the amount of carbonic acid by the quantity of oxalic acid used, since 1 cub. cm. of the oxalic acid solution corresponds to 0.25 cub. cm. of CO₂ at 0°C and 760 mm. of Hg.

Baryta water is to be preferred for absorbing carbonic acid; it absorbs it completely, even with a simple wash bottle, and even if the current of air is fairly rapid. Further, as the carbonate of baryta is deposited very quickly at the bottom of the wash bottle, the amount of carbonic acid can be watched and followed, while the sample is gradually being taken, and even estimated approximately, using certain simple precautions, by reading the height of the deposit. With this object it is sufficient to graduate the bottom of the wash bottle. This preliminary estimation will always enable the moment for stopping the test to be determined; it should

1 It is better with a solution of soda and potash, provided that the surrounding temperature does not fall too low and remains about +10, without which it is preferable to use a solution of equal volumes of soda N/3 and baryta water prepared as at +5. In case of very great cold, soda is employed without baryta. Under these conditions, the factors for the calculation of carbonic acid are different.
be the moment when the deposit formed is sufficient for an accurate estimation.

The rapidity with which the baryta water becomes clouded is in proportion to the amount of carbonic acid in the air. Thus, when aspirating at a rate of three litres an hour, 5 cub. cm. of baryta water placed in an ordinary wash bottle, either Cloez pattern or some other, become densely clouded:

- in twenty minutes if the air contains 5 parts per 10,000 of CO₂, which is about normal;
- in ten minutes if the air contains 1 per 1,000, as in confined or suspected air;
- in less than two minutes if the air has 4 parts per 1,000, which may be considered bad air.

A deposit of carbonate suitable for accurate estimation will be obtained at the end of the following times:

- in one hour if the air has 5 parts per 10,000;
- in thirty minutes if the air has 1 per 1,000;
- in ten minutes if the air has 4 per 1,000.

For making an estimation some drops are added of a mixture containing equal parts of alcoholic solutions of 1 per cent. phenolphthaline and helianthine; then it is titrated direct with N/4 nitric acid until two successive colour changes occur, shaking up the air meanwhile as much as is necessary to keep the liquid stirred.

The first change from red to clear yellow occurs at the moment when all the free baryta is neutralised; the second change from yellow to rose, when all the carbonate has been neutralised in its turn. The volume of nitric acid necessary to pass from one colour to the other indicates the carbonic acid and that alone 1 in the proportion of 0.0055 grm. CO₂, or about 2.80 cub. cm. for each cub. cm. of nitric solution 2.

**ESTIMATION OF OTHER ACID GASES**

The process mentioned above allows of direct estimation not only of carbonic acid, even if mixed in the atmosphere with other acid gases, but also of these latter.

1 Except when the air contains excessive traces of sulphuretted hydrogen, without reaction upon the helianthine; but it is easy to guard against this cause of error which would certainly not pass unnoticed.

2 If, in place of baryta, a solution of soda alone is employed, 1 cub. cm. N/4 used for titrating is the equivalent of 5.60 cub. cm. of CO₂; this method is not so sensitive; further, amongst other disadvantages there is that of no chromatic reaction being set up.

When it is a case of dealing with ordinary air, more or less confined, this distinction is scarcely of importance, for acid gases in addition to carbonic acid, are not found in appreciable quantities. But it may be otherwise in the case of so-called industrial emanations.

Following upon the estimation of carbonic acid, that of other acid gases is direct, depending for the purpose on a knowledge of the initial alkalinity of the baryta water used. It is then sufficient to subtract from the alkalinity which has disappeared that which has been definitely absorbed by the carbonic acid. Thus is ascertained at once whether the atmosphere contains other acid gases or not.

Here are the details of a test:

<table>
<thead>
<tr>

**Correction for CO₂ pre-existing in the baryta:** 0.1 cub. cm.

**RESULT**

| Total alkalinity absorbed by the acid gases | 0.90 cub. cm. |
| Alkalinity absorbed by carbonic acid | 0.90 cub. cm. |
| Acid gases other than CO₂ | nil |

**Volumetric strength of the air in CO₂:**

\[
\frac{0.90 \times 2.8}{4} = 0.63 \text{ cub cm.} \\
\text{or 6.3 per 10,000.}
\]
Several types of portable apparatus are in existence for rapid tests. Kohn-Abrest uses a metal vessel, with a zinc body and a copper lid, of a capacity of five litres, which, with its accessories, can be carried in a kind of portable cupboard. The air is aspirated by a water flow through flat Cloez flasks 1, independent one of another and arranged in series on a copper fixture to which they are connected by metal tubes with taps (see fig. 5). The fitting unscrews and allows the vessel to be refilled. Each flask is removable and ready for instant replacement. The best speed of aspiration corresponds to 120 or 140 bubbles per minute. The volume of air aspirated is given by the level N.

Generally there are four flasks for each fitting. Two ordinarily suffice for testing the healthy state of an atmosphere: one of them gives the strength of carbonic acid and is eventually also used for testing for and estimating the quantity of other acid gases, and also by means of a special arrangement for testing for carbon monoxide; the other verifies the absence of other injurious gases.

A process has also been suggested based on the time required to decolorise a drop of potash or baryta solution of a fixed concentration coloured by phthaline. The baryta solution keeps a long time; it is enclosed in sealed glass ampoules. When needed for use, the point of the ampoule is broken and the coloured solution is made to flow into a drop counter, which facilitates the deposition upon filter paper of the drops of liquid necessary for determining their time of decoloration in the polluted atmosphere. The same principle can be applied to an arrangement for testing for carbonic acid by the passage of a fixed volume of the air to be tested (Hébert-Heim).

For rapid estimation of amounts of carbonic acid, Hébert and Heim use a "carbicidometer", by means of which by passage of a definite quantity of air, the carbonic acid is fixed by means of potash in a wash bottle or in a sealed tube; the carbonic acid is then set free in an apparatus resembling a calcimeter, an apparatus used in agricultural chemistry, and measured exactly.

Other methods have been employed: thus, for example, Cristiani, of Geneva, has devised an apparatus composed essentially of a small bore wash bottle, containing 1 cub. cm. of a standardised solution of carbonate of soda coloured with some drops of phenolphthalein, into which the air to be analysed is passed. After having previously collected the air in a flask, it is displaced into the wash bottle by introducing into the flask previously boiled water from a graduated vessel. In the wash bottle the air gives off its carbonic acid which at a certain moment decolourises the solution. It then suffices to read off the number of cubic centimetres of water introduced, which represents the cubic centimetres of air sufficient to neutralise 1 cub. cm. of the solution. A simple calculation gives the amount of carbonic acid.

Lehmann recommends absorption in three batteries of Lunge tubes with ten

---

1 Flat wash bottles of a capacity of 15 to 20 cub. cm.; internal diameter of the vertical tube, 3 mm.
Haldane has designed a portable apparatus which enables the amount of carbonic acid to be determined on the spot. The method consists essentially in direct observation of the diminution in volume of a given sample of air resulting from the absorption of carbonic acid by a solution of potash. The air is introduced into a burette by lowering a reservoir of mercury, which is connected to it by means of an indiarubber tube. The volume of air required (25 cub. cm.) having been introduced, the tap for the entrance of air is closed; the sample of air is then made to pass into a wash bottle containing potash by raising and lowering the reservoir. After complete absorption of the carbonic acid the volume of the sample is again observed. The difference found between the first and the second reading gives the quantity of carbonic acid absorbed.

**ESTIMATION OF CARBON MONOXIDE**

Although for this investigation the blood process may be the best (see article "Carbon Monoxide"), by the help of a container an estimate may be made of the presence of carbon monoxide, which, if not extremely accurate, at least indicates its absence in proportions exceeding 1 part in 10,000.

For this purpose there must be adjusted to the ground glass mouth of one of the wash flasks (see fig. 5) on the supporting fixture, a tube of bent glass containing iodic acid, which can also be used for the detection of this gas in the atmosphere is described elsewhere (see article "Carbon Monoxide").

A standard portable apparatus has been recently suggested by Sayers and Yant (1924).

**ESTIMATION OF OTHER GASES**

The absence of most other gases may be determined by the aid of 5 cub. cm. of a mixture of a slightly acidulated solution of silver nitrate N/100, i.e. 1.7 grm. per litre, and of permanganate N/500, i.e. 0.006 grm. per litre.

When after aspirating 2 litres of air the solution remains rose coloured and does not show any turbidity, the absence...
of injurious gases in pronounced quantities may be presumed. This indication should nevertheless be confirmed by more precise tests, carried out by the aid of a series of wash bottles charged with appropriate absorbing reagents.

The reagent is prepared exactly in the following manner:

Solution A: nitric acid, 50; potassium permanganate 3 grm.; water sufficient to make up to 1,000.

Solution B: water 1,000; silver nitrate 3 grm.

A little before use, mix in the following proportions:

\[
\begin{array}{c|c|c|c}
A & 1 \text{ cub. cm.} & B & 20 \\
\text{Nitric acid} & 1 & \text{Water} & 50 \\
\end{array}
\]

This reagent, formerly recommended by Merpeix as a test for carbon monoxide which decolorises it, but not with any great sensitiveness, appears on the contrary sensitive to other injurious gases, which equally produce decoloration, and, according to the particular gas, will give white precipitates (in the case of cyanogen and hydrocyanic acid up to 1 per 5,000).

The presence of cyanogen seems important from the toxicological point of view, for it may be that minute traces of hydrocyanic acid, detected in the viscera of persons who have succumbed to the effects of illuminating gas, have no other origin.

**Situation of Certain Hydrocarbons**

The apparatus just described permits the person responsible for the healthiness of any atmosphere to test also for all the other poisonous gases. All he needs do is to provide himself with the reagents required for each particular case.

Among the industrial processes which are suspect from the point of view of the healthiness of the atmosphere where they are carried on, must be mentioned trade processes which bring into use solvents of india-rubber, fatty bodies, and acetate of cellulose such as benzene, carbon bisulphide, and chlorine derivatives of hydrocarbons, particularly tetrachlorethane. It is important that in these workrooms there should be no perceptible smell, the chemical test being then reduced to its most simple expression, for the absence of smell implies, as has been confirmed experimentally by Lehmann, the absence of quantities, excessive from the hygienic point of view, of harmful vapours of these solvents.

\[1\] Up to the present, however, tests for hydrocyanic acid in the blood of such cases have remained negative. It is, however, possible that investigation by extra sensitive processes may enable traces to be found.
Nevertheless, the estimation of traces of the aforementioned vapours can be easily made.

In the case of benzene, the air is aspirated using an empty four-litre flask (Vigreux, Liebig, Willim, but the last named uses a wash bottle of very small size) containing some cubic cm. of fuming nitric acid. An aspiration of twenty litres of air at the rate of about three litres an hour is sufficient.

Nitric acid, being diluted with water, according to the classic method, nitrobenzene appears in the form of a cloud, or, according to the amount, is precipitated in globules. The liquid is neutralised with soda which causes a characteristic odour; it is digested with ether, after separating from the ether by decanting and filtering through dry paper; it is evaporated either in the air; this last is saponified after a time and the chloride formed is estimated; the absence of free halogenes or their hydracids must be assured, or, if they exist, taken into account.

With an apparatus "for rapid testing" and an arrangement for detecting carbon monoxide, all the materials necessary for testing the salubrity of the air are at hand.

Nevertheless, it will be convenient in certain cases to provide oneself with a shallow box containing four dry flasks, empty of air or gas, of a capacity of four litres. These flasks are far preferable to india-rubber bags when it is a case of testing for all sorts of gases, such as chlorine, and even carbon monoxide or carbonic acid, which diffuse rapidly through india-rubber. A metal manometer shows cold or on a stove at 37° C. (free from humidity) and the residue weighed. In this way a tenth of a milligram of benzene per litre of air can easily be detected (1 part of nitrobenzene corresponds to about 0.6 of benzene, \( C_6 H_6 \)).

If the air is suspected of containing carbon bisulphide; the wash bottle is charged with an alcoholic potash solution; the solution of xanthate of potash is acidulated by acetic acid and precipitated by sulphate of copper.

The alcoholic solution of potash also allows qualitative and quantitative tests for traces of tetrachloroethane in the air; this last is saponified after a time and the chloride formed is estimated; the absence of free halogenes or their hydracids must be assured, or, if they exist, taken into account.

The attention of the expert will be chiefly focussed on escapes of the products of combustion, carbonic acid and carbon monoxide, and directed to the question of fumes. It is known that the production of carbon monoxide during combustion is most irregular and that it is scarcely possible to foresee the quantity of this gas which may escape into the atmosphere. The escape depends, among other factors, on the quality of the coal and also on the method of stoking. It would evidently be an advantage from the hygienic point of view only to employ, so far as is possible, fuel of a uniform type, such as coke, unless the more combustible gases, which are given off by raw coal on distillation, are used.

In order to show exactly how, in spite

**Fig. 9. — Bottles emptied of air by manometer.**
of all calculations, the production of carbon monoxide may remain undetected, some experiments have been made by Kohn-Abrest on a stove, of a pattern much used by the people of Paris, which acts at will either as an ordinary stove, or for slow combustion. All these experiments were conducted either with a brisk or a slow fire, on days when the atmospheric conditions varied very little and fuel was chosen intentionally from different kinds of coal, particularly from coal with very little gas, i.e. close burning coal, but rich in carbon, in fact allied to anthracite, and by contrast from coal very rich in gas, i.e. bituminous, or so-called house coal, resembling coal as extracted before being graded.

The numerical results of analyses of products of combustion taken in the pipe of the stove about a metre from the orifice of the discharge were as follows:

1. Brisk Fire (Normal Draught)

It is sufficient to examine these figures closely to find how they show unexpected and apparently contradictory facts as regards the production of carbon monoxide. It will be seen that the amount varies in the different experiments, even when, all the other conditions being equal, the quality of the fuel itself is not changed. Without insisting further, it may be stated that in the absence of the discovery of any fixed law, these experiments show that the most prudent course, whether the combustion be quick or slow, is to discharge outside by a good chimney all the products of combustion.

**INTERNAL-COMBUSTION MOTORS**

The gases which escape from petrol motors are very rich in carbon monoxide, even more so than those from lighting gas itself: they are troublesome from the viewpoint of economical combustion, and troublesome, if not dangerous, from that of health.

An internal-combustion engine can rapidly make the atmosphere of any place into which the exhaust gases escape fatally dangerous.

Samples of gas taken from the interior of the exhaust pipe of several types of internal-combustion engines give the following results:

<table>

These figures indicate that a considerable part of the petrol is wasted in certain internal-combustion engines, since, independently of carbides not burnt, it is found that in the combustion products the proportion of carbon monoxide is greater than that of carbonic acid. The result clearly indicates that in every instance the toxicity of these exhaust gases is great; herein lies the explanation of certain serious casualties.

As regards naphthalene engines, while they have other serious faults, they seem to use their fuel better.¹

Even in the open air, all trouble is not avoided, for it is known that when the atmosphere is calm, sheets of gas form which only diffuse very slowly into space. This is the reason why certain countries prohibit, at least at certain hours of the day, motor-cars from passing along somewhat enclosed roads.

**Gas Apparatus**

The products of combustion from gas fittings have been the subject of a number of investigations, especially of carbon monoxide.
concerning incandescent fittings, either upright or inverted.

Kling and Florentin, for example, have found that the production of carbon monoxide in upright incandescent burners is extremely variable, depending on the makes.

It is as high as five litres of CO per 1,000 litres of gas burnt in certain types, whilst in other Auer burners the production of carbon monoxide is very slight.

With inverted mantles it is on the contrary always high, even if they are supplied with synthetic gas free of CO; it frequently reaches eight and even ten litres of carbon monoxide per 1,000 litres of gas burnt. These results are disputed by other experts, but it is probable that the contradiction is only apparent.

It is evident that in calculating the proportion of carbon monoxide per 100 litres of gas burnt, and in taking into account the make of the burner, results are arrived at which seem to differ much from those where the proportion of carbon monoxide existing in the air of the room is alone referred to.

Moreover, it is for this reason that Kohn-Abrest considers it advisable always to refer to the production of carbon monoxide per unit of gas burnt, and, in a general way, only to take into account the relation between the carbonic acid produced and the carbon monoxide (index of toxicity).

An index of toxicity of illuminating fittings, of heating apparatus and of internal-combustion engines (relation CO/CO₂) has been proposed by Kohn-Abrest to enable a rapid determination to be made of the hygienic value of every means of using fuel of whatever kind.

Just as in metallurgy, the custom is, in order to keep under observation the steady working of blast furnaces, only to take into account the relation between the volumes of carbon monoxide and carbonic acid produced by combustion, so it is no more necessary in these circumstances to trouble about the exact spot where the sample is taken.

Sampling.—Two flasks each of a capacity of four litres with ground-in stoppers are fitted with tubes provided with taps. A vacuum having been first obtained, the two flasks are connected together and filled by aspiration with the same sample of air. In many cases, however, flasks of two litres, and even of one litre are used.

La production de l’oxyde de carbone par les bras à incandescence, in Chimie et Ind. et Industrie, 1921; and, previously, Comte Rendu Acad. Sc. T., 169, 1914, p. 1404.
The most valuable kinds of calcareous alabaster are those of Cairo, Algeria, Mexico, and Italy; of gypseous alabaster those of Italy, Greece, Great Britain, Germany, etc. The most important quarries for gypseous alabaster are to be found in Tuscany (Volterra, Pisa, Leghorn, etc.). The method of working and the maladies from which the miners suffer have been studied closely by Pieraccini, Giglioli, and Mori.

Only such details will be given here as are not stated in the article "Stone Industry".

**SOURCES OF DANGER**

Generally speaking, alabaster quarries are underground and extend ten and even a hundred metres below the level of the sea. The galleries are very long; sometimes the striking face is two kilometres from the entrance. Ventilation is bad, especially if there is but one entrance. Lighting is insufficient and even totally absent except for illumination obtained from acetylene lamps. Temperature varies according to the season (from 15° to 30° C.). Humidity also varies from one quarry to another — indeed very often much water accumulates in the galleries, and even at the entrance, generally situated on the banks of a stream (especially during floods). Sometimes the humidity rate reaches 70 per cent. No toxic gases are evolved, but the atmosphere is often vitiated by excess of carbonic acid gas emitted by the men, the lights, etc., and this is rendered worse by defective ventilation.

Transport of the blocks of alabaster is fatiguing from 20 kilos to several quintals (10-12). Rough shaping is practised on the spot (at the face) because it is a delicate operation.

**PATHOLOGY**

Alabaster dust, according to Giglioli, is injurious to the respiratory tract, setting up fairly severe lesions: this writer refers to workers with defective chest development, feeble health, respiratory diseases (75 per cent. being tuberculous), and suffering from haemoptysis apart from tuberculosis. Some authorities do not consider the dust injurious because it contains no silica, and Pieraccini, for example, questions it as the cause of the damage. He thinks it injurious not on account of its quality, but rather its quantity, aided by the sedentary life of the workers. De Hieronymis has studied the death rate from tuberculosis in the province of Pisa and in the town of Volterra, finding the mortality figure low for the general population of

**Alabaster**

**PROPERTIES**

Two kinds of alabaster of different chemical composition exist: calcareous alabaster or calcite (CaCO₃), which is a kind of calcium carbonate, and alabastrite, which is a sulphate of calcium or gypseous alabaster (CaSO₄·2H₂O).

One part of the sample serves for the estimation of carbon monoxide and the other for that of carbonic acid (atmospheric CO can be deducted quite easily). Kohn-Abrest shows the advantage of using as an aspirator a system consisting of a flask (No. 1) identical with that (No. 2) in which the air is sampled. A vacuum is first made in the aspirator, which is then put in communication by suitable tubing with the baryta wash bottle, the other tubing of which is connected to flask No. 2.

On carefully opening the taps of the flasks, air is drawn bubble by bubble through the baryta till the pressure in the two flasks is equalised. At this stage it is known that half the volume of air in the flask has washed through the baryta. Less air can also be aspirated and, in order to know the volume, the pressure in flask No. 2 is measured and used made of the formula \( V' = \frac{V}{H} \), where \( V' \) is the initial volume under the pressure \( H \) of the gas sampled. As a general rule \( H \) is only the atmospheric pressure, \( V' \) the volume remaining, \( H' \) the pressure in flask No. 1 at the end of the test (fig. 9).

The preceding table gives some interesting indices of toxicity *, and shows that for petrol motors the figure is extremely high; for acetylene motors the formula \( V' \) is two kilometres from the entrance. Ventilation is bad, especially if there is but one entrance. Lighting is insufficient and even totally absent except for illumination obtained from acetylene lamps. Temperature varies according to the season (from 15° to 30° C.). Humidity also varies from one quarry to another — indeed very often much water accumulates in the galleries, and even at the entrance, generally situated on the banks of a stream (especially during floods). **Alabaster**

**PROPERTIES**

Two kinds of alabaster of different chemical composition exist: calcareous alabaster or calcite (CaCO₃), which is a kind of calcium carbonate, and alabastrite, which is a sulphate of calcium or gypseous alabaster (CaSO₄·2H₂O).
Volterra, which town is well situated, and high for the workers in question. He is led to enquire if it is the dust which is responsible or rather the life led by the workers, since, in view of the fact that the tubercle bacillus is absent from Volterra, the dust cannot be said to favour infection. Mori is of the same opinion; he recalls that the workers are rejected from military service because of their poor chest development, short stature, and feeble physical constitution; but morbidity from broncho-pneumonia, gastro-enteritis, etc., is not greater among them than among other workers.

Rheumatism, on the other hand, is common and is probably due to the rapid change from a hot, humid internal atmosphere to the colder outside air, and common, too, are maladies due to chill (pneumonia, rheumatism, etc.). The abundant white dust which covers the miners from head to foot, making them resemble millers, is the cause of a diminution of the vertebral column: a scoliosis with a concavity of the spine. A scoliosis with pronounced hypertrichosis.

Accidents are not characteristic; a great many are caused by the tools, especially by the rubbing and polishing alabaster. Amongst alabaster workers working at the lathe an occupational callosity has its seat on the external third of the upper surface of the right clavicle.

**Legislation**

In France young persons under 18 years of age are prohibited from sawing and polishing alabaster dry if dust is given off freely. In Spain boys under 15 years and females under 21 are prohibited from rubbing and polishing alabaster. In Italy employment of boys under 15 and females under 21 is prohibited.

**Alcohol (Intoxication by)**

**Alcoholism**

Magnus Huss, a Swedish medical man, was the first (in 1853) to employ the term "alcoholism" to describe the effects produced by intoxicating drinks which depend on multiple agents—some chemical (the kind of drink), others biological (constitution of the individual), and others again social (environment).

The drinks producing these effects are obtained by fermentation (beer, wine) from sugary vegetable substances and have been known from time immemorial; others obtained by distillation (brandy, rum, whisky) are much more dangerous and of more recent introduction. Although men have been addicted to alcoholic drinks from remote times, alcoholism only commenced to spread after Arnoldo of Villanova in the thirteenth century discovered the formula for making *aqua vitae* or brandy.

Alcoholism, making steadily increasing progress for several generations, is a racial malady which may be considered to-day to have reached its culmination.

**Toxic Action**

Alcoholic drinks act: (1) by their content in ethyl alcohol, which varies according to the products absorbed; (2) by the impurities and essences they
contain (higher alcohol: propyl, butyl amyl; ethers, aldehydes), the effects of which vary — some inebriating, epilepticiform, others convulsive, tetanic and anaesthetic.

The distinction which it has been attempted to make between wine-drinking and alcoholism is open to criticism, because between ethyl and the higher alcohols there is only a slight difference in the degree of toxicity.

Alcohol acts after absorption by digestion and inhalation. Without calculating the long series of researches made, there is no doubt that alcohol ingested has no physiological properties. Only in the most restricted sense can it be held to be a food, and its energy-producing value is very rapidly counter-balanced by the toxic properties which manifest themselves on absorption of only a small quantity.

Empiricism and subsequent experience have shown that alcohol is equally toxic on inhalation. Orfila, indeed, intoxicated dogs, and Strauss rabbits, by way of the lungs. Sand found that inhalation of a mixture of alcohol and ether administered drop by drop to dogs set up, after a period free from symptoms, excitement, convulsions, etc. Killed five months after inhalation of the mixture the dogs showed specific lesions: haemorrhage and stasis in all the organs especially marked in the liver, kidneys and nervous system.

Authorities disagree as to the quantity of alcohol an adult in good health can consume with impunity, this quantity varying according to the physical and normal state of the individual, age, sex, constitution and temperament, heredity, state of health or disease of the various organs, individual resistance, mode of life, environment, occupation, and nature of the beverage absorbed (kind, composition, and proportion of alcohol in it). Alcoholic beverages do not usually produce their habitual baneful effects under the influence of moderate fatigue, of an open-air life, of exercise — conditions under which alcohol occasionally ingested can be consumed. Habit and custom produce a kind of mithridatism and in certain morbid states (diabetes, hysteria, dipsomania) unbelievable quantities of alcohol can be consumed.

According to Pouchet, for an average sized normal adult, neither under nor over developed, say for a man weighing 65 kg., 6 grm. per kg. may be a fatal dose; that is, 390 grm. of pure alcohol (corresponding to 850 or 900 grm. of brandy). Antheaume has determined the weight of living substance which can be killed by a litre of an alcoholic beverage:

<table>

<tr>
<td>Cognac (50 per cent.)</td>
<td>65</td>
</tr>
<tr>
<td>Brandy (Burgundy)</td>
<td>68</td>
</tr>
<tr>
<td>Kirsch</td>
<td>64</td>
</tr>
<tr>
<td>Brandy (plum)</td>
<td>68</td>
</tr>
</tbody>
</table>

Todd has reported the death of a man who had drunk a litre of rum, and Taylor that of child after absorption of 100 grm. of pure alcohol. Gréhant states that 1 grm. of alcohol can be tolerated per kg. of body weight, with a mean daily consumption varying from 50-70 grm., which corresponds to half a litre of vin ordinaire taken in the day. Maurel, of Toulouse, on the other hand, does not go beyond 40-44 grm., and Bianchi limits himself to 200-300 grm. of wine per meal.

Whilst diluted alcohol stimulates the functions of the living tissues with which it comes into contact, neat alcohol has an intense dehydrating and coagulating action on albuminoids; when insufficiently diluted it acquires anaesthetic properties, paralysing irritability, sensibility, contractility and the activity of the living cell.

The consumption of alcohol is very variable. In litres it is said to be per individual and country as follows:

The countries consuming, by preference, wine are Italy, France, Spain, Portugal, Switzerland, Argentina, Uruguay, and Japan. Beer is principally consumed in Germany and by Anglo-Saxon peoples; liqueurs in Sweden, Norway, Denmark, Finland, Rumania, Austria, Hungary, and Russia; and whisky in Great Britain.

Physio-Pathology

Pathology will only be dealt with in its relation to occupation. An acute and a chronic intoxication may be distinguished: As has been already stated, these two intoxications are a double function of the kind of poison, of the quantity ingested, and of the soil into which it is received. Its evolution can take place with changes scarcely visible or, on the other hand, in a very rapid and complicated manner with subacute signs or acute paroxysms. There are a number of factors which are able to retard,
counteract or precipitate the appearance of acute phenomena or to hasten the evolution of the malady.

Without entering into details as to the pathology of acute or chronic alcoholism, it will suffice to recall that alcohol does not spare any organ, that it exercises a sclerotic and degenerative action on the tissues, and that it brings about the most varied morbid symptoms.

The nervous system is affected from the start, alcohol acting on the higher functions of the central nervous system as a narcotic. Sensory effects are early, and can be most readily observed in course of the victims' daily occupations. The poison exercises its pernicious action on the centres of perception - a fact which may have the most unexpected and formidable consequences. Many industrial accidents are due to the incompetence of drinkers whose senses have been dulled. Among visual troubles, dischromatopsia, central and paracentral scotomas, and diminution of visual acuity are noted. Railway companies provide for the withdrawal of alcoholic mechanics in whom a certain degree of Daltonism prevails, clear distinction of coloured signals. Among defects of hearing abnormal perceptions are to be noted: external sounds become exaggerated or discordant. The other senses are dulled and a sort of multisensory daltonism is created.

All the organs are affected: stomach, heart, discharge of the victims' daily occupations. The poison exercises its pernicious action on the centres of perception - a fact which may have the most unexpected and formidable consequences. Many industrial accidents are due to the incompetence of drinkers whose senses have been dulled. Among visual troubles, dischromatopsia, central and paracentral scotomas, and diminution of visual acuity are noted. Experience shows that many athletes who have imbibed alcohol to excess have died of phthisis; others have become insane. The assertion that intense muscular work can be done with greater impunity by resort to large doses of alcohol is false (Gréhan).

A great number of experiments by Destrées, Gilbaud, Chauveau, Galeotti, Herxheimer, etc., have shown how disastrous is the effect of the consumption of alcohol on muscular work.

In chronic alcoholism, the very slight, small, fibrillary tremor, sensible only to the eye when the hand is stretched out as the fingers held apart, suffices to destroy the manual dexterity of the worker.

Though tradition and popular prejudice incline to the belief that alcohol increases strength, it is none the less true that empirical observation has brought to light important facts which confirm scientific observations. In the ports of the Black Sea and the Bosphorus, the Turks, who are abstainers by religion, are engaged in carrying heavy loads, more especially coal, and this under a tropical sky; while they can stand the strain without difficulty for twelve hours the Rumanians, Bulgarians, and Wallachians have reached the limit of their strength after two or three hours and have to seek recuperation of their energy by resting.

The same proof has been given in the colonial services (e.g. the Indian army). The greatest explorers excluded alcohol from their daily diet (Livingstone, Nansen, the Duke of Abruzzi, etc.) and muscular force has been obtained from sugar rather than alcohol (experiments of Prantner, Stovasser, Mosso, etc.). In sport it is notorious how alcohol has been given up both during exercise as well as in rest time. Runners, swimmers, etc., the winners of great competitive trials try to remain abstainers. During the war all the Governments exerted themselves in a struggle against alcohol in order to keep up the energy of the masses.

**Alcohol and Physical Labour**

Physical exertion is impeded by consumption of alcohol, which excites and then depresses the nervous muscular system. Power to work after its absorption is only increased temporarily. The fact that for a time it stimulates muscular energy and causes fatigue to be forgotten accounts for the fact that certain individuals are willing to allow it to take the place of the material and moral satisfaction yielded by good living, instruction and education. In assuaging however the feeling of fatigue, it favours the onset of acute overstrain (from a state of febrile exhaustion to death by acute intoxication), or of chronic overstrain (physical wreckage favouring the development of morbid nervous or pulmonic affections).

Experience shows that many athletes who have imbibed alcohol to excess have died of phthisis; others have become insane. The assertion that intense muscular work can be done with greater impunity by resort to large doses of alcohol is false (Gréhan).

A great number of experiments by Destrées, Gilbaud, Chauveau, Galeotti, Herxheimer, etc., have shown how disastrous is the effect of the consumption of alcohol on muscular work.

In chronic alcoholism, the very slight, small, fibrillary tremor, sensible only to the eye when the hand is stretched out as the fingers held apart, suffices to destroy the manual dexterity of the worker.

In sport it is notorious how alcohol has been given up both during exercise as well as in rest time. Runners, swimmers, etc., the winners of great competitive trials try to remain abstainers. During the war all the Governments exerted themselves in a struggle against alcohol in order to keep up the energy of the masses.

**Alcohol and Intellectual Work**

Alcohol diminishes intellectual work and, under its anaesthetic influence, the
mind becomes torpid, memory defective, fancy exalted, the senses dulled, the power of inhibition loses control and human personality gradually disappears.

The belief that alcohol is useful and leaves the higher functions unimpaired is wrong. Certain celebrated authors and artists may have been great drinkers, but it would be easy to cite others who have been temperate or abstainers. For some people alcohol may act as a stimulant, but nothing proves that to this is due the value of their work.

Before the stage of noisy manifestations of excitement is reached, consequences of the gravest importance from an occupational point of view may ensue.

The new habits as shown in the altered mentality of the drunkard, the weakened sensibility and moral dementia which appear rapidly, affect every aspect of mental activity (relations with himself, his people and with outsiders), and modify his social and occupational duties, his activity for work, power of production, and duties as a citizen. His mental deficiency shows itself early by modifying all that constitutes the normal acuity of mental activity: attention powers of reasoning, adaptability to circumstances. In the exercise of a daily occupation, where comparison is easily possible, drinkers frequently appear to be the laziest, sleepiest and dullest of the workers. They show less aptitude and skill in their actions, make mistakes, are forgetful, decide lightly, come to fantastic conclusions, etc.

[At the terminal stage of the malady, it should be remarked, hallucinations are entertained, a constant characteristic of which is that the victim believes himself back at his employment, thinks he is in the workshop, is foreman over his fellows, is doing his work, etc.]

Alcohol and Industry

The rôle that alcoholism plays to-day among workpeople cannot, and ought not to, be misunderstood; but account must be taken of the fact that certain conditions of labour tend too often to drive the worker to indulgence in drink, and so aggravate the lesions which the environment or the toxic products handled can engender.

The problem of alcoholism in its relation to industry should be examined from the point of view of the reaction (a) of alcoholism, as affecting the individual in the exercise of his occupation, and (b) of the occupation on alcoholism, the work serving to incite intoxication, which would then appear to be occupational. Having discussed the general effect of alcohol on physical or intellectual work, some further points remain.

Among chronic alcoholics distinction must be drawn between those who drink during working hours (during meals or in rest intervals) and those drinking only in their own time. In some trades where consumption of alcohol is forbidden during working hours, the persons employed often indulge in it during their free time.

There is no doubt that in these cases alcohol increases the harmful nature of certain occupational poisons. Thus, for example, the risk of work in high temperatures is notoriously increased by alcohol, favouring as it does the occurrence of heat stroke; it brings about earlier than would otherwise be the case a condition of fatigue, and has an unfavourable action on the heat regulating mechanism of the body, thus leading to a relative insufficiency of all the functions. Drunkards run an even greater risk in hot and humid atmospheres because in this case the evaporation of sweat and elimination of moisture from the lungs are interfered with by the high hygrometric condition of the air.

Alcohol is equally dangerous when working at low temperatures. Experienced alpine climbers know that alcoholic drinks induce a state of congestion, because though at first alcohol produces a feeling of warmth and well-being, as well as an increase of the peripheral temperature, it exercises rapidly thereafter, as a result of paralytic dilatation of the cutaneous vessels, a hypothermal action lowering the peripheral and central temperature and involving the possibility of passive congestion from cold. As a matter of fact, a fall of the central temperature to 30° and even 25° C. has been noted amongst drunkards.

Alcohol is also dangerous in compressed air work (caisson workers and divers), for which work young men who are abstainers are required. Experts and legislators agree in recognising that those addicted to alcohol or suffering from heart disease ought to be the first to be excluded from compressed air work, because of the risks to which they are exposed.

Chronic poisonings become aggravatgd when associated with chronic alcoholism, as a mixed intoxication is thus produced. Everybody recognises the influence of excessive drinking on the outbreak of lead colic, of gout, hysteria and saturnine epilepsy, as well as on
the mortality of workmen employed in lead industries.

Absence of data prevents reference to the joint effect of alcohol with mercury, carbon bisulphide, or opium, although there is no doubt that these poisons exert a very much more pernicious action on alcoholic subjects.

If liability to occupational poisoning is increased, and such poisons are also rendered more injurious by alcohol, they in their turn lessen resistance to alcoholic intoxication. Biondi and Giglioli have shown that workpeople suffering from mercury poisoning become drunk after consumption of a small glass of wine, and suffer from headache or giddiness after having smoked a cigar. Biondi has noted the same phenomena in a man employed in casting antimony.

The same facts hold in the case of acute intoxications.

The combined action of alcohol and aromatic compounds has frequently been described among T.N.T. workers in the explosives industry. According to Leymann, this is explained by the fact that the toxicity of all poisons soluble in alcohol (and little soluble in water) is increased by the consumption of alcohol. Nitrophenol, nitrobenzol, aniline, and many other poisons). In the case of aniline notably, it has been observed that persons who have worked for many years with this substance without showing ill-effects go under if they absorb large quantities of alcohol after their work is over. The probability is that aniline absorbed by the skin and lungs and set free in the stomach is dissolved by the alcohol and so enters the general circulation, or that the resistance to poisoning by aniline is diminished by the absorption of a small quantity of alcohol, or that the alcohol causes the latent poisoning to become manifest (Niggemeier and Chilian).

Thus it is that in all these unhealthy industries consumption of alcohol is forbidden during working hours, and the workers are well warned to abstain. Somewhat similar observations have been made in the case of calcium cyanamide, which renders the workpeople more sensitive to erythematous eruptions (copper itch).

In the same way, alcohol favours occupational cramp — particularly writer's cramp.

An enquiry made recently (1922) in Great Britain among navigation companies has revealed how alcoholism caused reduced efficiency among sailors.

Monday is the day of the week when the number of absences from work is highest. In some industries in France and Belgium absences were formerly so numerous that it was found not worth while to light the furnaces on Monday.

A question of the first moment is the relation of alcoholism to industrial accidents. The danger run by an alcoholic with the increase in machinery need not be insisted on. According to statistics of 800 accidents collected by the Ministry for Railways in Belgium, one-half was said to be due to alcohol. In France an average of 450 cases of accidents of one kind or another is due to the same cause.

Further, the particular nature of industrial work contributes to the occurrence of accidents amongst tipplers. Industrial work does not demand so much excessive muscular effort, as attention, agility, delicacy of movement and absolute mastery and control of oneself, which alcohol tends to slacken, diminish or suppress.

In spite of the undeniable fact of the influence of alcohol on accidents, and the numerous researches made both in the laboratory and factory, this influence cannot easily be expressed in figures. Though statistical analysis does not always yield satisfactory results, it can at any rate be concluded that.

(1) Chronic alcoholism would appear to be an important factor in the causation of accidents, alcoholics running three times the risk of abstainers or moderate drinkers. According to the statistics of the Leipzig Sickness Insurance Society, this is the case especially for the class of workers from 15 to 34 years and is proportionally highest in the group of severe accidents.

(2) Drunkenness properly so called is not frequently the direct cause of accidents at work principally because consumption of alcoholic liquors during working hours has lessened. About one-quarter of the total number of non-occupational accidents is attributable to drunkenness, occurring usually in the worker's spare time.

(3) Intemperance during work increases the risk of accident. Regulation of the sale of alcoholic beverages and the abolition of the practice of serving beer free of charge, so frequently practised, formerly, in some industries, has reduced the number of accidents by 30 to 70 per cent. In a German foundry the average number of accidents per 1,000 workmen, which used to be 32.8 when the free sale of drink prevailed (1897-1900), fell to 3.6 when this was regulated (1901-1904). Large businesses in America attribute to prohibition the fall in the number of accidents as much as 65 to 75 per cent.
Intemperance outside hours of work is the commonest form. But it is extremely difficult to estimate exactly its influence on industrial accidents. Statistics as to drunkenness on the different days of the week related to accident rates, whether general or occupational, seem to be most convincing. They regularly reach a maximum on Saturday and Monday. The statistics of Leprain and Picraccini show more especially that it is on Monday that intemperance on the Sunday takes effect. The co-efficient of accidents on that day is higher than on other days of the week with the exception of Saturday. Actual drunkenness on Monday, properly speaking, does not exist but rather its sequelae, of which the following are the most notable: disturbance of faculties and mental balance, inability to focus attention, dullness, reaction time prolonged, distaste for work, tremor, awkwardness.

Careful analysis, however, of Sunday's excess only partly explains the high accident rate and lessened output of the Monday.

On the other hand, regular drinking by the night shift, before going to the factory, shows itself in a high accident rate early on in their work.

It is by the gravity rather than the frequency of accidents that alcoholism exerts its most noticeable influence. The lesions set up by alcohol in the heart muscles, the effect on the heat regulating centre, the complications resulting from lesions or sickness of every kind which are so frequent in alcoholics, serve to explain the great tendency for cases to terminate fatally when an accident occurs or surgical interference is required. As experienced has shown that metamorphical repair processes are more irregular and slower in the brain of alcoholised animals, so also it is known that alcoholism retards the union of broken bones and proves a serious obstacle to recovery after any surgical or medical attention.

Drunkenness on the part of a workman may diminish or cancel employer's liability for compensation in the case of accident. Thus, for example, in France obvious intoxication of the workman constitutes the inexcusable fault provided for in section 20 of the Act of 9 April 1898 giving grounds for diminution in the pension. In certain countries persons indulging immediately in alcohol are excluded from certain work requiring accuracy of judgment (railways and navigation), whilst in other countries only abstainers are accepted for such work. Similarly certain industrial establishments forbid the use of intoxicating liquors, and others refuse all workers who are not abstainers.

Certain Swiss and British insurance companies accept a smaller premium from abstainers, while others refuse to accept drunkards.

Occupational Alcoholism

The numerous causes of occupational alcoholism can be reduced to two chief ones: need of stimulants and exercise of an occupation exposing to drinking habits.

Occupational alcoholism has certainly found, just as has general alcoholism, a suitable soil in the conditions under which modern industry has developed.

In the country, it is limited in the main to people in easy circumstances who seek to while away the time in inns. Certain circumstances, however, favour alcoholism and seasonal alcoholism can be spoken of as due to overwork and abuse of drink at the principal agricultural times (harvests, vintage, gathering of beet).

Allevi gives some Italian statistics (Amaldi) showing a high percentage of alcoholic psychoses among country folk. Without being able to quote exact statistics for other countries, alcoholism is well known to be widespread in the agricultural districts of France, Ireland and Poland.

Urbanisation is certainly a factor of the first importance in the spread of alcoholism. In towns, among the middle class temperance and abstinence are constantly on the upgrade. If this class furnishes a smaller number addicted to alcoholism than the proletariat, it is especially because they rarely are engaged in professions which make them take to drink. Nevertheless, chronic alcoholism is widespread in certain professions where it is customary to negotiate business in cafés (commercial travellers, wholesale merchants, etc.) or to spend time for pleasure there (officers, students).

As Montegazza has written, enumeration and classification of the drinkers of a country suffices to reveal the powerful influence that culture has over the taste for alcohol.

Among the labouring class, the taste for alcoholism may be partially attributed to the need to the worker of some distraction after his day's work. The effects of this need are increased sometimes by environment in the clubs and recreation halls where the workers meet and indulge in alcohol.
The narcotic effect of alcohol diminishes the sensation of distress brought on by work carried on under depressing conditions, and badly organised industries are especially those in which the largest number of workers take to alcoholic drinks. Long hours, Sunday work, speed of machinery, overtime, the monotony of modern work—all these have been frequently adduced as causes. An enquiry carried out in France (see Bulletin du Ministère du Travail, January to March 1923) shows the benefit derived from moving the population into the suburbs, from the development of workmen's gardens, the creation of popular libraries, and educational courses, increase in leisure, introduction of summer time, but, above all, the 8-hour day, which has done most to suppress the need for artificial stimulants during or after work.

Occupational alcoholism is met with particularly in certain industries or professions which may be said to predispose to the consumption of alcohol.

Though vinedressers do not show a high proportion of acute cases of intoxication (in the preparation of wine), they are sometimes exposed to poisoning by carbon dioxide (in the fermenting halls). On the other hand, almost all those whose livelihood depends on the sale of alcoholic beverages—and especially of spirituous liquors—are fataly addicted to intoxication, e.g. wine merchants, travellers in wine, butlers, wine tasters, distillers. Intoxication in such cases is the more dangerous because of its insidiousness, and from the fact that frequent alcohol taken in small quantities often brings on chronic alcoholism without any appearance at all of intoxication.

Of 44 men examined at the Laennec Hospital, Paris, Grandmaison found 22 wine merchants and potmen, and all were alcoholic.

Sometimes a genuine occupational alcoholism can be shown to result from the inhalation of alcoholic vapour. An individual who is sober but is obliged, owing to his occupation, to live in an atmosphere impregnated with alcoholic vapour can present all the toxic phenomena of ethyl poisoning from drunkenness (workers in distilleries, wine depots, customs house employees, etc.), especially when certain operations are carried on in a restricted, badly-ventilated place, with long hours of work. (Carozzi, in Italy, noted before the war that in certain liqueur factories the hours were 14 per day with four 1-hour intervals. Obviously, under these conditions even abstainers would finish by getting drunk.) Further, workmen in industries using alcohol may be cited in this connection—such as those employed in the making of felt hats, gunpowder works, manufacture of artificial silk, etc. In the smokeless powder and artificial silk industries, for example, mixtures of alcohol and ether are used, creating an intoxicating atmosphere. In these cases, the dangers of alcoholism can assume quite grave proportions.

Alcoholic excesses are more frequent in some trades and professions than in others, as recognised customs play an important role in the spread of habits of intemperance. Each trade has, in some district or other, a traditional form in which alcoholism shows itself.

Individual habit varies infinitely, especially in relation to the life which circumstances impose. The occupational environment (to some extent modified by educational influences), the social atmosphere and its customs, are tyrannical. Tipping for instance plays a definite part in the story of alcoholism, and similarly the manner of drinking, as e.g. gratuitous supply of drink (e.g. in breweries).

All jobs at high or low temperatures, and above all dusty work (mines and quarries notably) predispose to alcoholism, more especially when the employer has taken no measures for providing fresh water, and most of all when the measures for the prevention and elimination of dust are inapplicable or inadequate.

In dusty industries, the paralysing action exerted by alcohol on the vibratile cilia of the respiratory passages attenuates or suppresses their defensive action, thus favouring the entry of dust into the deepest recesses of the respiratory tract. Pneumonocnosis thus prepares the ground for phthisis.

Even apart from dust, the relation between alcoholism and tuberculosis is a very intimate one. Bertillon has shown by occupational statistics that the trades with the highest consumption of alcohol show the highest mortality for phthisis.

According to Imbert's well-known statistics, alcoholic subjects are met with most frequently in the following trades (proceeding from highest to lowest): vendors of alcoholic beverages, hotel keepers, pedlars, cooperers, day labourers, transport workers, carriers, cabmen, labourers, bakers, cooks, butchers, pork butchers, waiters, locksmiths, chauffeurs, mechanics, domestic servants, packers, printers, painters,
Among women the categories in which alcoholism is most prevalent are: hotel servants, hawkers, waitresses, domestic servants, cooks, hairdressers, con-
cierges, housemaids, charwomen, women without an occupation, seamstresses, milliners, artists in café-concerts, artists' models, hospital nurses.

More recent statistics prepared by Heilig show that in Germany day-
workers constitute 54 per cent. of the alcoholics; peasants 15 per cent.; em-
ployees, members of the liberal professions and business people 24 per cent.;
accountants, tailors, shopmen, shoemakers, ostlers, hotel keepers and waiters 19 per cent.

Occupations which begin at an early hour predispose to the matutinal "schnapps"; intertemperance during work is also frequent amongst those who have to make great muscular effort and are not kept under strict discipline (dockers, carters, quarrriers, builders, labourers, sailors).

Alcoholism is very widespread among: zinc smelters, either from the tradition that alcoholic liquors are an antidote to the zinc and other metallic toxic substances, or to counteract the action of heat, dust, fumes and fatigue; aviators (an accident has often followed on the morrow of excessive consumption of alcohol); miners (during their rest time), etc. In America, among soldiers, the rate has fallen from 35 per 1,000 in 1907 to 6.97 per 1,000 in 1920.

**STATISTICS**

So far as morbidity is concerned, statistics reveal the frequency of alcoholic psychosis—one of the gravest effects of alcoholic intoxication. In France, on 1 January 1907, of 71,547 cases of insanity 3,008 cases were exclusively the result of alcoholism; among 3,285 others, the alcoholic affection was complicated with mental degeneration or debility or a history of alcoholic parenage. In 3,639 insane persons suffering from different maladies, alcoholic intoxication was one of the determining causes. A total, therefore, of 9,932 cases (13 per cent.) can be ascribed more or less directly to alcoholism. This is in accordance with statistics of Mirnal, whose view is that 13.60 per cent. of the total inmates of asylums in France is made up of alcoholics.

In Italy, according to Amaldi, cases of alcoholic insanity (from the period 1909-1921) among asylum inmates are as follows: industrial class, 43 per cent.; agricultural and analogous classes, 33.6 per cent.; employed in commerce, 8.3 per cent.; liberal professions, 6.5 per cent.

If these figures be compared with those of the period 1903-1905, a slight diminution will be seen to have taken place among the industrial workers (43 per cent. as against 49.8 per cent.), an increase in agricultural labourers (33.6 per cent. as against 21 per cent.) and a notable diminution in the group of the liberal professions (in the middle and lower middle class population).

When mortality statistics, are examined in the professions where alcoholic excess is noticeable, their relative increase is striking. According to Jaquet, 1,000 adult males between 39 and 49 furnished at Paris an annual death rate of 36.1; whilst for 1,000 publicans at the same age the figure is 46.9 The figures for Switzerland are similar. As against 25.8, the general mortality rate per 1,000 adults, that for publicans is 42.59.

According to the English official statistics, phthisis accounts for the death of 67 clergymen and 105 doctors, as compared with 448 publicans and 607 barmen.

With a comparative mortality figure of 100 for alcoholism and diseases of the liver, that of dock labourers is 167 for the period 1900-1902, and 187 for that of 1910-1912.

From the Supplement to the 75th Annual Report of the Registrar-General for England and Wales (Part IV: Mortality of Men in Certain Occupations in the Three Years 1910, 1911, and 1912), it is at once easy to show that the comparative mortality figure for alcoholism has fallen from 43 to 23, that is, a drop of 47 per cent. The total number of deaths from alcoholism and diseases of the liver, which was 294 per million in 1900, is only 156 in 1910, and 84 in 1920. The death rate for alcoholism in the different social classes works out as follows:

<table>

Note. — The figures in brackets indicate the ratio between the mortality from alcoholism in each group and the general mortality.

---
This table shows that the mortality from alcoholism, expressed as a percentage of the general population, is pretty well constant.

Among skilled workers the mortality for all causes varies from 45% (gardeners) to 1,196% (potters) and it is apparent that mortality from alcoholism increases pari passu with the general mortality figure, except in the case of publicans and the like, where the percentage is higher. The relation between mortality from alcohol and the general mortality of industrial workers is constant, but is different when workers engaged in the sale of alcoholic liquors are in question, proving that alcohol has a direct influence on mortality.

Comparison between different groups alike in regard to environment and social status, but one of which is more or less addicted to alcohol enables account to be taken of the relation between the general mortality figure and consumption of alcohol. Thus, on the one side, there are the inn and hotel keepers and wine, beer and spirit dealers, and on the other the general group of shopkeepers (drapers, grocers, butchers, stationers, ironmongers, retail tobacco shops, chemists, etc.).

| MEAN ANNUAL DEATH RATE PER THOUSAND LIVING, 1910-1912 |
|---------------------------------|----------------|----------------|----------------|----------------|----------------|
| Age                        | Brewers | Inn, hotel keepers | Inn, hotel servants | Waiters | All males |
| 15-20 years                 | 3.54    | 2.19              | 2.08              | 2.49    | 2.88       |
| 20-25 years                 | 3.38    | 2.47              | 3.55              | 3.18    | 3.72       |
| 25-35 years                 | 6.75    | 2.72              | 2.85              | 5.77    | 4.89       |
| 35-45 years                 | 5.95    | 7.26              | 7.82              | 11.81   | 7.99       |
| 45-55 years                 | 2.15    | 2.54              | 3.06              | 21.58   | 16.62      |
| 55-65 years                 | 36.06   | 41.32             | 33.54             | 35.36   | 29.69      |
| Over 65 years               | 97.00   | 114.21            | 73.43             | 92.95   | 83.33      |

<table>

</tr>
<tr>
<td>All professions</td>
<td>109</td>
</tr>
</tbody>
</table>

Vernon's study of the figures shows that the changes noted in the general mortality of industrial workers must be attributed to some cause other than alcohol, such as unhealthy conditions of work which diminish the standard of general health and render the workers more sensitive to the action of alcohol. Attention has been already frequently called to this point. On the other hand, lessened vitality renders the workers more inclined to seek enjoyment in alcohol.

Really, the general mortality figure is sufficiently low in the open air professions (railway workers, shipbuilders, etc.) or under roofs (sawing, carriage making), and increases the more the professions are carried on in interiors (carpenters, boiler makers, printers) and becomes most marked in dusty industries or at high temperatures (iron, steel, and glass works and in hot mines). For unskilled workers the figures for Great Britain on this point are as follows:

<table>
<thead>
<tr>
<th>Profession</th>

</tbody>
</table>

The middle and upper classes comprise principally the liberal professions and office workers. How their general mortality is lowered while that for alcoholism increases is proved by the following British statistics:

<table>
<thead>

</tbody>
</table>

According to this table, doctors, lawyers and artists has a low general mortality, but a rather high one from alcoholism (higher than that of industrial workers), which can be explained by the nature of the drink consumed.

The diagnosis of acute or chronic alcoholism raises no particular importance. It should be remembered, however, that the clinical aspect of alcoholism resembles that produced by certain industrial poisons (petroleum, benzene, carbon bisulphide, carbon monoxide, etc.).

**Prophylaxis**

Without desiring to repeat all that can be said and prescribed in regard to personal and social prophylaxis against alcoholism, nor again all that comes within the domain of social prophylaxis in regard to this form of poisoning, it is necessary to bear in mind certain points relative to prevention of excessive drinking in industry.

At the outset, workers whose constitution has been injured by alcoholism must be prohibited from taking up certain trades. Thus, for example, alcoholic subjects who are found to be suffering from lung or kidney disease ought to be kept out of explosives factories. Similar examples could be multiplied indefinitely.

On the other hand, reduction in the amount of alcoholism can only be expected by improvement in the hygienic and social conditions of the industrial environment. All labourers, agricultural or otherwise, who drink are under the impression that they cannot perform their daily task without stimulants. This would appear to be really true in some measure of certain jobs in the factory and on the land. Improvement in the conditions of work, a veritable revolution in the way in which work is organized, are indispensable for reducing alcoholism among the working classes and agricultural labourers.

**Legislation**

Details as to legislation on this subject cannot be given—the more so as it extends over a much wider field than industrial hygiene alone. In this connection legislation makes provision for special measures such as: prohibition of the introduction of alcoholic beverages into workrooms especially where poisonous products are handled, or in works coming under the Factory Act; prohibition or the payment of wages to workmen in kind; or part payment in kind (wine, beer, etc.); or allowing workers (as in breweries, etc.) free access to drink. Alcoholic drinks should not be granted certificates of fitness when required in certain occupations...
(e.g. compressed air work, chauffeurs, etc.) or should not be accepted for other kinds of work, e.g. manufacture of white lead, lead oxides, etc.

**Prof. G. Allevi**
(Milan).

### Aldehydes

Under the name of aldehydes are understood the organic substances containing the atomic group H — C=O from the oxidation of alcohols and constituting the transition products between these and the corresponding acids.

The oxidation product of ethyl alcohol known under the name of aldehyde is only acetic aldehyde or acetaldehyde (see that article).

Amongst other aldehydes there should be recalled anisyl aldehyde, obtained (see that article) by direct oxidation.

It is of interest to note that aldehyde can be transformed into alcohol by hydrogenisation on nickel at 140° C. It is prepared industrially by hydration of acetylene in a solution of mercuric bichromate of potassium or soda and sulphuric acid. The mercury salt is recovered. When all the mercury salt has combined, the complex is decomposed by boiling with dilute sulphuric acid. The mercury salt is recovered and the volatile aldehyde which is given off is sent into a hydrogenisation apparatus in which the catalyst is deposited. The fumes of aldehydes not transformed are condensed at the exit by powerful refrigerating agents.

"While the manufacture of alcohol starting with aldehyde reached a high degree during the war, it is at present of slight importance; but the inverse reaction may now become very important, for ordinary aldehyde is used in the preparation of acetic acid (see that article) by direct oxidation.

Ordinary alcohol is easily transformed into aldehyde by simple dehydrogenation (CH₃CH₂OH=H₂+CH₂COH), easily effected by contact with light copper at 300° C.

The oxidation of ordinary aldehyde in acetic acid is at present an industrial process. It is effected by air or oxygen in the presence of oxide catalysts (oxides of vanadium, uranium, cerium, etc.) and certain acetates (manganese, cerium, etc.). The aldehyde is first introduced into the cast-iron apparatus (oxidisers) and then the oxide catalyst or the salt. The reaction is set in motion by heating slightly.

For pathology, hygiene, etc., see article "Acetic Aldehyde".

***

### Alizarin

French: Alizarine. — German: Alizarin. —
Italian and Spanish: Alizarina.

**Chemical Properties**

Alizarin is the colouring matter of madder, from which at one time it was exclusively obtained, but synthetic alizarin is now obtained from anthraquinone.

Chemically pure alizarin [formula: C₆H₄(CO)₂C₆H₂(OH)₂] crystallises in the form of orange needles: melting at 290° C. is insoluble in water, soluble in boiling alcohol, in ether, in mineral acids, etc.

Commercial alizarin is usually in the form of an ochre yellow paste containing 30-40 per cent. of dry colouring material, but it may however be powdered or in small pieces. With a mordant colouring agent it dyes textiles (cotton, silk and wool) red with alumina mordants, orange with tin mordants, crimson to chestnut with chrome mordants, and violet with iron mordants.

**Alizarin purple** is a reddish brown paste almost insoluble in water, soluble in alkalis, in fuchsin red and in sulphuric acid.

**Bordeau or China alizarin**, used for dying cotton with alumina, chrome, and iron mordants, is another well-known variety. Many varieties varying slightly in preparation and in the degree of purity are known in commerce.

**Method of Preparation**

Alizarin is prepared synthetically in great quantity and is got from anthracene, first transformed into anthraquinone by treatment with bichromate of potassium or soda and dilute sulphuric acid in presence of heat. The raw anthraquinone is then purified with fuming sulphuric acid giving monosulphonic anthraquinone, which in turn gives alizarin by repeated heating with concentrated caustic soda (preferably with the addition of a little nitrate or chloride of soda). Production is effected in cast-iron kettles provided with stirrers. Alizarin purple is obtained by oxidising alizarin with peroxide of manganese and sulphuric acid and Bordeaux or China alizarin by oxidation with fuming sulphuric acid.
**USE IN INDUSTRY**

Alizarin is used as a mordant dye for dyeing cotton, silk and wool. These dyes will not by themselves combine with the fibre, but combine with metallic oxides to form "lakes." The material or hanks of yarn are impregnated with the dye, a process known as "padding" and the mordant is applied by passing the hanks through vats or if in the piece through troughs known as "jigs". The categories of workers exposed to the effects of alizarin are: workers handling the product in process of production; dye-workers coming in contact with alizarin dyes, chiefly "padders" and "jiggers", and bobbin winders in cotton mills engaged on the process known as "halching" where yarns dyed with alizarin are manipulated. These workers wind the yarns and use them to tie up hanks taken from the winding frames, using the index finger to break the three or four-fold tie.

**SYMPTOMS**

Skin affections of an eczematous type have been found amongst workers handling alizarin. One authority, in a statistical table of 84 cases of eczema occurring in a synthetic dye-stuffs factory, shows 13 as having occurred amongst alizarin workers. Cotton mill workers engaged in halching were found to suffer from a mild dermatitis, occasionally with blistering of the skin on the fingers, chiefly the index finger. If the workers' hands were chapped, cracked or sore, they became inflamed and festered. Grandhomme considers the danger from alizarin to be comparatively slight. Workers engaged in the preparation of the product and also in dyeing are likewise exposed to chrome poisoning (see article "Chrome"). The possibility of epitheliotomatous ulceration due to alizarin among the above-mentioned categories of workers must also be taken into account. ***

**Alkalies**

The manufacture and use of alkalies (caustic soda or potash, ammonia, etc.) and their more or less concentrated solutions (lyes) are a very common cause of lesions of an occupational character.

In the soap and grease industry particularly and in the chemical industries the use of alkalies is common; in dilute solutions they are used in the textile industries (e.g. in wool washing before dyeing, in mercerising cotton, etc.), in engineering and the metal industry, in the rubber trade, in bleaching, in restaurants (dish washers), and even in the home for washing table ware, etc., in industry generally for washing the hands when soiled by grease, oils, colours, etc.

Alkalies are caustic both in the solid state or in concentrated solutions. Their local action is generally more potent and more extensive than that of acids. They do not, it is true, coagulate the proteid substance of the tissues, but by dissolving the layer of natural grease which protects the skin they cause this to dry, harden and crack, and so render it more susceptible to the action of micro-organisms than do other physical and chemical agents.

The lesion caused by alkalies is typically weeping, humid, nummular. The dermatitis takes on the most varied forms, but is generally an eczema.

The nails undergo a more or less profound degeneration; they become fragile and fall off. This action is more marked if the alkalies are in dilute solution. Fragments of caustic dust or droplets of liquid alkali exert very injurious action on the eyes. The ocular lesions, especially of the conjunctiva and cornea, are, however, less dangerous as a rule than those set up by acids. Of the alkalies, ammonia (see that article) penetrates most deeply into the tissues of the eye.

**STATISTICS**

As in the case of acids, it is possible to complete the data concerning the pathology of workers employed in the chemical industries by those dealing with the departments of alkali manufacture. These statistics, prepared by Leymann, treat of them, however, for different periods, as is seen in the following table:

<table>

1,468 | 511 | 1,283
Burns from alkalies numbered 78 in 1881, 88 in 1890 and 28 in 1900.

Ocular lesions caused by alkalies numbered 50 for the period 1881-1890, 36 for the period 1890 to 1900, and 18 for the period 1900 to 1904.

(See also the article "Chemical Industries ")

HYGIENE

Generally the same precautionary measures are necessary as have been described in the case of acids, especially in regard to transferring, transport, filling of bottles, etc.; arrangements as to manufacture and manipulation of alkalies are laid down in the articles "Ammonia" and "Caustic Soda Lye", etc. For the treatment of effluents see article "Waste Water".

The most important point to attend to in the treatment of burns is to dilute the corrosive substance either by water or by slight acid solutions (acetic acid or even vinegar). Treatment should be as prompt as possible while waiting for the surgeon. Overall, gloves, goggles, etc., should be worn as described in the article on acids. Ointment (e.g. lanoline) can usefully be rubbed on the hands and forearms.

LEGISLATION

Young persons of less than 16 years of age are prohibited from work in the manufacture or use in dangerous quantity of caustic lyes in the United States in the States of Alabama, California, Kentucky, Maryland, New Jersey, Ohio, Oklahoma, Wisconsin, and under 15 years of age in the State of Delaware (preparation of chemical lyes); boys under 16 years and girls under 18 in Greece in alkali manufacture; boys under 16 years and females under 21 in Spain in the manufacture of caustic alkalies (see also the articles "Ammonia", "Caustic Soda Lye", etc.). The regulations are analogous to those set out in the article "Acids" and are to be found in the same regulations.

Thus, for example, the British regulations of 11 July 1922 require in works or parts thereof in which:

1. Caustic pots are used;
2. Chlorate or bleaching powder is manufactured;
3. (a) Gas tar or coal tar is distilled or is used in any process of chemical manufacture;
   (b) A nitro or amido process is carried on;
   (c) A chrome process is carried on;
4. Crude shale oil is refined or processes incidental thereto are carried on; or
5. Nitrile acid is used in the manufacture of nitro compounds:

Every caustic pot shall be of such construction that there shall be no foothold on the top or sides of the brickwork or flues; and, the edge of every such pot constructed, rebuilt or replaced after these regulations come into force shall be at least 3 feet in height above the adjoining ground or platform.

Lastly the Russian regulations of 10 April 1922 deal with the manufacture of caustic bases, and of sulphate of soda, etc.

Ulceration of the skin set up by caustic liquids is treated as an accident for the purpose of compensation in the British Workmen's Compensation Act and in New South Wales; the eczematous conditions in Western Australia; conjunctivitis in Japan. Lesions set up by lyes are also subject to compensation in Japan, Finland, and Switzerland. 

Allyl Alcohol

Allyl alcohol is a liquid with a pungent smell, the formula of which is CH₃=CH.CH₂OH. It is very soluble in water, boils at 98° C., and the specific gravity is 0.8573 at 15°. It is obtained in small quantities from dry distillation of wood. Industrially it is obtained by heating glycerine with oxalic and formic acid. Glycerofomorlic ether is formed which decomposes between 200° and 260° C., giving allyl alcohol. It is separated by distillation. Allyl alcohol is used in the preparation of bromide and iodide of allyl, allyl ethers, and cinnamon and salicylic acids.

One of the most important derivatives of allyl alcohol is essence of mustard formed chiefly of allyl cyanate. It can be extracted from mustard seeds, but is often also obtained by distillation of allyl iodide with sulphocyanate of potassium.

Medical literature records only cases of severe irritation of the mucous membrane with lachrymation, conjunctivitis, increased nasal secretion, etc., amongst workers exposed to the fumes of allyl alcohol in course of its manufacture.

For further details, see article "Ethyl Alcohol".

Alum

Ordinary alum or potassium alum (for the other varieties, chrome, iron, etc., see articles "Chrome", "Iron and Steel Industry", etc.) is a double sulphate of aluminium and potassium \([\text{SO}_4, \text{Al}, \text{SO}_3, \text{K}_2+24\text{H}_2\text{O}]\) in the form of a colourless transparent crystallisable salt soluble in 10 parts of cold water and 5 parts of boiling water. Its density is 1.735; it melts at 90° C. In an anhydrous state it forms calcined alum, white, friable and slightly caustic. The active principle of alum is aluminium sulphate, with the result that the latter, or sodium aluminate, is becoming more and more frequently substituted for it.

Alum is recovered from certain kinds of earth containing, at the same time, aluminium sulphate and potassium sulphate (natural alum, alumite) or the elements which go to their formation (aluminous earth, aluminous schists). Natural alum is chiefly found in volcanic regions (Italy: Neapolitan Campagna, Stromboli; Greece: Milo; Switzerland: the Canton of Uri; United States: Tennessee).

Alum is obtained, from the natural product, by dissolving in water and crystallising the solution, or from alumite by roasting the mineral, treating with hot sulphuric acid, adding potassium sulphate and crystallising, or again from aluminous earth and aluminous schists by oxidising the mineral in presence of air, lixiviation and crystallisation of the solutions after addition of potassium sulphate, or finally from alumminium sulphate (the solutions of potassium sulphate and aluminium sulphate being mixed in equimolecular proportions).

Alum is used in the textile industry (dyeing and printing as a mordant — especially anhydrous alum); in the leather and hide industry (tanning, currying, tawing, morocco dressing, and for leather dyeing); in the paper industry (for gluing paper); in the colour and varnish industry (manufacture of lakes). It is further employed for fireproofing wood and cloth and for clarifying water, etc.

According to White, immersion of the hands in a solution of alum may set up cutaneous irritation, a crust of aluminium oxide with a corrosive action forming on the skin, which becomes hardened, tanned, and cracked. Bauer states that alum may cause ulceration of the toes and particularly of the ungual groove of the large toe.

During the operation of roasting the alumite, gas containing about 3 per cent. of sulphurous anhydride is given off. The kilns used must therefore be airtight and the sulphurous gases drawn off by an exhaust apparatus and thereafter absorbed, preferably by means of chambers or towers and the application of water with soda or potassium in solution. On the other hand, the material requires to be broken up prior to roasting. This operation should be effected in closed mixers (ball mills or disintegrators), and any dust which may escape should be withdrawn by local exhaust and subsequently filtered.

Ordinary measures of hygiene are called for in relation to the workshops (floors, walls, etc.) and also removal of fumes and acid vapour, installation of ventilation treliss and decantation and purification of all waste water before leaving the factory.

Aluminium

Properties

Aluminium (symbol: Al) is not found as a metal in a pure state in nature, but nevertheless it is extremely widespread in various combinations. It is even the commonest metal in the soil, and, with the exception of oxygen and silicon, the most widespread substance in the world. One finds it in numerous mineral matters — clays, granites, porphyries, micas, etc. — and in precious stones such as rubies, sapphires, corundums, etc.

Aluminium is generally obtained from bauxite (hydrated aluminium \((\text{Al}_2\text{O}_3,2\text{H}_2\text{O})\), the strata of which are found in the South of France, Calabria, Hungary, etc.) and cryolite (the double fluoride of aluminium and sodium \((\text{Al}_2\text{F}_3,3\text{Na}_2\text{F})\) found in Greenland, Iceland, Alaska, Denmark, etc.).

In a pure state aluminium is a bright, silverly bluish, white metal. In structure it is slightly fibrous; its consistency is not very great, but if, in this respect, it is weaker than copper and its principal alloys, it is, on the contrary, harder than tin or zinc.

The atomic weight is 27.1; its specific gravity varies with its state, corresponding to 2.64 when in the molten state and
268° C. in laminated form, and 270° when drawn. Aluminium melts between 625° and 655° C. and boils at 1,800° C. Its heat conductivity is 0.345 at 0° and its co-efficient of expansion 0.000231.

Further, it is interesting to note that its specific heat is very high (0.235 at 100 degrees) and it is the same in regard to its melting point, so that therefore, in comparison with other metals, it calls for a great quantity of heat to melt it.

Aluminium is very ductile and malleable; in this respect it comes next to gold. It stands exposure to air well notwithstanding its affinity for oxygen. Exposed surfaces become covered with a layer of oxide, hardly perceptible, however, which does not detract from the pleasant look of the metal, and serves as a protection against further attacks.

While aluminium offers very strong resistance to certain substances, it is on the contrary attacked violently by others. It is highly resistant to acetic acid, formaldehyde, oxygenated water, fats and fatty acids. This makes it very serviceable for domestic use. It also resists very well the action of water if free from foreign metals.

Aluminium vessels strongly attacked by certain waters may be rendered refractory by a "re-baking" at 250° C., especially if this is repeated several times, in an oxidising atmosphere. This operation results in coating the surface with a layer of oxide sufficient to protect the metal against attack from dangerous waters.

Recently (1924) Hatfield has shown, in reference to the presence of soluble aluminium sulphate, that the limit of insolvability for aluminium is between 5.7 and 7.3 (hydrogen ion concentration). In waters clarified by aluminium sulphate of which the hydrogen ion concentration is below or above these figures, soluble aluminium might be found.

The sensitiveness of aluminium to mercury is so great that the slightest trace of this substance in the water gives it a great power of attack.

Aluminium is a reducing agent acting energetically on the oxides and numerous metals. It is dissolved in hydrochloric and sulphuric acids giving off hydrogen; on the other hand it is not acted on by nitric acid. Aluminium is rapidly dissolved by soda and potash with evolution of hydrogen. It is attacked by the halogen group.

Aluminium readily forms an amalgam with mercury which is obtained directly by placing mercury in contact with aluminium in the powder or by heating aluminium with a 1½ per cent. solution of sublimate. In the presence of water this amalgam decomposes it rapidly and at the oven temperature, forming synthetic ruby, hydrate (AlO.H₂) and giving off hydrogen.

Compounds of aluminium are numerous — e.g. the chloride [Al Cl (3)], prepared by passing a current of hydrochloric acid gas over aluminium turnings, is a substance used in organic syntheses; oxide of aluminium (see above), a white powder, insoluble in water, melting at 2,050° C. and used in the preparation of refractory materials and the manufacture of artificial precious stones; synthetic ruby, obtained by melting, with the oxyhydrogen blowpipe, aluminium mixed with chrome oxide; ultramarine, a very beautiful colouring matter, the composition of which is not known, but which is obtained by heating, in the absence of air, either a finely powdered mixture of kaolin, sulphur and soda, or a mixture of kaolin, Glauber's salt, sulphur and carbon. During the reaction a large quantity of sulphurous anhydride is given off.

INDUSTRIAL PROCESSES

Aluminium has only been manufactured on the industrial scale recently because of the difficulties in its production. Large sources in electrical power were necessary before an abundant cheap production was obtained. The primitive methods are now done away with and constant improvements make production easier and easier.

The methods actually in vogue are based on the principle of according to electrolysis a solution of alumina (oxide of aluminium) in a bath of cryolite melted at a high temperature. (carbon electrodes are used). In theory only the alumina should be decomposed; the metal passing to the cathode is deposited on the bottom of the furnace and the oxygen set at liberty with the carbon of the anode (which is rapidly consumed) becomes oxidised, forming carbonic oxide, which, on burning, becomes converted into carbon dioxide.

From the point of view of the output from these processes, Ullmann states that it should be possible to produce 0.337 grm. of aluminium per ampere hour with 3 volts, which corresponds to 42.1 grm. per B.T.U. and 365.7 kg. per kw. A normal bath would allow of a theoretical utilisation of the current of 90-95 per cent. But many causes of loss lower the effective utilisation of 60-65 per cent. corresponding to a yield of 210-275 grm. of aluminium per kw., which theoretically is equivalent to a production of 1 kg. of aluminium from the use of 1,889 grm. of alumina and 333.5 of carbon at the anode (or 696.7 kg. of carbon in CO₂). But in practice higher quantities are required.

The metal thus produced contains 98-99 per cent. of aluminium (it may reach 99.5 per cent.). The principal impurities are silicon and iron — sometimes copper. Sodium, as has already been said, is the substance which is most injurious to the metal.
The cryolite which serves for the composition of the electrolytic bath is to-day often obtained artificially, or its place is taken by other fluorides; the production of these substitutes deserves attention from the point of view of hygiene because of the troubles and danger they may bring — the danger being the same as those common to the chemical industries and particularly manipulation of fluorine and its acids. Further, it is important that these products should be as free as possible from silicic acid.

But by the decomposition of the alumina oxide in the course of the process of electrolysis the bath reaches a stage when there is not enough alumina; the cryolite can then itself undergo electrolytic action (which in practice is frequently the case), and so it comes about that, as the result of the decomposition of the fluorides of aluminium and sodium, gases of fluorine are given off at the anode and sodium is deposited at the cathode. Alumina will not tolerate the presence of sodium even in traces, because the quality of the metal so obtained is faulty. It is necessary, therefore, constantly to feed the bath with alumina to maintain the necessary proportion of cryolite. The success or otherwise of the operation depends to a large extent on how the bath is constituted and maintained, and equally the experience gained in each factory permits the use of baths of differing composition with a view to better production.

The temperature of the baths is not always the same, but as aluminium commences to melt at about 650° C., their temperature must necessarily be higher than this; it can vary between a minimum of 700 and 1,000° C.; in practice it varies from 800° to 900° C.

Alumina to be used in making aluminium must be as pure as possible. It is obtained from bauxite, an aluminium hydrate poor in water, which, submitted to a preliminary treatment, is converted into pure alumina, after elimination of iron and silicon. The processes of purification resemble each other generally, and consist in the treatment of bauxite with caustic soda. The alumina is converted into soluble aluminate; the iron and the silicon are eliminated by filtration. Carbon dioxide is then passed through the solution of aluminate, which precipitates the pure hydrated aluminium. The solution of aluminate also can be mixed with a small quantity of hydrated aluminium; the dissolved alumina is carried down by precipitation and the alkali is liberated (Bayer). Pure aluminium is also prepared by utilising solutions of aluminate of soda remaining over from the manufacture of ammonia by the process of Serpek (see article "Ammonia").

**Uses**

In consequence of the fall in the price of aluminium, its use for culinary utensils has recently greatly increased; it is gradually but constantly replacing copper, enamelled iron and earthenware. The vessels are either cast or manufactured out of sheets of metal or finally hammered. Aluminium can even be used for chemical and industrial purposes (special cast vessels, etc.).

The waste from these manufactures is used, after being reduced to powder, in the production of bronze powders (see later).

Aluminium reduced to a fine powder, and suspended in varnishes or drying oils, serves for ornamental painting, or for a protective coating (e.g. against rust). The very fine powder is used in lithographing and also in the production of explosives (ammonal).

Aluminium further plays an important rôle in metallurgy in the casting of irons and silicas, or it is added in small proportions (0.02-0.05 per cent.) to reduce the dissolved oxide of iron. It serves also in the making of alloys such as aluminium, bronzes, and special light alloys for aeronautical work.

The aluminium bronzes are very numerous; there are two important groups according as the proportion of copper or aluminium preponderates. The bronzes predominating in copper contain 5 to 10 per cent. of aluminium and those predominating in aluminium have only 3 to 6 per cent. of copper.

Mention should be made further of the bronzes properly so called (tin, copper) which contain aluminium also and are special bronzes in which aluminium is present only in very small quantities (less than 1 per cent.). In such an alloy the aluminium only plays a deoxidising rôle. Larger quantities would increase the brittleness of the mass.

The aluminium bronzes are alloys of copper and zinc in which the aluminium enters in variable quantity but always slight (from 0.3 to 4 per cent.). The use of aluminium for electric cables instead of copper is extremely important, because even though there is required for an equivalent conductive power greater thickness of aluminium.
wire than of copper wire there is an advantage in using aluminium instead of copper as it weighs less and consequently effects a considerable economy in the manufacture of the supports.

Aluminium is also used in the preparation of metals such as chrome, tungsten, molybdenum, for the reduction of their oxides.

Alumino therm. A metal or its alloy having reducing properties acts upon a metal compound in such a way that, lighted at its end, it continues to burn of itself with development of high temperatures. The metal reduced, after oxidation of its active elements, then separates, forming a solid mass and a liquid residue. The phenomenon has this peculiarity, that the operation goes on without the mixture receiving any additional heat from outside necessary for the reaction.

Aluminium is the most important of the reducing agents; in practice the action is used especially in the case of oxides, more rarely on sulphides, chlorides, and nitrogen salts.

The name "thermite" is given to a mixture of aluminium and iron oxide, which, on being ignited by a small quantity of an inflammable mixture, gives rise to a special reaction; at the end of the operation in the still hot crucible a molten mass is formed, consisting of a layer of ashes and a metallic block. Thermite is used to solder rails end to end; it was used during the war to make incendiary pastilles.

TOXICITY — SOURCES OF DANGER

Aluminium is not, properly speaking, a toxic metal, and its presence in animal tissues, at any rate in appreciable quantities, has not been found. Very minute proportions have been traced in the intestines coming from food.

Aluminium compounds are only slightly toxic and fatal poisoning by them is quite exceptional.

From the point of view of industrial hygiene any ill-effects due to aluminium have been occasioned in the course of its manufacture: hydrofluoric acid vapour (see article "Hydrofluoric Acid") and carbon monoxide; accidental burns from spurtting of the molten metal; conjunctivitis set up by the bright and very long flames produced on the combustion of the gas; dangers of fire and explosion; and risk of electrocution.

The furnaces call for constant supervision: a single workman can watch several at the same time, but his vigilance must be directed to different points and particularly to the feeding of the bath.

Apart from the dangers incidental to manipulation, sometimes complicated, of objects at high temperature, particularly in a molten state, and danger of electric shock, there is intense evolution of toxic gases (fluorine, carbon monoxide).

The carbon monoxide is mostly burnt as it is formed, and seeing that plenty of oxygen is present, this risk in normal manufacture is slight.

It is not so, however, with the fluorine given off in considerable quantity, and this gas should be recovered and fixed in such a way as to be rendered inoffensive. To eliminate the fluorine which becomes immediately converted into hydrofluoric acid (and also into hydrofluosilicic acid, due to the presence of silicon from the carbon electrodes) there has been suggested the installation of hoods placed directly over each furnace and leading to a collecting chamber where the gases would come into contact with the fixing agent. This arrangement is not provided in all plants. It does not ensure elimination of all the fluorine, because it is often necessary to raise the hoods to see to the furnace.

In other factories the gases produced during electrolysis are allowed to escape freely into the furnace room, and, as a result of the high temperature on leaving the furnaces, they ascend rapidly and escape to the outer air through outlets specially arranged above. In other factories an attempt is made to fix them by making them pass through sprays of water placed all round outside the building. These procedures do not suffice to hinder the action of the toxic gases on the vegetation, and indirectly on the cattle near by.

In work with aluminium consideration has to be given to different manipulations. The work of the metal itself comprises casting, moulding, forging, rolling, stamping, compressing, assembling, soldering, finishing, polishing, etc., and, lastly, granulating and pulverising, in addition to the different treatment meted out to the powders according to their needs. Making aluminium bronze presents very serious risks. In the course of the different operations—especially of polishing—big explosions often occur, the cause of which is very obscure. Sometimes obviously they are dust explosions; but at others, in the presence of slight moisture, hydrogen gas is formed,
which, with the air present in the apparatus, forms an explosive gas on application of a light.

HYGIENE

Exploitation of aluminium preparations should be subject to special regulations; the machines should be placed in rooms set apart for the purpose and started and stopped from the outside.

The works should be situated away from human habitation, as well as from cultivated and pasture land (Cristiani).

The buildings should be of fireproof materials with impermeable flooring, etc.; electrodes of the furnaces should be controlled from a distance; decontamination and neutralisation of the residual waters should be carried out; the workers should have coloured goggles placed at their disposal; risk of electrocution and neutralisation of the residual materials, etc., should be prevented; apparatus for capturing dust, effective exhaust and ventilation, etc., should be provided (see articles "Fluorine" and "Hydrofluoric Acid").

LEGISLATION

Up to the present time, no regulations specially affecting aluminium factories have been made, although these may be classed under the heading of chemical or electro-chemical industries. Factories in which compounds of aluminium are manufactured come under the Chemical Regulations, 1922 (No. 731), in Great Britain. Special Rules for preventing accidents in the preparation of aluminium bronze powders were issued in Germany (1 July 1925).

Amber

French: Ambre. — German: Bernstein. —
Italian: Ambra. — Spanish: Succino.

Amber is a fossilised resin, from the coniferous trees of the tertiary period, which has become solidified, crystallised and transformed in the earth. It is a hard, brittle body. Its density is 1.10 and it has an agreeable odour (some experts say it is odourless). It is generally yellow and translucent, but at times brownish-yellow or honey-coloured, yellowish white, hyacinth-red or black ("Iceland jet"). Pieces of a beautiful green shade are also found, but they are rare. Real amber melts between 250 and 300° C. and burns with a smoky flame. It is insoluble in water, slightly soluble in alcohol and ether. Its best dissolvent is chloroform. Distilled dry at 400° C. it decomposes into succinic acid and an oil and leaves a resinous residue known as colophany (rosin) used in the preparation of varnish. Amber can be cut and pared, but can neither be welded nor glued together again. It can be worked on a lathe like ivory or bone.

The principal deposits lie along the Prussian coast (Koenigsberg), and along the Courland, Livonian and Finnish coasts, in the Baltic Sea, on the west coast of Jutland, in the North Sea, in Siberia and in the Ural Mountains. Small quantities are found on the coasts of Madagascar and Sicily and in certain countries of Asia and the American continent. In France amber is chiefly extracted from the River Gard, where it is found mixed with lignite.

It is gathered on the banks or shore where nodules ("sprock"), surrounded with clay and algae, are thrown up by the waves or taken from the water in nets. It is subsequently extracted by excavation, sometimes in the open, sometimes from amber strata known as "blue earth", located at the level of the ground, and sometimes as far as fifteen metres below sea level.

At Koenigsberg amber is worked as a home industry by women. The waste is sent to factories where it serves in the manufacture of varnish
If OH is substituted twice for H, diphenol posed to the risk of poisoning, fire and taken into account as possible sources of danger. In the manufacture of the latter, the waste particles are caused to distend by the application of carbon disulphide, ether, benzol or petroleum spirit; they are then placed in a mould where they are subjected to strong pressure at a temperature of 300° C. The mass is then removed from the moulds and dried in the open air.

Artificial amber is produced from copal resin mixed with a little colophany (rosin). Imitation amber can also be made from celluloid, to the composition of which resin solutions (copal or gum lac) have been added. Amber is used for the manufacture of pipe stems, cigar and cigarette holders, jewels, heads of sticks, etc.

Sachs notes serious cases of dermatitis amongst women engaged on the manufacture of artificial amber ("bakelite"). Hot fumes of carbolic acid, formaldehyde and hydrochloric acid were given off during the processes and set up conjunctivitis, bronchitis and a distinctly reddish swelling of the face and forearms. Spitzer reported three cases in Vienna (1924). Wintersteiner, in 1893, drew attention to the case of a worker who was obliged to bend over his work on account of shortsightedness and in consequence numerous minute particles of amber were found to have penetrated the cornea. Rambousek, on the other hand, recalls the danger of lead poisoning presented by the use of lead blocks on which the amber is cut.

The use of solvents referred to above in the manufacture of varnishes and compressed amber must also be taken into account as possible sources of danger. Workers are further exposed to the risk of poisoning, fire and explosion.

Aminophenols

Several aminophenols are known: they are slightly acid bodies, like phenol, and at the same time bases, as they form salts with acids. They further act as powerful reducing bodies, and precipitate gold and silver from their salts. Their special use is in photography or the preparation of synthetic organic colours.

When in the benzene molecule a monovalent group OH (hydroxy) is substituted for H, phenol is formed (see that article). If OH is substituted twice for H, diphenol is formed. On considering the symmetry of the benzene nucleus, however, it will be seen that the substitution can be made in these different ways yielding isomers (with the same percentage composition and the same formula; ortho-diphenol or "pyrocatechene", meta and para or "hydroquinone", the physical and chemical properties of which differ by reason of the different positions of the same atoms in the three molecules, when the substitution extends to three atoms, the triphenol of C₆H₄(OH)₂, 1, 2, 4, is "pyrogallol" or pyrogallic acid. If the monovalent radical NH₂ is substituted for a hydroxyl group OH the aminophenols result with the three isomers: ortho, meta and para, of which the last is the most used.

When for two groups of the monovalent radical two hydroxyl groups of a molecule of triphenol are substituted diamino-phenol, for instance, is obtained (ortho-paradiaminophenol).

The paraminophenol yields another body when an H of the NH₂ is replaced by the monovalent radical CH₃ (methyl). The monomethyl-paraminophenol thus obtained is an amine which, with the acids of the crystallisable salts, and particularly with sulphuric acid of the sulphates, yields sulphate of monomethyl-paraaminophenol, which is the "metol" so much used in photography.

"Iconogene" is derived in a rather more complicated way of which it is not necessary to speak.

These bodies called "developers" have the property of reducing silver salts when acted on by light. They are in common use to-day, but whilst hydroquinone gives hardly any trouble, the other aminophenols may affect persons manipulating them. (See article "Photographic Plates").

Industrial Processes

The preparation of the hydrochloride of diamino-phenol which is taken as a type, comprises the following series of operations:

Dinitrophenol is introduced into a wooden vat with commercial hydrochloric acid and mother liquors of crystallisation very rich in hydrochloric acid, then with small quantities of white cast-iron filings. The acid, decomposed by the iron, gives off hydrogen, which reduces the dinitrophenol; basic diamino-phenol is formed, which combines with the hydrochloric acid to form the hydrochloride. When the reaction has ended, the liquid is run into wooden vats; a solution of common salt is added to precipitate the hydrochloride of diamino-phenol. The precipitate collected in a bag is placed to drain on flannel filters.

The greyish white mass obtained is dried on stoneware filters, or filtration is carried out under a vacuum. The
crude salt, after solution in hot water, is filtered over animal charcoal. Hydrochloric acid is added to the liquid collected in stone vats and in this the hydrochloride is only slightly soluble and crystallises out. The crystals, dried on a filter under a vacuum, are redissolved in water; another filtration and drying on a filter under a vacuum, areuble and crystallises out. The crystals are scratched, giving rise to small haemorrhages which become covered with crusts. The eczema may extend to the chest, the neck and the face; sometimes it occurs on the genital organs. The workmen suffer from an intolerable pruritus preventing rest and sleep. One old worker, on being questioned by Lenoble, complained that he had had no proper rest or sleep for six months, he would have been glad to have been able to give up the manufacture of aminophenols.

All the commoner forms of treatment are almost useless. The only way of effecting a cure is to give up all contact with the materials in question. Acclimatisation does not take place; the workmen who recover and return to work at once succumb a second time in the same manner.

The individuals who generally stand the work best are those of spare physique and nervous temperament. Those who suffer most, on the contrary, are the fat, the alcoholic, the tubercular and syphilitic — in short, those whose resistance is diminished, or in whom elimination is poor, or whose skin is easily irritated. Lenoble has described several cases of susceptibility in a French factory, as well as other cases among photographers. The latter are also attacked (but not so frequently as those who manufacture the materials) with plaques, papules, on the back of the hands, and excoriations and vesicles on the fingers and hands.

The alkalinity of the baths has been shown not to be the cause because diaminophenol is used in neutral baths, and because, further, in the process of manufacture the dermatitis is worst where the salts are constantly acid.

**Prevention**

Prophylaxis consists in covering the vats with wooden covers, providing a shaft to carry away the fumes to the outside air, avoiding all contact with products likely to set up the condition; provision, consequently, for the workmen, of the necessary tools, furnished with long handles, and kept clean; provision of rubber gloves and respirators for persons employed in sieving; provision of proper washing facilities, etc. In spite, however, of all measures taken, subjects particularly sensitive cannot continue to work.

**Risk of Poisoning**

The manufacture of diaminophenol and paraminophenol exposes the workmen to the acid vapours of hydrochloric acid when the process is commenced, and, to a slight extent, subsequently, during stoving; though during this latter operation exposure to risk is very short.

In the manufacture of metol, the workmen may be exposed to the vapours of methyl sulphate, which is excessively irritating to the eyes and bronchial mucous membrane.

Workmen employed in preparing diaminophenol find themselves exposed, when charging the vats, in more or less direct contact with dinitrophenol, which turns the skin yellow in a degree only slightly less than that of picric acid.

Erich Meyer, in his researches on intoxication by nitrobenzene (see that article), has found in the urine of persons poisoned with this substance, the intermediate bodies p. nitrophenol and p. aminophenol, which are said to cause methaemoglobin.

Although no effects other than localised skin irritation, of not so much importance, are attributable to contact with the acids, and the characteristic yellowish colourisation of the skin to diaminophenol, without specific illness, the use and manufacture of the aminophenols set up a dermatitis remarkable for its relative frequency, tenacity and intensity among those coming into contact with them; and more rarely, but of a very tiresome character, among photographers using these materials in developing.

This eczema, according to Lenoble, shows itself within a week of taking up the work in the factory. The skin, first at the root of the nails and in the interdigital spaces, and later on the back of the hand, the wrist and forearms become inflamed, swell and are painful. If work is continued, papules and vesicles may appear which ulcerate either spontaneously or when they are scratched, giving rise to small haemorrhages which become covered with crusts. The eczema may extend to the chest, the neck and the face; sometimes it occurs on the genital organs. The workmen suffer from an intolerable pruritus preventing rest and sleep. One old worker, on being questioned by Lenoble, complained that he had had no proper rest or sleep for six months, he would have been glad to have been able to give up the manufacture of aminophenols.
Eczema and dermatitis, whether occurring amongst those who manufacture the products or amongst photographers, are statutorily notifiable in the Netherlands. They are included in the diseases for compensation under Workmen’s Compensation Acts in those countries which schedule poisoning or its sequelae from nitro and amido derivatives of benzene and its homologues.

**Bibliography**

---

**Ammonia**

**Properties**

Ammonia is a solution in water of ammoniacal gas, which at ordinary temperature is a colourless gas with a very strong and pungent smell having the formula NH₃ and a density of 0.596. It is very soluble in water, which dissolves 1,148 times its volume at 0°C and 760 mm. It can be condensed at an ordinary temperature by compression into the liquid state, boiling at —33.7°C and solidifying at —75°C. The evaporation of the ammoniacal liquor is accompanied by a great absorption of heat; on this account it is employed in refrigerating machines.

Atmospheric air always contains a certain quantity of salts of ammonium (up to one part of salt to 10,000 parts of air). The saturated aqueous solution of ammonia, which has a density of 0.835, is generally employed instead of the gas itself since it is more easily dealt with. It is caustic, has a strong alkaline reaction and neutralises the strongest acids forming salts of ammonium.

**Production**

The principal sources of ammonia are: night soil and sullage water; the nitrogen from combustible fossils and atmospheric nitrogen.

Night soil contains nitrogen especially in the form of urea which when acted upon by a ferment becomes carbonate of ammonia; the latter when distilled with lime gives ammonia. A cubic metre of sullage water can in this way furnish 2 to 4 kg. of ammonia.

These materials are brought to special factories where they are left for a month in large basins called night soil depositories (dépotoirs). Sludge is deposited which on being dried becomes a manure called “poudrette” (dried and powdered night soil). The decanted liquid which contains ammonium carbonate is distilled with or without the addition of lime in apparatus similar to that used for obtaining ammonia from coal. The gases which escape in the process of distillation have a very offensive smell and should be led away and destroyed.

The recovery of ammoniacal liquor which is deposited in the vats, scrubbers and washers of gas and coke works is of great importance. That, with the nitrogen of the air, is the source of nearly all ammonia used in industry.

At gas or coke works ammonia is produced in the form of sulphate of ammonia, concentrated liquor or caustic ammonia. The last two are obtained by treating the crude liquor in apparatus similar to that of Savalle for alcohol (see that article). Lair’s apparatus consists principally of a tower with shelves on which milk of lime is spread, which displaces the ammonia. Mallet’s tower is supplied with a mechanical stirrer which prevents fouling by the lime.

The ammonia gas on leaving the distilling apparatus is collected in water or is liquefied by compression in steel cylinders. In the last case it is necessary to subject it first to careful purification by washing it with petrol and a solution of soda, then passing it through animal charcoal and lastly drying it with quick lime. The recovery of ammonia from the gases of blast furnaces is actually carried out by a process almost the same as for lighting gas.

The transformation of atmospheric nitrogen into ammonia can be carried out by means of metallic nitrates, or by passing the atmospheric nitrogen through calcium cyanamide, or by direct union of nitrogen and hydrogen in the presence of a catalyst.

The only industrial application of the first method is that of Serpek, in which a mixture of bauxite (impure natural alumina) and charcoal is passed into a furnace provided with a long tube heated electrically and traversed by gas from a gas generator (N+CO). The reaction with nitrogen gives nitrite of aluminium and carbonic oxide. The nitrite of aluminium when treated with soda gives ammonia and a pure aluminate of soda which can be used in the preparation of alumina.

Calcium cyanamide (see that article) prepared by means of atmospheric
nitrogen and carbide of calcium decomposes into ammonia and carbonate of lime when acted upon by water. The process is carried out in an autoclave at a pressure varying between 3 and 10 kg. per square centimetre.

Direct combination of nitrogen and hydrogen is carried out according to the process of Haber, especially in the German works of Oppau and Merseburg. These works, in order to prepare gas for the purpose of catalysis, start with hydrogen which has been water-gased by water:—

— "Gas (Industrial)" and air. The solution of carbon monoxide is oxidised into anhydrous dioxide by steam in the presence of a catalyst and the carbonic acid is dissolved in water under pressure. Any traces of carbon monoxide are removed by treatment with an ammoniacal solution of copper formate. Hydrogen and nitrogen are the only gases left and the mixture is compressed at 200 atm., then passed into catalysing tubes heated to 550° C. The catalyst consists of iron which has been specially treated and contains very little alumina. The yield being only from 4 to 5 per cent. of ammonia for each passage through the catalyst, it is necessary for the process to be carried on in a closed circuit, that is to say, the residuary gases repass to the catalysing tubes after the ammonia formed has been dissolved by water and amounts of nitrogen and hydrogen have been introduced into the circuit corresponding to but not exceeding the quantity of ammonia formed. In this way a 20 per cent. solution of ammonia is obtained.

In order to increase the yield of ammonia, Claude compresses the gases at about 1,000 atm. before introducing them to the catalysing tube. As the result of the great pressure, the ammonia obtained is liquid; it is collected as such and not in the form of a solution. Claude produces nitrogen by distillation of liquid air, and he has proposed to obtain hydrogen from the gas of coke ovens by freezing out the other congealable constituents. He has also under consideration using gas from coke ovens for synthetic ammonia. In a similar process an apparatus is used by which hydrogen is extracted from water-gas.

Some Italian works employ a process attributed to Casale. The gases pass under a pressure of about 750 atm. into special electrically heated converters supplied with apparatus for varying the temperature. This work is also carried out in closed circuit and gives ammonia in a liquid state. Hydrogen and nitrogen are produced in a special way. Electrolysis of water gives hydrogen, of which an excess is mixed with air followed by combustion; there results synthetic water and a mixture of hydrogen and nitrogen which is passed to converters.

The process of Jausser, which is also employed in Italy, only differs from the process of Casale in structural details. From the hygienic point of view it presents the same advantage. (See figure, page 113.)

**USE**

Liquefied ammonia is supplied for industrial use in steel cylinders. The aqueous solution of ammonia is also very often used, known as ammonia or volatile alkali. The chief uses of liquefied or distilled ammonia are: the preparation of sulphate or chloride, or nitrate of ammonia; the manufacture of nitric acid (see that article), of soda by the Solvay process, of urea, of artificial ice, of cyanides, etc. It is also employed as a reagent in laboratories, in pharmacy and in numerous operations of the chemical industry (organic products: aminated derivatives, etc.).

Hydrazine (N₂H₄), utilised in aqueous solution as hydrate of hydrazine, N₂H₂·OH, has not yet taken its place in practical industry. For nitrate of ammonium and methylamine, see article "Explosives".

Finally, it must be remembered that Claude has drawn attention to the interest, from the viewpoint of producing artificial manures, attached to the transformation of synthetic ammonia into ammonium chloride by the aid of chlorine lost in immense quantities in the Solvay soda industry.

**SOURCES OF POISONING**

(a) In the course of the manufacture of ammonia, workers are exposed to ammonia vapour; to fumes of sulphuric and of metaphosphoric acids; to offensive smells set free when ammonia vapour comes into contact with acid fumes, such as sulphuric acid, and when non-volatile compounds of ammonium are disintegrated by caustic alkalis; to pyridine, phenol and tar (by-products of ammonia manufacture); to sulphured hydrogen and compounds of cyanogen. Workers may also be exposed to the action of lead, etc.

(b) In the course of certain industrial processes or in the use of ammonia, risk is associated with handling glass or
of calcium, of colours, such as indigo and amaranth, and of lacquers; in dyeing phosphate and sulphate of ammonia. Great quantities in the gas-lighting industry when great amounts of ammonia are set free, especially when tarry water is used and when it is distilled; with preparing phosphate and sulphate of ammonia due to the combined action of lighting gas, sulphuretted hydrogen and cyanogen compounds. There is also exposure in refineries for petrol and certain industrial oils which contain alkalis (0.8 to 2 per cent. of caustic soda, 1.5 per cent. ammonia); in the Solvay soda industry; in glue works; in the manufacture of explosives, of nitro-cellulose, and of artificial silk; in the preparation of salts of ammonia. Ammonia is further set free in tanneries, and certain industrial oils which contain alkalis; in making and working of refrigerating plants wherein ammonia gas under pressure is used in the apparatus; in sugar refineries; in making animal charcoal; in the manufacture of carbide of calcium, of colours, such as indigo and amaranth, and of lacquers; in dye works; in bleaching with peroxide of hydrogen; in the treatment of Tussore silk after the acid bath of dilute hydrochloric acid, hydrogen; in the treatment of Tussore silk with sulphuretted hydrogen and cyanogen compounds. The absorption is more complete if the exposure is of short duration and, if the exposure is prolonged, the quantity of gas absorbed does not diminish in a marked manner. The effects do not vary very much whether the ammonia is inhaled by the nose or by the mouth. Whichever way it is, most of the ammonia is rapidly absorbed by the mucous membranes and by the saliva. With weak concentrations any action upon the throat and the deeper air passages is slight.

A strength of 0.1 mg. per litre of air produces only a slight irritation and a strength of 0.25 mg. can be borne without injury, but not without discomfort. With dogs an acclimatisation to the action of ammonia has been observed with inhalations, repeated over two to three weeks, of air containing 0.8-1.0 mg. per thousand of this gas. According to Ronzani 0.1 mg. is tolerated for 30 days by guinea pigs without injury, whereas they react with a dose of 0.4 mg. and show diminished resistance to infections. The opinion given by Hober (1913) that the lungs are impervious to ammoniacal fumes has not been confirmed.

A strength of from 2 to 4 mg. per litre, inhaled by animals not accustomed to it, causes serious irritation with ulceration of the conjunctiva and of the respiratory passages, oedema of the larynx, pulmonary haemorrhages, and pneumonia of an atypical type.

STATISTICS

Industrial poisonings are not common. They occur mostly among workmen at gas works employed in the sublimation of ammonium carbonate and generally in the preparation of salts of ammonia. However, according to certain experts the poisoning is to be ascribed to fumes containing sulphuretted hydrogen and compounds of cyanogen rather than ammonia.

In the United States, Fairbrother, in 1887, reported three fatal cases and one serious poisoning by ammoniacal fumes among four workmen employed in repairing a refrigerating apparatus in a brewery.

In Great Britain the following cases have been reported: 1914, 4 (1 fatal); 1917, 4 (1); 1918, 6 (1); 1919, 8; 1921, 9 (1); 1922, 8 (1); 1923, 5 (1); 1924, 1.

In Switzerland, the Government department for the prevention of accidents had reported to it a case of poisoning in 1919 and another in 1920; one case of ulceration was also reported in 1918, two in 1921, and five cases from 1922 to 1925.

SYMPTOMS

Generally the cases notified only present lesions of the skin, such as irritation and caustic wounds, which may nevertheless reach the stage of a burn of the second degree, affecting exposed mucous membranes, eyes, throat, and upper respiratory passages, when caused, for example, by ammonia gas escaping from refrigerating apparatus. If the fumes are inhaled in great quantity, an acute condition may supervene with the gravest of symptoms extending even to pulmonary oedema (2 cases, Hamilton), and sometimes to a fatal issue (one case in a
Dutch brewery and another in an American one). From the industrial point of view, chronic poisoning is not of importance. The general troubles reported are due much more to the action of compounds of sulphur, e.g. ammonium sulphide and sulphuretted hydrogen.

The action of ammonia upon the eyes deserves special attention. Conjunctivitis may be accompanied by the formation of pseudo-membranes, and days later became very deep with increase of intraocular pressure followed by perforation and hernia of the iris; Abadie, Denig and other experts quote similar cases with diminution and even loss of sight. These cases show that if ammonia infiltrates slowly into the corneal tissue, it causes very serious deteriorations after it has penetrated. Trantas has studied the case of a workman who, following a long exposure to the action of ammonia vapour, had a corneal lesion closely localised in cases caused by the strong action of ammoniacal fumes lesions of the cornea may result. At first the reaction may seem to be slight, but later, after one or two weeks, a parenchymatous lesion appears and possibly softening of the tissues.

Pichler mentions chronic conjunctivitis among grooms obliged to remain for long periods in ill-kept stables. Troussseau has recorded the case of a mechanic at an ice factory who had ulceration of the cornea, which twelve to the area bounded by the palpebral border.

As regards dermatitis caused by ammonia compounds, it is sufficient to recall that the nitrate in certain conditions of temperature and subdivision depending also on the peculiarity and predisposition of the individual, causes dermatitis, accompanied by unbearable itching, especially at night, and erythema. These lesions are, however, sufficiently well defined. (Case of P. White, 1916.)
Hygiene

Consideration must be given to the raw materials; to their storage in impermeable and airtight vessels, to preventing the escape of offensively smelling fumes, and the contamination of the subsoil. Closed receptacles only must be used. Efficient exhaust ventilation must be installed over apparatus which gives off fumes and vapours. Steps must be taken to prevent the escape of any noxious gas, and for thorough condensation of gaseous ammonia. Gases not condensed should be burned; and the workshops be kept thoroughly ventilated. Chimneys should be high; and close supervision exercised over the discharge of waste waters. Apparatus and joints should be carefully luted; and gases which cannot be dissolved in water should be condensed in a vessel containing a dilute mineral acid.

From a practical point of view, it must be borne in mind that it is not desirable to conduct offensively smelling fumes to a furnace, for the sulphuretted hydrogen will give troublesome sulphurous acid; this method should then only be used after having absorbed the sulphurous fumes by lime, or used them to produce sulphuric acid.

Legislation

The Spanish law excludes boys of less than 16 years and women of less than 21 years from ammonia works; in Greece boys of less than 16 years and women of less than 18 years are excluded from compressed gas factories (compressed ammonia); in Italy boys of less than 15 years and women of less than 21 years are excluded from ammonia works as well as from compressed gas factories.

In Holland, in places where ammonia is given off in quantities considered injurious by the factory inspector, young persons of less than 18 years and women are only admitted on condition that they obey the inspector’s orders for preventing danger of poisoning, e.g. an obligation for each worker to have a medical certificate, not to eat in the workplace, and not to keep food or pass his spare time there (art. 33, cat. P, of the law of 1920). (See also article “Alkalis”.)

Special legislation laid down by Great Britain (Chem. Works, 1922) deals, among others, with factories where ammonia and salts of ammonia are made.

The injuries caused by ammonia are compulsorily notifiable in France and Holland, and compensated in Finland, New Brunswick, and in Switzerland; eye lesions only receive compensation in Argentina, Bolivia, and Brazil. ***

Amyl Acetate

Amyl acetate, of which the formula is CH₃COOC₂H₅, is in its pure state a colourless, light, neutral liquid with an agreeable smell resembling that of ripe pears. Its specific gravity is 0.875-0.886 at 15° C. and its boiling point is 138-139° C. Searcely soluble in water it is soluble in alcohol and ether. The crude acetate has usually a pale yellow colour and its disagreeable odour somewhat resembles that of crude amylc alcohol. Its density and boiling point vary. The commercial article generally contains as impurities, alcohol, amylc alcohol, acetic acid, sulphuric acid and hydrochloric acid.

Preparation.—Amyl acetate is prepared by heating and distilling a mixture of ordinary amylc alcohol, sulphuric acid and acetate of soda or calcium, and purifying the distillate by washing with a solution of bicarbonate of soda. The final product is rectified.

Use.—Amyl acetate is used as a solvent in preparing the basis of photographic and cinematographic films (dissolving nitrocellulose); in making varnish (acting on nitrocellulose or celluloid); in making lacquer (used in lacquering metal or jewellery); in making and in special products for rendering aeroplane wings impermeable (see article “Tetrachlorethan, “); in preparing patent and buff leathers; for special processes in cleaning and graining leather, for the pastes used in the manufacture and finishing of boots; in the manufacture of art glass; in the making of incandescent electric lamps, dry batteries and accumulators; in the preparation of fruit essence, etc.

Absorption.—It is absorbed by the respiratory passages. Lehmann (1913) found by experiments upon cats that 29 mg. per litre of air inhaled for nine hours and a half produced no effect; that 28 mg. during four hours and a half to six hours produced only slight symptoms of irritation; 35 mg. caused loss of equilibrium at the end of three hours and narcosis at the end of seven hours. It has not been found to have a fatal effect. In man a strength of 60 mg. in 12 cubic metres of air produces at the end of an hour some slight symptoms of irritation (cough, dryness of the throat) which are however easily borne. These
slightly irritating to the skin and so favours the onset of dermatitis.

Lacquering by the cold process in badly ventilated places exposes the workers to the action of the disagreeable vapours of amyl acetate.

The vapour causes nervous symptoms, pains and heaviness in the head, giddiness, nausea, torpor, digestive troubles, palpitation, inflammation, and irritation of the respiratory system, a sensation of heat and slight fainting attacks.

No case of chronic poisoning has been reported. Koelsch, in the course of an enquiry made in 1912 to determine the harm caused by amyl acetate, came to the conclusion that workers only complain at the commencement of work and never when the workshop is thoroughly ventilated. The symptoms which he experienced himself were a sensation of oppression of the chest, fatigue, cough, pains in the head and giddiness which disappeared at the end of two to three hours. Habituation to the action of this product has not been observed. On account of the high price it is often replaced by benzol. In order to determine the toxic action of amyl acetate, one must take into account the concomitant effect of the other elements which go to make up lacquer (acetone, benzene, amyllic or methyl alcohol, etc.).

Among the substitutes which have been proposed may be mentioned amyl formiate, cyclohexanolformol, methyl-cyclohexanolformate—which does not seem to be so inoffensive as cyclohexanolacetic— and above all cyclohexanolacetic which though about three times more poisonous is at the same time three to five times less volatile than amyl acetate.

Hygienic measures are concerned with the collection and removal of the vapour.

No special legislation exists.

### Amyl Alcohol

Eight amyllic isomeric alcohols are known. The most important is the amyl alcohol of fermentation, got from fusel oil to which it imparts its burning taste and nauseous odour. It is a liquid with specific gravity of 0.81, boiling point 131° C., and solidifying at 134° C.

It possesses a strong bactericidal action and is highly poisonous. The serious effects of alcoholism are attributed, by certain authorities, to this alcohol which is present in most liquors.

Amyl alcohol is used in the manufacture of amyl acetate (see that article), to dissolve acetate of cellulose, and in the preparation of isoprene and synthetic india-rubber, in the preparation of certain aniline colours, certain fruit essences, amyl nitrite and valeric acid. The latter when transformed into a sodium salt and treated by sulphuric acid and alcohol gives valerianic ether, the odour of which is characteristic, resembling raspberries. Amyl alcohol is also used in the production of amyl acetate, having an odour of pears or bananas. It is used alone or mixed with ethyl alcohol in the manufacture of powder and explosives and it is present as an impurity or a by-product in the manufacture of chloroform, etc.

Of all forms of alcohol used amyl alcohol is the most toxic; 1.50 grm. suffices to kill an animal averaging 1 kg. in weight, while 7.75 grm. of absolute ethyl alcohol and 6 grm. of methyl alcohol are required to achieve the same result. Fumes of amyl alcohol are more highly toxic than those of the alcohol ether mixture. The toxicity of amyl alcohol increases when evaporation is favoured by simultaneous evaporation of ether or ethyl alcohol.

The fumes cause very severe and uncomfortable irritation of the throat, headache, vertigo, and cannot be tolerated in repeated doses.

Injuries due to amyl alcohol an compensated in Finland.

For further information see article “Ethyl Alcohol.”

---

**AMYL ACETATE**

**AMYL ALCOHOL**
**Amylene**

Amylene, the symbol of which is $C_4H_8$, belongs to the group of olefines (non-saturated hydrocarbons). It is a colourless liquid with an odour resembling petroleum spirits. It is volatile and very inflammable. Its boiling point is 37.30° C. and its specific gravity is 0.667.

Industrially amylene is got from a mixture of different amylene isomers, containing pentane, by heating fusel oil in presence of zinc chlorides. This product, commonly but incorrectly designated “amylene”, is a colourless liquid with a particular odour very volatile and inflammable; its specific gravity is 0.660 and its boiling point between 30 and 40° C.

In 1917, in a Dutch factory where “blue gas” was produced using as basis hydrocarbons with a high boiling point, several workers were found to suffer from violent pains in the back, stomach and chest and from vomiting. A strong odour of gas was noted in the workshop containing the amylene tank and the compressor.

Analysis of the atmosphere revealed the presence of poisonous volatile substances, principally ethylene, amylene and pental. The first and last of these exercised a narcotic action, whilst the amylene acted as an irritant (giving rise to cramp).

***

**Anguillulosis**

French: *Anguillulose.* — German: *Anguillulosis.* — Italian and Spanish: *Anguillulosi.*

The *anguillula intestinalis* (or *Asterocoralsis; Pseudorhabditis stercoralis* or *intestinalis; Rhabdonema intestinalis* or *Strongyloides*) is a parasite widely dispersed through the whole of the torrid zone in Asia, in the Indian archipelago, in America (Brazil, Panama, the Antilles) as well as in Europe where it chiefly affects miners.

The etiology of this disease is quite analogous to that of ankylostomiasis. The experiments of Durma, Gonder, Loos, Hermann, Marzocchi, and Perroncito have long since proved that the mode of entry of this parasite is principally by way of the skin and that entry by the mouth is very much less frequent. It would even appear that larvae introduced by way of the gastric system do not enter the intestine directly, but traverse the wall of the digestive tube and thus arrive in the general circulation and behave similarly to larvae which have penetrated by way of the skin.

Perroncito, who made a study of this parasite simultaneously with the ankylostoma at the time of the great St. Gothard epidemic, was led to enquire if the *anguillula intestinalis* and the *pseudorhabditis stercoralis* belonged to the same species or two different species, or if, as Grassi and Parona thought, the *pseudorhabditis* was the demorphobiotic form of the anguillula. It is now known that there are two kinds of adult anguillulae: a parasitic or intestinal form which comprises only parthenogenetic females, and the free form — stercoral or rhabditoid — which develop in faecal matter outside of the human body. Male and female forms of this kind are observed.

The parthenogenetic females of parasitic form are generally situated in the wall of the intestine itself and the eggs are often laid in the chorion or the glandular tubes. Teissier has proved that the embryos can pass into the circulatory system instead of maturing in the intestine.

Embryos or eggs evacuated with the faeces develop into rhabditoid larvae, which quickly reach the adult stage at a temperature above 20° C., and represent the second free form (sterctal). Copulation takes place outside the body. The female (ovoviviparous) presents in the uterus eggs enclosing a completely formed embryo and liberates rhabditoid larvae which are soon transformed into strongyloid larvae.

**Pathogenesis**

The anguillulae (female) penetrate by breaking their way into the *muscularis mucosae* of the intestine, exercising an irritant action resulting in destruction of the epithelium, congestion of the blood vessels, etc., and creating a mode of entry for secondary infection. It is probable that, apart from the process of setting up anaemia which it exercises in obtaining nourishment, the anguillula also exercises a toxic action analogous to that of the ankylostoma; it is however difficult to determine just what rôle is to be ascribed to the anguillula, since it is very often associated with the ankylostoma.
intermittent diarrhoea, sometimes blood-stained, and patulous bowel movements (noted by Perroncito amongst the workers).

Clinically its presence is manifested by digestive disorders, enteritis with intermittent diarrhoea, sometimes blood-stained, and pain, by fairly marked anaemia and a rise in temperature (noted by Perroncito amongst the St. Gothard workers).

Prophylaxis

Prophylactic measures to be adopted are those described under ankylostomiasis (see that article).

Aniline

Properties

Aniline (formula $C_6H_5 - NH_2$) is derived from benzene; it is obtained by replacing one of the hydrogen atoms of the benzene ring by an amido group. Unverdorben was the first to prepare it in 1826 by dry distillation of natural indigo; in 1824 Runge separated it from coal tar. The first preparation effected by reducing nitrobenzene (using ammonia sulphate) was carried out in 1842 by Zinin; but the technical preparation and use, on a big scale, of aniline dates from about 1860, and corresponds to the development of the industry of coal tar dyes.

Pure aniline, freshly distilled, appears as a colourless, oily liquid, gradually turning brown when exposed to the air; it possesses a peculiar slightly aromatic smell of its own. Its specific gravity is 1.0254 at 15° C., its boiling point is 189° C. It has not yet been possible to apply industrially such other processes as electrolytic reduction, reduction by sodium sulphide, preparation by means of chlorobenzene and ammonia under pressure and at a high temperature.

Preparation, by the ordinary process of reduction, is carried out technically in an apparatus chiefly composed of a vat with a stirrer, a cooling vessel with reflux and a pipe for carrying off the steam. The injection of steam heats the mixture and this helps on the reaction at the start and makes it possible to empty the apparatus when the process is concluded. The apparatus, which is large enough to treat several cubic metres at a time, comprises also tanks, for decanting and holding aniline, and monte-jus (pumps). The process is regulated by gradually adding nitro-benzene and the proper quantity of iron filings into the disintegrator. Reduction takes about ten hours. Salt or lime is then added which releases the aniline, then the current of steam is increased in intensity so that the released aniline is swept through the cooler into a tank, where it accumulates. For this purpose steam is used which is charged with aniline that has been produced from cauldrons fed with water already containing this product and coming from the tanks into which it has been decanted. In this way loss owing to...
the solubility of the amine in water is avoided. The same process is used in the manufacture of derivatives, in order to recover any aniline which has not entered into reaction.

Crude aniline after decanting is transferred into a reservoir by means of special pumps.

The crude aniline is purified by distillation under reduced pressure at about 170° C. in apparatus of great capacity. The first and last parts of the distillation, composed respectively of mixtures of aniline and benzene, and of aniline and water, are purified by fresh distillation.

Preparation of the homologues of aniline is carried out in a similar manner by reduction of the corresponding nitro-derivatives: nitro-toluences and nitro-xylences. In the preparation of xylidine, starting with a mixture of different nitro-xylences, separation is effected of the isomeres contained in the commercial xylidine, which is first procured. The para- and meta-derivatives have as a matter of fact special technical importance. The separation is done by transforming the products into sulphonic acids, or into salts and then utilising variations in the solubility of these bodies.

**Uses**

Aniline, its homologues and derivatives are almost exclusively used in the dye industry. It is used in a small way for pharmaceutical synthetic products (antifebrin; preparations of phenetidine and pyrazolone). Aniline is further used to a limited extent in the preparation of rubber, as a solvent and an accelerator when vulcanising by heat. In both cases the fumes of aniline which are set free have been known to give rise to poisoning. The use of aniline in the form of aniline salt (chlorhydrate) is more common (see later): it is used in aniline black dyeing by oxidation on the fibre. In that work poisoning also occurs (see later). Other uses to which it is put, such as the manufacture of black dyes for leather, are of secondary importance.

Aniline is used in the preparation of colouring matters, either directly or after having passed through a series of transformations into intermediate products by means of substitutions in the amic group or in the nucleus.

The most important products both as regards the technique and the hygiene of industry are the alkylated and arylated amines (toluidines) among which must be mentioned: mono- and di-methylaniline; (C₆H₅) — NH — (CH₃) (C₆H₅) — N — (CH₃); mono- and di-ethyl aniline (C₆H₅) — NH — (C₂H₅), (C₆H₅) — N — (C₂H₅); benzylanline (C₆H₅) — NH — CH — (C₆H₅); and diphenylamine — (C₆H₅) — NH — (C₆H₅).

The alkylated and arylated amines are especially used for the preparation of dyes derived from triphenylmethane (see further on) and of diphenylamine. Their physical and toxicological properties are similar to those of aniline and its homologues. They are obtained by heating in an autoclave to 200°-250° C. the hydrochlorate of aniline with the corresponding alcohols, or sometimes by heating aniline with halogen compounds, such as chloride of benzyl. In order to prepare diphenylamine, one simply has to heat a mixture of aniline and hydrochlorate of aniline.

The most important by-products obtained by substitution in the nucleus are sulphonic acids (C₆H₅SO₃H), which makes possible the manufacture, among others, of azo dyestuffs and nitro-aniline (NO₂C₆H₅NH₂). As regards sulphanilic acids it must be pointed out that the derivative (metanilic acid) is directly prepared by the reduction of metanitro-benzensulphonic acid without passing through the aniline stage; the para-derivative, sulphanilic acid, is obtained by the furnace process, by heating sulphate of aniline to 200°-250° C. on sheet iron in a furnace which is generally in the shape of a tunnel. When the transformation is completely effected, the mass is dissolved in water with the addition of soda; the excess aniline is removed by a current of steam, and then purified by crystallisation. This process is equally useful for the manufacture of other sulphoaniline acids, such as naphthionic acid. It causes a liberation of aniline vapours which must be carried off by an exhaust draught.

Sulphonic acids themselves are substances soluble in water, and not as a rule toxic; they are non-volatile and present little affinity for fats. Thus they are not dangerous and have but little interest from the point of view of industrial hygiene.

Of the two nitro-anilines, the meta-derivative, obtained by the reduction of meta-dinitrobenzene by means of polysulphide of sodium, is of technical importance.

Reduction, as well as filtration of the sulphur, which separates out during the reaction, is carried on in boiling water in a closed boiler. Efficient exhaust draught must be connected to the apparatus wherein these operations
are carried out, for the first and final products are both very poisonous, but may easily be caught by steam.

*Paranitranilin* can also be obtained by nitrating formanilide or acetyllyl and then saponifying, for the acyl group protects the amido group. The elimination of orthotranilin, which is formed simultaneously, is effected by washing with hot water, but as this isomer may be carried off by steam this operation may be dangerous. The risk of poisoning may be avoided by furnishing the filter with a cover or with a cowl communicating with an exhaust draught.

To avoid the setting free of dust during the grinding and packing of the finished product, it is necessary to protect in the same way the mills and finished during the grinding and packing of the exhaust draught.

Commercially, aniline, its homologues and derivatives are used for the preparation of two large groups of *colouring matters*: the dyes of di- or tri-phenylmethane and azo dyes; the preparation of aniline salt for direct dyeing belongs to a class by itself.

**Dyes of Di- and Tri-Phenylmethane**

This group of dyestuffs, which constitutes the "aniline dyes" in the strictest sense of the term, is characterised by a combination of two or three phenyl groups attached to the carbon atom of methane.

\[
\text{H}_4 - \text{C} \quad \begin{array}{c}
\text{C}_3 \text{H}_4 - \text{NH}_2 \\
\text{C}_2 \text{H}_4 - \text{NH}_2 \\
\text{C}_3 \text{H}_4 - \text{NH}_2
\end{array}
\]

The development of the aniline industry dates from the preparation of derivatives of this group and particularly from the discovery of aniline red (fuchsin) by Nathanson and Hoffman (1856-1858), as well as the determination by Hoffman, Perkin, Verguin, etc., of its composition and the chemical conditions under which it is formed.

The preparation of its derivatives constitutes another very important part of the industry of colouring materials. This group, in addition to the primary colours, red (fuchsin), violet (crystal violet), blue (aniline blue, and light blue) and green (malachite green, Victoria green, and light green), includes colouring matter obtained by the substitution of alkylated and arylated groups for the hydrogen atom of the amido group. These last colours are obtained by the introduction of alkyl or aryl groups into the finished product, or by treatment of the corresponding alkylated or arylated amines in place of the primary amines, such as aniline and toluidine.

The manufacture of these colours is sometimes done following the original process by oxidation, and sometimes by different processes of synthesis by condensation. Fuchsin is prepared exclusively in the first way, whilst the violets and greens are obtained by the second method. The process of synthesis of fuchsin by oxidation, in which the carbon atom of methane is furnished by the methyl group of toluidine consists in melting a mixture of aniline, para- and ortho-toluidine (Rötol) for the preparation of fuchsin with an oxidiser. The operation is carried out in a boiler at 160°-180° C. Violets and other colours are obtained in the same way, but by treating alkylated or arylated amines.

The arsenic process in which arsenic acid is used as an oxidiser is to-day completely replaced by the nitrobenzene process, on account of the dangers of poisoning which arsenic acid affords, as well as the residues and finished products which always contain a little. The nitrobenzene and nitrotoluene used at the present time with chloride of iron answer the purpose of oxidising agents and at the same time of raw material. As a matter of fact they replace one part of the aniline and of the toluidene. The melted mass is then composed of aniline, isomeric toluidenes and nitrobenzene or nitrotoluene. The fumes of amine which arise during the reaction mixed with the water which is formed are condensed in a refrigerator and are used afresh. When the fusion is completed, the hot and viscid mass, still containing aniline and toluidene, is run into a vat, where it cools and crystallises. Then the solidified mass is taken out, broken up, and boiled with water in a closed vessel and filtered while still hot. The colouring material is next precipitated by salting and purified by crystallisation. Fumes of aniline and toluidene may be set free, especially when the vessel is being emptied and the mass is being cooled. There is also a danger of this during the filtration of the hot solution. It was in the fuchsin-melting workshops that the first cases of aniline-cancer were reported.

The different processes of synthesis by condensation are nowadays much improved, as much from the chemical point of view as from the technical. They are based on the ease of condensation — it might even be said on
the tendency to condensation — which the aliphatic and aromatic aldehydes (formaldehyde, benzaldehyde) present. In fact they furnish quite easily their carbon atom of methane which brought in contact with amines and give colouring materials or their white derivatives. Melting by oxidation is omitted in most of these synthetic condensation processes.

Azo Dyestuffs

These constitute the second group of colours prepared by starting from aniline or its homologues and their derivatives, particularly from their sulphonic acids. This group includes very numerous derivatives characterised by the reunion of phenyl groups, diphenyls or naphthyls, by means of the azo group \((-\text{N} = \text{N}-)\).

This grouping is formed by diazotisation of aniline or other primary amine. Other aromatic nuclei may easily be fixed to one of the carbon atoms of the nucleus, which leads to the formation of colouring materials. With this object the primary amines can be used with one or several aromatic nuclei of alkylated or arylated amines, phenols, naphthols or sulphonic acids.

The amines capable of being diazotised and the compounds that can be used for this synthesis being very numerous, a large number of colouring materials can thus be produced. Thus, as it is possible to cause multiple fixations of groupings on several azo groups at a time (diazidised dyestuffs), the number of dyes which can be obtained by these methods is practically unlimited. Further, as the reactions of these syntheses occur fairly readily, and as they closely resemble one another, investigations in this domain have not presented particular difficulties. This is why this branch of the industry has developed very rapidly and to-day forms the principal branch of the manufacture of colours from tar.

The industrial preparation of these colouring materials is remarkably uniform. It is based on the transformation of aniline or of other aromatic amines into corresponding diazo compounds, a transformation which takes place under the action of nitrous acid in an acid solution. That is diazotisation. These compounds then quite easily combine with phenol, naphthols, aromatic amines, and their sulphonic acids and give the colouring materials (coupling). In the industrial process this operation is most often carried out in an apparatus arranged in three stages. The base or the corresponding chlorohydrate is first dissolved in a mixture of water and hydrochloric acid, in an open vessel furnished with a stirrer. The clear solution is run into the diazotising vessel which is placed below. It is cooled by means of pieces of ice, and the necessary quantity of hydrochloric acid and nitrite solution is added. Diazotisation occurs almost immediately. The compound with which the coupling is to be made is first dissolved in a vessel with a stirrer, then the solution is passed into the coupling vessel, into which the diazo base is also run. The separation of the dye generally takes place spontaneously, but it is facilitated and completed by salting and heating; then it is treated in a filter press to remove the mother liquor, and dried. In this way an almost pure commercial product is obtained.

In addition to the preparation of these two large groups of dyestuffs, aniline finds an important use in the synthesis of indigo by the glycine process. In this process the commencing product is phenylglycine obtained by the action of chloracetic acid on aniline.

Toxic Effect

Aniline exercises its toxic effect chiefly on the blood and the central nervous system. From the clinical and pathogenic aspect the most important phenomenon is its action on the blood and particularly on haemoglobin. In poisoning by aniline the oxyhaemoglobin of the red cells is transformed into methaemoglobin; marked cyanosis, which appears very rapidly in the clinical picture, is an early sign of progressive diminution in the power of the blood to absorb oxygen, to which are due the secondary symptoms of internal asphyxia, detectable first in the central nervous system. But it would not be accurate to ascribe all the symptoms of poisoning by aniline, and, in particular, the nervous symptoms, to secondary phenomena due to the transformation undergone by haemoglobin. As a matter of fact when poisoning is produced experimentally, these precise symptoms predominate, especially among herbivorous animals which possess comparatively good resistance to the action of aniline on haemoglobin.

On the other hand it is precisely by its action on the nervous system that poisoning by aniline, in the case of man and of animals, differs from other poisons which lead to the formation of methaemoglobin — poisoning by nitrates for instance. Contrary to what happens with the nitrates or carbon monoxide,
which particularly cause symptoms of internal asphyxia, aniline produces an early narcotic effect, as well as other fundamental phenomena affecting the central nervous system, before any sensible diminution in the capacity of blood for carrying oxygen is produced. Moreover, the specific action of aniline upon the nervous system seems to be sensibly feebler than that of nitrated aromatic bodies, which is probably due to its smaller affinity for lipoids.

According to fresh researches undertaken particularly by Heubner, Ellinger, and Lipschuetz, the action of aniline and most of its homologues and derivatives on haemoglobin is not to be attributed to these substances themselves, but to certain intermediate states of oxidation which occur within the organism. The same applies to the corresponding nitro-derivatives. In the body aniline undergoes especially oxidation into paramidophenol (OH — C₆H₄ — NH₂), with the intermediate formation of phenyldroxylamine (C₆H₅ — OH). Paramidophenol then unites with the sulphuric acid and is subsequently eliminated in the urine. This oxidation constitutes rather an anti-toxic phenomenon, since it leads to an acid compound which is comparatively slightly toxic and easily eliminated by the kidneys, namely: paramidophenol-sulphonic acid (NH₂ — C₆H₄ — O — SO₃H). On the other hand the intermediate products of this oxidation particularly phenyldroxylamine and paramidophenol possess to a high degree and in contrast with aniline itself, the property of reducing oxyhaemoglobin into haemoglobin. On the other hand, the transformation of haemoglobin into methaemoglobin is reversible. This inverse reaction is rapidly effected in the case of slight poisoning when the poison has been eliminated.

In addition to this action on haemoglobin, aniline, its homologues, and aromatic nitro-amino derivatives possess also the power of destroying red blood cells. This action shows itself comparatively slowly in serious and acute cases, that is to say, after the disappearance of the first serious symptoms, and is shown by haemoglobinuria and a deeply yellow coloured jaundice, and even, after some days, by an intense secondary anaemia.

Generally speaking this haemolytic action of aniline and aromatic amines is less marked and less lasting than that of the corresponding nitro derivatives. In particular the action of the former in causing chronic anaemia is a diminishing one.

The direct action of aniline, its homologues and their derivatives upon the nervous system shows itself first by a state of excitement followed by a paralysis of the central nervous system. At the onset of the condition, excitement occurs with acceleration of the respiration, followed by fatigue, inertia, loss of consciousness, and coma. The effect on the peripheral nervous system is shown by paraesthesias and hypoaesthesias, both sensitive and sensory. The increase of the blood pressure which is noticed at the commencement, and which moreover in serious cases is followed by a fall of pressure sufficient to cause collapse, may be interpreted as a vaso-motor disturbance.

The lowering of temperature, which is associated with the action on the central nervous system, explains the use of certain compounds of aniline, such as acetaniline and preparations of phentodine, as temperature reducers. But, on the other hand, it is probably this same phenomenon which causes delayed oxidation with partial internal asphyxia and brings about collapse.

In all serious cases secondary phenomena affecting the central nervous system are due to internal asphyxia (dyspnöea, profound coma, cramps, etc.), and are associated with symptoms arising from direct action on the nervous system.

Experiments on animals have made it possible to determine the fatal doses of aniline: 0.1 to 0.2 grm. per kilo for cats; 0.5 grm. per kilo for dogs; and 1 to 2 grm. per kilo for rabbits, which possess a fairly vigorous resistance to the formation of methaemoglobin. Calculating from a fatality caused by a dose of 25 grm. of aniline, Fr. Mueller estimated the fatal dose for man at 0.3 grm. per kilo; but the dose would actually be smaller when the aniline is completely absorbed.

The local irritant action of aniline has been studied experimentally on the cornea and conjunctivae of frogs. This action has been also reported among men employed in using aniline black in dye works. However, it probably should not be attributed to the aniline itself, but to products of oxidation which occur during dyeing and are very irritating. Cases of irritation of the mucous membrane of the respiratory organs by aniline fumes are not known.

As regards individual susceptibility it is generally accepted that women are more sensitive than men to acute poisoning. However, this only seems probable with regard to withstanding chronic anaemia induced by aniline and other aromatic amines. It has
also been suggested that resistance to the poisoning is less among thin people, or those of poor constitution, but that susceptibility is particularly increased in the early stages of infectious diseases. Numerous experiments have established the fact that even moderate consumption of alcohol may cause aniline poisoning to flare up suddenly among workmen who are employed on nitro or amido aromatic derivatives, and that habitual use of alcohol lowers resistance to this poison. These phenomena are probably explained by the rapid setting free of small quantities of poison accumulated in the fat of the body, where it remains inert until set free.

The action of aniline and other aromatic bases on the mucous membrane of the bladder and urinary tract is quite characteristic. It is shown in serious cases by irritation of the mucous membrane of the bladder, by strangury and later by haematuria. These facts were first described by Grandhomme in 1877, and then noticed in the experimental poisoning of animals by naphthylamine. The worker who passes some years in contact with aniline or other aromatic bases sometimes contracts a chronic irritation of the bladder, or even benign (papillomata) or malignant (carcinomata) tumours of the bladder. It has not yet been possible to decide whether this irritation and these tumours are caused by the bases themselves, eliminated as such, or by certain products of assimilation formed by the introduction into the molecule of one or several oxhydro groups: amido-phenols and amidonaphthols. This last supposition seems probable; however, a strong irritant action on the bladder found particularly in acute cases (Stark, Friedlaender) is attributed to paratoluidine, which is eliminated generally without undergoing any change. This has not been observed only with the primary amines (aniline and its homologues, benzidine, toluidine, alpha- and beta-naphthylamine), but it has also been noticed with dimethyl-aniline. Probably it arises with quite a number of aromatic bases.

The sulphonic acids of the amines, which, as a matter of fact, are only toxic in a slight degree, do not seem to have any effect on the bladder. Experience does not permit of the admission that aniline and benzidine, contaminated with aniline, are alone able to cause diseases of the bladder as suggested by Nassauer. As a matter of fact beta-naphthylamine, even when not contaminated by other aromatic bases, is one of the most formidable causes of tumours. Similarly the true cause of aniline tumours cannot be attributed to the presence of arsenical compounds as impurities in the finished article (A. Hamilton), for this hypothesis is in contradiction with the fact that diseases of the bladder have not been found among men who work with nitro-derivatives, naphthols and the sulphonic amines. Accumulated experience shows that tumours appear among workmen who have been exposed for a fairly long time to the poison — three years at least — and that at the same time prolonged even very small quantities is sufficient to cause the disease. There is no need for there to have been any previous attack of acute poisoning or any reaction to toxic absorption, for apparently such manifestations do not play any part in the outbreak of the disease. Naphthylamines, for instance, never cause symptoms of toxic absorption.

There is not sufficient proof that absorption of fumes alone, and then even in the weakest concentrations, may cause diseases of the bladder, as Nassauer suggests. However, continued exposure to aromatic bases, or to their vapours, seems sufficient to cause these diseases. As a matter of fact, most of the cases have been observed in places where the following conditions were realised: melting rooms in factories which manufacture dyes derived from tri-phenylmethane, autoclave rooms in the works for intermediate products, workplaces for the manufacture of sulphonic acids by the kiln process. It must be borne in mind that tumours of the bladder may sometimes appear several years after the cessation of work.

From the toxicological point of view, other homologues of aniline which have a technical importance, and its basic derivatives, in particular the alkylated and arylated amines, act in a manner quite analogous. They all easily form methaemoglobin and also possess the other properties of aniline: it is noted especially that they exercise the same action on the nervous system, which in some cases is even more marked. Data are not available as to the relative toxicity of toluidine isomers of nitro-anilines and of alkyl substituted amines. Toluidines cause in vitro a
much stronger formation of methaemoglobin than does aniline. Serious cases of poisoning, with blood-stained urine, have been noted, caused by splashes of toluidine on the skin. The meta-derivatives are the most poisonous, the ortho-derivatives the least. Experiments carried out on animals corroborate the following results: they act on the central nervous system, and produce cyanosis although less marked. The comparative effect on haemoglobin undergoing change.

Aniline, its homologues and basic derivatives are very easily absorbed by the skin, for they are excellent lipid solvents. The intact skin constitutes then a very important path of entrance for acute industrial poisoning. Experience has shown that in factories most of the serious acute poisonings occur when the workers have had their clothing (or skin on the occasion of accidents with the apparatus) soiled by aniline. Such occurrences may be considered as typical of aniline poisoning.

The possibility of absorption by this channel is again shown by casual accidents due either to wearing boots dyed black with aniline, or to rubbing the skin with aniline by mistake.

Lewis, it is the meta-which is the most toxic for animals. The para- is the compound which in practice causes the greatest number of poisoning cases, of dermatitis, and of conjunctivitis.

Among the nitro-anilines, para-nitraniline, an important body in technical processes, is the most poisonous and seems to be considerably more so than aniline. The fatal dose for dogs is 0.3 grm. per kilo for ortho-, and is certainly smaller for para-nitraniline. According to Lewis, it is the meta-which is the most toxic for animals. The para- is the compound which in practice causes the greatest number of poisoning cases, of dermatitis, and of conjunctivitis.

The toxicity of alkylated and arylated amines resembles almost that of aniline. As has been seen above, elimination of aniline is carried out chiefly by the urine under the form of par amidophenolsulphonic acid (NH₂—C₆H₄—O—SO₂H). Some traces are, however, eliminated by the urine without transformation (Fr. Mueller, von Engelhardt, Frank, and Beyer); and some quite considerable quantities, representing up to 1 per cent. of the dose absorbed in twenty-four hours, are eliminated by the breath (Rambousek). The introduction of a hydroxyl group into the para-position, in place of the amido group, and the partial elimination in the form of the corresponding para-amidophenolsulphonic acid, or in the form of glycoroninic acid, have also been observed, or presumed, with certain homologues and derivatives of aniline. Para- toluidine and para-nitraniline are eliminated for the most part without undergoing change. The formation of methaemoglobin by these bodies is probably due to a reversible hydroxylation of the nitrogen atom with the formation of phenyl-hydroxylamine.

**Sources of Danger**

Aniline, its homologues and basic derivatives are very easily absorbed by the skin, for they are excellent lipid solvents. The intact skin constitutes then a very important path of entrance for acute industrial poisoning. Experience has shown that in factories most of the serious acute poisonings occur when the workers have had their clothing (or skin on the occasion of accidents with the apparatus) soiled by aniline. Such occurrences may be considered as typical of aniline poisoning.

The possibility of absorption by this channel is again shown by casual accidents due either to wearing boots dyed black with aniline, or to rubbing the skin with aniline by mistake. Lehmann was the first to show, by his experience on animals, the possibility of aniline being absorbed by the intact skin and that it may rapidly bring on fatal poisoning. This ease of penetration through the skin, which is explained by the high lipoid solvent power of aniline, is also found among its homologues and with all aniline derivatives, which also dissolve fats and especially with the alkyl substituted anilines. The sulphonic acids do not, however, possess this property.

In the second place as a cause of industrial poisoning, the absorption of aniline in the form of vapour by the respiratory passages must be considered. This applies also to the homologues and derivatives which are sufficiently volatile, but not to sulphonic acids. According to the experiments of Lehmann, the vapour pressure, which at certain times can exhibit aniline, is sufficient when it gives strengths of 1.2 grm. at 20° C. and of 0.9 at 15° C. per litre of air.

In the immediate vicinity of apparatus air may momentarily show such high percentages of aniline. These quantities are due to the volatility of aniline and many of its derivatives at high temperatures. Aniline vapours are particularly liberated in the manufacture of dyes from tri-phenylmethane when the melted mass still hot is withdrawn from the furnace. The same dangers occur in the manufacture of sulphonic acids by the furnace process and by the autoclave process, when the apparatus is insufficiently airtight. Then, again, in a series of operations account must be taken of the ease with which the compound is carried over by steam.

According to Lehmann and his pupils, man and animals can remain without perceptible effects for a quarter of an hour to half an hour in an atmosphere containing 0.3 mg. of aniline per litre of air. Larger quantities absorbed during a longer time bring on serious or fatal results both in men or animals.
ANILINE

With cats 0.64 to 0.36 mg. of aniline per litre of air inhaled over 4 to 6 hours causes death in 7 to 12 hours after the absorption; 1 to 2 mg. of aniline per litre of air cause death as soon as two to three hours after exposure. The experiments of Lehmann also show that part of the aniline present in the air can be absorbed by the skin. It is probable that in practice absorption of aniline from the air is greater than that which corresponds to absorption by the respiratory passages alone; for, given a certain strength of aniline in the air, account must also be taken of absorption by the skin of aniline vapour which has condensed either on the skin or on the clothes.

Generally speaking, however, aniline vapours rarely give rise to serious acute poisoning when attention has been paid to precautions for preventing their escape into places where industrial operations are carried on which are liable to set free these vapours, either momentarily or continuously. Among these operations must be placed first handling and washing the melted mass during the manufacture of dyes from tri-phenylmethane, the use of aniline and its homologues in the autoclave or furnace processes (see above).

Danger from aniline vapour is very much greater during hot weather, and especially when the day is close and stuffy. At these times, when the work is over, numerous cases are observed of slight cyanosis and acute or chronic symptoms of aniline poisoning. These disorders are probably caused by disturbances in ventilation due to atmospheric conditions and by the sweat which increases the absorbing power of the skin.

The absorption of aniline and its homologues and derivatives by the mouth and respiratory passages does not play an important part in industrial poisoning.

Speaking generally, it may be said that the preparation of aniline and its homologues causes much less occupational poisoning than their use and the subsequent manipulation which they undergo. At the present time the preparation of aniline is carried out almost exclusively in hermetically-closed apparatus in large works provided with every technical improvement and hygienic arrangement that can be desired.

When work is normal the men cannot come in contact with the finished product, within closed apparatus whence pipes carry it into reservoirs, or tanks on wheels (wagon-s-citernes), or take it straight into workrooms where it is immediately subjected to fresh changes. Removal of the iron residue which forms in the reducing vessels and cleaning it off these vessels, as well as drying and further utilising the residue (for example, in the manufacture of sulphate of iron), do not present any danger. As a matter of fact, pure steam is used to sweep out the aniline at the end of the reduction; the residue is then free from all trace of aniline, as well as the water which has condensed in the apparatus.

In these factories workmen can only be contaminated with aniline when unexpected accidents occur or during repair work. As a general rule liberation of aniline vapour, or of steam containing aniline, during the reduction or during the transport of the product can be avoided by constructing suitable apparatus and, if necessary, by using exhaust draughts. The same remarks apply to the purification of raw aniline by distillation in vacuo.

Numerous cases of severe poisoning occur during the preparation of the derivatives of aniline and its homologues when open vessels, in which the manipulations are effected, are accidentally upset. Further, the formation of aniline vapour and steam containing aniline cannot be avoided in many of these operations as completely and certainly as during reduction. Among the processes giving rise to these dangers, may be specially mentioned the extraction of "Retour-oil", that is, distillation carried out in apparatus which is insufficiently closed; the preparation of aniline salt in a trough open or only covered with a wooden lid which is not airtight; gathering, crushing and drying the salt; drawing the furnace of the hot mass in the preparation of phenylmethane dyes and their transformation into sulphonic acid; the preparation in an autoclave of the alkylated and arylated derivatives. It is in these industries, so it seems, that tumours of the bladder have been most often noticed.

Aniline has also caused acute poisoning fairly often in the rubber industry, where it is used in the extraction of raw rubber and as an accelerator in vulcanising, as well as in aniline-black dyeing, where it is used in the form of aniline salt. Cases of aniline poisoning have also been notified in the manufacture of synthetic indigo, for phenylglycine always contains unconverted aniline. These cases, acute or chronic, occur most often in the filtering and drying departments, and
during transportation. There must also be borne in mind dangers due to nitrous fumes and chloracetic acid, which causes very painful burns and serious desquamation of the hands.

STATISTICS

It is not always possible to give complete statistics of cases of poisoning by aniline, for very often these cases are classed with those due to other substances, such as benzene and nitro- and amido-derivatives, or they are grouped under the general term of nitro- and amido-derivatives.

However, it is possible to give the following statistics:

Austria. — Several cases of eczema by para-nitraniline were reported in a workshop for printing textiles; two cases of poisoning by aniline oil in a linen factory were reported during the period 1914-1916; nothing is known of para-nitraniline poisoning during 1919 and 1920.

In 1921 a worker employed in grinding colours in a paper-works was affected by slight poisoning by aniline; in 1922, as a set-off to this, several cases were reported in an aniline factory due to leaky apparatus.

Germany. — According to the figures collected by Lehmann (1906) for the period 1896 to 1904, 1,161 workers employed in a factory for aniline, nitro-benzene and by-products showed 41 cases of diseases of the nervous system, 6 of the circulatory system, 141 of the respiratory passages, 35 of the digestive organs, 144 cases of infection, 221 cases of various kinds of disease; 35 of burns, 136 of other external lesions, 75 cases of diseases of the locomotor apparatus, 233 cases of diseases of the skin.

The same authority declares that one case of aniline poisoning was reported in 1886-1887, 3 in the following year, 42 from 1891 to 1896, 10 from 1897 to 1898, 65 from 1899 to 1900 (including, however, cases due to nitro- and dinitro-benzene), and 17 from 1901 to 1904. Reports of factory inspectors for 1913 refer to 8 cases of aniline poisoning in Prussia, and 8 in Bavaria, whence cases of poisoning from para-nitraniline and para-chloraniline are also announced. In the State of Baden cases of dermatitis and conjunctivitis, due to safranine in an aniline works, are also mentioned during the year 1913.

Inspectors were only aware from 1914 to 1918 of cases of tumour due to aniline and its homologues (see tumours caused by occupation). In 1919 cases of poisoning were notified in Prussia, one of which was caused by bromaniline; some slight cases have also been notified at Hanover in a rubber factory, due to aniline oil which may also have caused poisoning in a railway-carriage works, for aniline oil is the principal constituent in the red colour used for colouring wood. In Hesse 2 cases have been notified caused by para-nitraniline. In Bavaria 2 cases only have been reported caused by nitro- and amido-derivatives (see article "Tumours").

In 1920, of 17 cases of aniline poisoning reported in the Wiesbaden district, most were due to nitrochlorobenzene. In 1921 a dozen slight cases observed in a chemical products factory in the Saar likewise occurred, chiefly among workmen employed in the production of para-nitraniline; 29 cases were notified in Baden; most of these, however, except those in which the bladder was involved. In the following year 38 cases of aniline poisoning occurred in the same district, among the workmen of two factories; only caused by splashing of liquid chloraniline, had a fatal issue. Ten cases of dermatitis and eczema have been reported among workmen employed in aniline dyes and dinitrochlorobenzene. In Bavaria several cases of dermatitis have also been notified caused by safranine, violanthene, and chlorbenzanthrene. This last also shows a pronounced sensibility to light. In 1922 some 117 cases were due to para-nitraniline were reported.

Great Britain. — The reports of the Chief Medical Inspector of Factories mention 18 cases of poisoning by nitro- and amido-derivatives in 1910 (aniline poisoning, 1; dermatitis, due particularly to dinitrochlorobenzene, 17); 21 in 1911 (aniline poisoning, 18; dermatitis due to dinitrochlorobenzene, 3); 9 in 1912 (aniline poisoning, 4, of which 1 was fatal; dermatitis, 5); 8 in 1913; 38 in 1914 (aniline poisoning, 32, of which 2 were fatal; dermatitis, 6); 4 (2 of which were fatal) in 1917; 7 in 1918 (of which 4 were fatal). In 1919 1 case of a worker suffering from aniline poisoning was reported. An enquiry made in 1921 by Dr. Henry in 23 dyeworks using aniline black, where there is double risk from aniline dyes and dinitrochlorobenzene, from chrome ulcerations, emphasises the fact that, from the hygienic point of view, the most important operation is that of "ageing", which precedes chroming. The exact chemical reactions which take place in the ageing chamber, or ager, in the oxidising process are not known, but it is certain that there is a liberation of aniline fumes. Further, chlorine may be formed. In the same way in the steam process, the chemical reactions are very complex and it is very difficult to avoid the liberation of steam which carries with it aniline vapour.

In addition, the ager has to be periodically cleaned.

A clinical examination undertaken by Dr. Williamson of 39 aniline black dyers and 3 aniline makers, enabled him to report a distinct diminution in the percentage of haemoglobin, or in the number of red cells. There was also a diminution in the white cells, with a relative increase of the lymphocytes. The examination showed further a lower colour index, and an alteration, in certain cases, in the blood pigment. These changes, but more marked, were observed in the urine of the aniline makers. Signs of slight absorption were noticed by Dr. Henry in 17 workers
and more serious in 14 making 46 per cent. of those examined; pallor in 31 cases; anaemia was noted in 14, or 21 per cent.; cyanosis in 12, or 18 per cent.; and tremor in 6, or 9 per cent. In some cases the workers complained of headaches, vertigo, and loss of appetite. As regards the frequency of symptoms, according to processes, the following returns were made: dry agers, 83.3 per cent.; impregnators, 68.6 per cent.; mixers, 40 per cent.; dryers, 40 per cent.; steam agers, 20 per cent.; skin dyers, 10 per cent. In this same year 4 cases are mentioned as affecting three workers and a chemist employed in sieving para-nitraniline.

In 1924, 24 cases of aniline poisoning were notified, and in 1925 (the first year of compulsory notification of cases of aniline poisoning) 31 cases.

Prosser White reports that in a factory for weaving coloured cloth about 30 persons were affected with serious eruptions accompanied by itching of the face, neck and hands (the interdigital spaces), etc., due probably to indigo blue.

Netherlands. — In 1914 a case of aniline poisoning was notified in a brush factory. It was attributed to handling vegetable fibres dyed with aniline. In 1916, two cases were reported by the factory inspectorate, of which one was a chemist and the other a weaver; two cases were also notified in 1917, one of which was a workman employed at an aniline boiler and the other in weaving, where the work consisted in using aniline as a mordant. In 1919 two cases of aniline poisoning were reported, and in 1920 one case affecting a negro employed as a laboratory boy, who had upset twenty litres of aniline oil and, although warned of the danger, had not taken the precaution of changing his soiled clothes after having cleaned the place where the aniline was upset.

Switzerland. — The cases of poisoning by aniline and other aromatic bases numbered 2 in 1911, 8 in 1912, and 2 in 1917; 5 cases of aniline poisoning and 1 case of para-nitraniline poisoning in 1919; 7 in 1920; 2 of aniline poisoning and 1 of dermatitis in 1921; 8 cases of chronic aniline poisoning in 1922; 3 acute, 5 chronic and 6 cases of dermatitis in 1923; 5 acute, 7 chronic, and 5 of dermatitis in 1924; 10 chronic cases and 6 cases of dermatitis in 1925.

United States. — In the State of Ohio, prior to the Act of 4 August 1921, 71 cases of aniline poisoning were known; from 1 July 1920 to 30 June 1925, 33 cases were notified; 11 cases had been caused by para-nitraniline, 3 by paratoluidine, and 1 by xylidine. In the State of New Jersey, 23 cases of aniline poisoning were notified in 1917 and 23 in 1920.

A doctor attached to a factory where the workmen manipulate great quantities of diethyl-aniline treated several cases of poisoning by this substance which caused the same symptoms as aniline. A case caused by meta-nitraniline is reported by Hamilton. It concerned a workman who had been cleaning an apparatus which contained meta-nitraniline. The chief symptoms were vomiting, headaches, pronounced cyanosis, and loss of consciousness. Another case is reported in the returns of the Labour Department of New York.

Cases of poisoning by ortho- and para-toluidine seem to be fairly frequent (Hamilton), but more precise figures are not available. Hamilton mentions also 2 cases of serious poisoning by 'dimethyl-aniline observed in 1916 in a dyeworks where the workers came in contact, one with liquid aniline and the other with fumes of aniline coming from a vat full of violet dye prepared from dimethyl-aniline, phenol, and other substances.

**Symptoms**

**Acute Poisoning**

The clinical picture of acute aniline poisoning is characterised by the action of aniline and its derivatives on the blood and particularly on the haemoglobin. The earliest symptom — which is often noticed before the actual appearance of subjective disorders accompanying the poisoning — is pronounced cyanosis, which is known by a bluish-grey colouration of the skin, which at the onset is particularly noticeable at the extremity of the nose, ears, cheeks, and nails. It is distinguished from cyanosis due to lack of oxygen, especially in an advanced stage, by a more marked bluish-grey produced by the transformation of haemoglobin into methaemoglobin which makes the blood of a brownish colour.

As regards the nervous system, a state of slight excitement, analogous to drunkenness, first appears, combined with a certain feeling of physical fitness, which gives a false sensation of wellbeing. These are the only symptoms observed in slight cases of aniline poisoning, and they disappear completely in a few hours or in a night. In serious cases the cyanosis increases rapidly. The diffuse dark bluish-grey colour of the skin and particularly of the mucous membranes, makes a great impression on persons who are not used to these symptoms and contrasts, at this period, with the absence of other symptoms characteristic of serious poisoning. The blood takes a brown colour and may even become black as tar.

Instead of the symptoms of excitement observed at the onset in the case of the nervous system, signs of paralysis are noticed at this phase of the poisoning: fatigue, somnolence, weakness, vertigo, sometimes with vomiting and headache. Paraesthesias — a sensation of numb-
ness in the extremities — singing in the ears, and dimming of the field of vision are also observed. The follow-
total loss of consciousness and coma, together with contraction, and then dilatation and paralysis of the reaction of the pupils. At this stage are also noticed symptoms of internal asphyxia, a sign of progressive formation of methaemoglobin: dyspnœa, then slow and irregular respiration and cramps.

According to the statements of some writers, the blood pressure is increased at the beginning, the action of the heart is stronger and quickened, then, in the place of vaso-motor excitement, paralysis appears accompanied by the following symptoms: diminution of the blood pressure, feeble pulse, moist and cold skin, collapse. In serious cases the temperature of the body is greatly and rapidly diminished. Next is observed, especially in fatal cases, a very low temperature characteristic of collapse.

In acute poisoning death takes place during profound coma; it is caused by central paralysis accompanied sometimes by cramp and dyspnœa. In non-fatal cases recovery is often very rapid, even when the symptoms have been very severe. Notably cyanosis with methaemoglobin disappears very rapidly and completely — often during the first twenty-four hours in slight poisonings, and in a few days in the serious cases. This disappearance is much more rapid than in poisoning by nitro-derivatives of the aromatic series, probably because aniline becomes changed more quickly into hydroxylated products capable of being eliminated by the urine. In slight cases the disappearance of the methaemoglobin takes place rapidly and brings about a complete cure. In serious cases, quite often in the first days of the poisoning, strangury occurs and the urine is slightly blood-stained. The urine is dark, brownish (approaching green); it becomes much darker when its alkalinity is increased and then resembles carabolic urine.

In serious poisoning, even when not accompanied by haematuria, not only does the urine contain haemoglobin and methaemoglobin, which can be detected either chemically or spectroscopically, or yet by the microscope in the form of drops of Boström, but there is present a yellow colouring material derived from the decomposition of red blood cells. In a few days the number of these cells diminishes considerably. Secondary anaemia shows itself; it is accompanied by a diminution of the colour index and a regeneration of the red blood cells with formation of normal cells or giant cells with nuclei. The jaundice is slight and momentary: it is less pronounced and less frequent than in poisoning by the aromatic nitro-derivatives. Complete recovery may be much retarded by the secondary anaemia.

Chronic poisoning by aniline is caused by prolonged absorption of small quantities of poison and is generally due to the accumulation of the haemolytic effects of aniline. In addition to this action a chronic action of aniline on the nervous system may also be noticed, chiefly characterised by a slight secondary anaemia. The colour index of the blood and the number of red cells are diminished; microscopical examination, however, rarely shows regenerative changes, that is to say, no indications are found of a return to an embryonic state of erythropoiesis. But it is possible to find young red blood cells containing colourable granulo-flamentous substance, fresh or as a polychromatic substance (dry colouring) (Biondi). In the same way, contrary to what occurs in chronic occupational aniline poisoning where benzene and dinitrobenzenes are handled, jaundice is almost always absent. Cyanosis does not come into the clinical picture of this chronic poisoning by aniline and is only seen momentarily as long as the worker continues at work. Curschmann also mentions as a symptom of chronic aniline poisoning an increase in blood pressure. Among the troubles caused by the secondary anaemia, subjective symptoms must be noticed, such as loss of appetite, digestive troubles, feeling of weakness and fatigue, tendency to giddiness and headaches, and, in serious cases, disorders of locomotion and of sensation.

Diseases of the bladder, which have been mentioned above, are a late sequela of prolonged contact, over several years, of the worker with aniline or other aromatic bases. They may appear several years after cessation of work, and in three distinct forms; these forms, however, only constitute different stages of the affection of the bladder, which terminate by degenerating into malignancy. These three stages are as follows: (1) simple recurring haemorrhagic cystitis; (2) benign papilloma, which is often a multiple papillomatous condition of the bladder; (3) malignant tumours of the bladder (carcinoma).

Haemorrhagic cystitis which is frequently the cause of severe haemor-

— 127 —
blood through the mucous membrane of the bladder, with formation of haemorrhage, for varying as to size from that of a pin's head to that of a coin. They are localised to the region of the openings of the ureters and the trigone. Cure may be quite rapid. Papillomata also are situated as a rule in the vicinity of the trigone. They show a very strong tendency to recur. Malignant tumours of the bladder, which have no particular localisation, are fairly often the sequelae of recurrent papillomata; but they may be primary tumours. Up to the present the formation of tumours in the upper urinary tract (the calyces and ureters) has only been rarely noted. Recurrent papillomata; but they may show a very strong tendency to recur. Papillomata also are situated as a rule of the openings of the ureters and the bladder, haemorrhagic foci varying as to size from that of a pin's head to that of a coin. Symptoms typical of aniline poisoning. By Jacquemin, Letherby, Cromer, and Gautier, or Maquenne, containing 10 c.c. of distilled water, or, better, of a weak solution of sulphuric acid. A volume of 10 litres or less of air should be drawn through.

For qualitative analysis the liquid from the absorption tube is poured into a small distilling apparatus and water from washing the same, absorbent tube is added. If acidulated water has been used, it must be rendered alkaline by adding some drops of potash or soda lye. The alkali sets aniline free from its combination with sulphuric acid. After distillation about 1 c.c. of the liquid is collected, which includes almost all the aniline contained in the retort. The small volume of liquid obtained is submitted to qualitative tests.

Among the different reactions proposed by Jacquemin, Letherby, Cromer, and others, the most practical for use in industrial hygiene seems to be that of chloride of lime. This consists in adding to the liquid for analysis some drops of an aqueous concentrated, and fresh solution of chloride of lime. A violet coloration is obtained more or less deep according to the proportion of aniline.

For quantitative analysis it is an advantage to estimate the aniline vapours, if they are in any considerable quantity, in the air by the method of weighing. Hebert and Heim de Basil have employed the following method: fix the aniline in an absorbing tube by a weak solution of sulphuric acid (0 per cent. empty into a beaker and add the washing water; estimate the aniline in the fixing liquid by bromine water which precipitates it in the form of bromobenzidine which is almost insoluble (1 part in 69,000 parts of water); collect the precipitate on a weighed filter paper; weigh again after cold drying under a bell jar, which a vacuum is maintained, in order to avoid decomposition by heat. The weight of tribromaniline obtained allows the weight of aniline, from which the tribromaniline has been derived, to be calculated, knowing that 1 part of tribromaniline corresponds to 0.28 parts of aniline by weight. Toluidines also give a precipitate with bromine water; but this precipitate is comparatively soluble (1 part in 6,450 parts of water), so no considerable error in the results follows, the more so since the proportion of toluidine in the air of workshops is always small.

In the urine. — Paramidophenol is easily detected in the urine by saponifying sulphuric acid which has been combined by heating with dilute hydrochloric acid. To obtain this, the urine is acidulated with hydrochloric acid and chloride of iron are added, and then ammonia; this produces a deep blue coloration. It can also be diazotised while cold by means of nitric acid and coupled with alpha-naphthol in weak sodium solution; the reaction produces a dark red coloration.

Search for paramidophenol in urine can also be easily made by using nitric colour reactions.

Detection of aniline in organic materials is carried out by various methods. According to that of Oliver and Bargeron, the materials to be analysed are heated with sulphuric and arsenic acids; in this way aniline is transformed into fuchsin (sulphate of rosiniline). The residue is treated with alcohol, precipitated by acetate of lead, filtered, the excess of acetate of lead is eliminated by the addition of dissolved sulphate of sodium and filtered again; the solution is then rendered alkaline by potash and distilled in an oil bath; the distilled product contains free aniline, which is transformed into sulphate. Searches delicate reactions enable the sulphate to be distinguished.

It must, however, be borne in mind that commercial aniline is almost always mixed with the higher homologous products (toluidines) the presence of which modifies the colour reactions of the aniline itself.

**ANILINE**

**DETECTION**

**In the air.** — Fixation of aniline vapours is easily obtained by passing air, at the rate of 1-2 bubbles a second, through an absorption tube of the pattern of Liebig, or Gautier, or Maquenne, containing 10 c.c. of distilled water, or, better, of a weak solution of sulphuric acid. A volume of 10 litres or less of air should be drawn through.

For qualitative analysis the liquid from the absorption tube is poured into a small distilling apparatus and water from washing the same, absorbent tube is added. If acidulated water has been used, it must be rendered alkaline by adding some drops of potash or soda lye. The alkali sets aniline free from its combination with sulphuric acid. After distillation about 1 c.c. of the liquid is collected, which includes almost all the aniline contained in the retort. The small volume of liquid obtained is submitted to qualitative tests.

Among the different reactions proposed by Jacquemin, Letherby, Cromer, and others, the most practical for use in industrial hygiene seems to be that of chloride of lime. This consists in adding to the liquid for analysis some drops of an aqueous concentrated, and fresh solution of chloride of lime. A violet coloration is obtained more or less deep according to the proportion of aniline.

For quantitative analysis it is an advantage to estimate the aniline vapours, if
HYGIENE

The most important point in preventing ill-effects from aniline and its homologues lies in the construction of apparatus and the use of adequate procedures of manufacture. By reason of the facility with which these substances penetrate the intact skin and are absorbed by inhalation it is necessary to avoid, as far as possible, all contact with the raw materials, as well as the liberation of aniline vapour or of steam containing aniline. Hermetically-closed apparatus must therefore be used, and transport of the liquids must be effected through closed channels. Whenever possible transfer from one vessel to another should be effected by the aid of compressed air or by vacuum. Liberation of vapours containing aniline should be avoided by condensing, or absorbing them, or evacuating them by exhaust draught. This elimination should be done at the actual place where the vapours are formed, for instance, at the outlet of the furnaces in the preparation of triphenylmethane.

In the same way all vats, receptacles, or other open apparatus used in the industry of dyestuffs must be supplied with covers.

Natural change of air in the workshops must be assured as far as possible by suitable construction of the building and by well-arranged windows and skylights. Artificial ventilation may even be required.

It is indispensable that floors be kept clean, especially in factories where aniline is converted and prepare by-products. As a matter of fact, the handling of liquid by-products, and particularly of solid products (breaking up) in the vats for reducing and grinding, is a cause of uncleanliness. The floor must not be of asphalt or tarred, for it would then absorb aniline and other aromatic amines.

Personal prophylaxis is also very important. Working clothes should be changed often and regularly. Cleanliness must be scrupulously attended to; baths must be taken at regular intervals. Workers must be warned of the poisonous nature of the substance handled, of the danger arising from dirty clothing and the necessity of immediately changing clothes which are too soiled, and of the special risks which attend the taking of alcohol. It is of the greatest importance to exercise regular medical supervision so as to keep oxygen in reserve for treating cases of poisoning as quickly as possible (see below, "Legislation").

In order to prevent diseases of the bladder a very rapid change-round of workers has been prescribed and regular analyses of urine, so as to discover haemorrhages early. This last measure is not really of great prophylactic interest, but it makes it possible for the worker who is already ill to receive surgical treatment as early as possible.

LEGISLATION

As regards the work of women and young persons see articles Chemical Trades, Benzene, Nitrobenzene, Trinitrotoluene, etc.

Medical examination on engagement is provided for by British and German legislation (during the first fortnight following engagement) and periodical monthly examination is laid down in Great Britain and Germany.

A circular of the Minister of Commerce and Industry of Prussia, dated 21 October 1911, on the setting up and working of the manufacture of nitro- and amido-compounds contains some very interesting measures, applicable also to factories which make other reactive benzols, toluols, xylols, nitrated once or several times, and their chlorine compounds, the naphthalenes nitrated once or several times, the phenols and naphthols nitrated once or several times, aniline and its homologues (toluidine, xyline, cumidine), anisidine, phenetidine and their compounds with chlorine, nitre, alkyl and aryl, phenylendiamine, tolylen diamine, benzidine, diaminidine, phenylhydrizane, etc., the manufacture of fuchsin, blues and blacks, etc.

The workplaces must be lofty, very airy and capacious. Buildings arranged in floors are not recommended; the construction of platforms is admissible provided there is a free space of at least three metres between them, and that there is reserved between these platforms and the walls a free space of from 50 cm. to a metre. No platform must be situated above melting boilers or distilling apparatus, except where there are special appliances for preventing the liberation of gas or vapour.

The floor must be impermeable, well levelled, easy to clean with a suitable slope to a drain channel. Floors made of stone flags, or tiles set in cement, are very good and easy to keep in order, but the tiles should not have any deep grooves. Concrete has not always given satisfactory results; above all it must not be porous and must present a smooth surface. It is affected by acids and hot liquids. Factories which work with acids use flags of sandstone impregnated with tar and fill up the joints with asphalt. This type of floor offers very great resistance to acids, but it is not suitable for departments of nitro- and amido-compounds, for they combine with tar and asphalt.

The walls must be covered, with a
wastable coating or whitewashed. In that case the whitewashing must be done once a year.

If compounds of the benzene or napthalene series, nitrated two or three times, are produced in the factory, the building must be constructed of incombustible materials, for in case of fire, sudden decomposition of highly nitrated compounds may occur.

The operations should be controlled and the work managed in such a way that the workmen come in contact as little as possible with nitro- and amido-compounds. When they are in liquid form, they should as far as possible be conveyed in closed channels (by means of pumps, extractors or compressors); if they are in a soluble form, or in form of dust, they should be transported, poured from one vessel to another, or drawn off by means of mechanical apparatus or exhaust.

Aqueous solutions of phenylendiamine and toluyldiamine are also both very toxic, and dilute solutions may act on the skin. Hence the same precautions must be taken for these solutions as for the products themselves.

Air used for compression, as well as for exhaust, always contains a little aniline in the form of liquid (droplets) or vapour; for this reason this air should be conducted above the roof, and, if possible, purified to avoid any risk for the neighbourhood.

Liquid or solid compounds must be kept in closed receptacles (liquids) or covered containers (solids).

Operations which liberate vapours, dust or gas, and in particular those of crushing, sifting and packing, must, if possible, be done in a closed apparatus with localised exhaust. The receptacles used for collecting distillation products must be kept constantly closed. In order to avoid blocking, the pipes must be surrounded with a steam jacket or heated in some other way.

Evacuation should be so provided as to avoid any danger of vapours escaping at the moment of opening, or drawing, or filling (compression), drying chambers, melting boilers, autoclaves, and other receptacles under compression.

Solid products, melting at a temperature which is not very high, should be collected by distillation, etc., in closed receptacles connected to an exhaust apparatus and heated by steam. On passing out of these receptacles, they are poured while in the liquid state into small moulds, or on to cooled cylinders. Special arrangements should prevent the escape of vapours during these operations. But the withdrawal of cooled materials from the receptacles where they have been collected is always dangerous. Drying must be done in hermetically-closed apparatus with efficient exhaust draught.

Experience has shown that it is advisable to use over again the compressed air, which is charged with dust or gas, in such a way that it forms a closed circuit, and thus avoid having to purify it specially.

Dryers must be emptied after complete cooling, and during the emptying exhaust draught must be in constant use.

Absolute cleanliness of workplaces must be preserved, and traces of products upset or scattered about. Nitro- and amido-products should be taken up by sprinkling with sawdust, which is then swept up. It is best to burn the sawdust in small quantities. Substances in the form of dust can be advantageously taken up by aspiration by means of vacuum abstractors.

Workers should be taught the danger to which their work exposes them; and reminded that immoderate use of alcohol is always very dangerous even outside working hours.

Provision for personal hygiene is needed, as for all unhealthy industries, such as provision of overalls, footwear, lavatories, douche, baths, cloakrooms, etc. Overalls, shoes, or glides impregnated with nitro- or amido-compounds, or soiled in such a manner that the skin is in direct contact with these compounds, must be immediately removed.

Repairs of receptacles, pipes, etc., must only be done after thorough cleaning. Every possible precaution must be taken to avoid poisoning, which is too often fatal, by nitro- or amido-compounds, carbides of hydrogen, gases or vapours of these compounds, or by acid and ammoniacal gases or fumes.

The work should always be carried out under the constant supervision of a responsible person, instructed in his duties and not engaged in the actual work. After having removed, if possible, the covers and stirring appliances, the apparatus, before anyone enters it, should be subjected to boiling, or filled with water, or freed from all noxious gases by blowing air through or by exhaust draught. If these precautions cannot be carried out, the workers should be supplied with respiratory apparatus, and care should be taken that the air sent into the helmet is fresh and is delivered in a regular manner.

If it is not possible to open the covers, or if it is only possible to open them partly, the workers should have a rope attached to them; they must not remain in the apparatus more than ten consecutive minutes the first time, and they should only re-enter after a rest of at least an equal period. Pure air should be constantly blown in during the stay of the worker in the apparatus. After finishing work, the worker should take a bath or a douche, and change his clothes and shoes.

In Great Britain the second part of Regulations No. 731, dated 11 July 1922, relating to the manufacture of chemical products, applies also to factories or parts of factories in which work on nitro- or amido-compounds is done. It provides means for avoiding, as far as possible, liberation of dust or of vapours during the crushing of crystalline substances, or the stirring of solutions by hand; the installation of drying chambers provided
with brisk ventilation; the entrance of workers into drying chambers only after a current of fresh air has been introduced. Every receptacle in which nitro- or amido-derivatives, benzene or phenol, or their homologues are subjected to the action of steam must be closed, the object being to prevent the escape of steam or vapours into any workroom; efficient exhaust draught is required for dust or vapour, as well as during grinding, crushing or mixing, etc., of nitro- or amido-compounds. These operations ought to be done in separate places where the floor must be of cement or other smooth impermeable and incombustible material, which must be cleaned daily.

The Regulations further provide for placing at the disposal of workers, and keeping in repair, overalls or suitable and sufficient working clothes and suitable boots. The clothes must be washed, cleaned, or renewed at least once a week. Persons for whom overalls or working garments must be provided shall have the use of a suitable cloakroom and a mess-room separate from the cloakroom, which shall be in the charge of a responsible person. These installations must be kept in a clean condition, well aired, and heated in cold weather. Further, these workers shall have at their disposal lavatories with soap and nail brushes, and an installation of douche or other baths, with hot and tepid water, soap, and towels in sufficient quantity. A bath register must be kept, where the date on which each person takes his bath must be recorded.

Poisoning by aniline and its homologues is compulsorily notifiable in France, Great Britain, the Netherlands, and Russia, and compensation is provided in Finland, Western Australia, British Columbia, Great Britain, and Switzerland. But it must be noted that compensation and notification are in certain countries laid down under the heading of "nitro- and amido-derivatives of benzene and homologues"; it is so as regards notification in Bavaria, France, Russia, and the Netherlands, and as regards compensation in Germany, Western Australia, British Columbia, Great Britain, the States of Minnesota, New York and Ohio, and Switzerland, Finland and Queensland.

### Anisidines

These organic bases [formula, \( \text{C}_6\text{H}_4\text{NO}_2\text{H} \) (NH₂) (OCH₃)], derivatives of metallic ethers, of the nitrophenols or nitroanisols (see article "Phenols"), have three isomers, of which the ortho and para, and their salts, are used in making artificial colours.

Among the derivatives of the anisidines mention should be made of the *nitro-anisidines* [formula, \( \text{C}_6\text{H}_4\text{NO}_2\text{H} \) (NH₂) (OCH₃)], obtained by nitrating acetyl-anisidine. They are solid substances of which the para product is used in textile printing, the preparation of reds and pinks on beta naphthol.

Dianisidine is obtained by a process analogous to that employed in the preparation of benzidine (see that article), but starting with nitro-anisol (ortho). It occurs in the form of violet crystals (in the air), insoluble in water. The hydrochloride, soluble, on the contrary, in water, is used to prepareazo colours. The dianisidines are to-day very largely used in the preparation of direct dyes for cotton.

Dianisidine, which is a dioxymethyl benzidine, has an action analogous to that of benzidine (see that article).

Lauenberger classes this substance among those that can produce tumours of the bladder in aniline workers (see article "Aniline").

Dianisidine figures in the Swiss list of substances for which compensation as for an accident can be claimed.

***

**Ankylostomiasis or Hookworm Disease**

The presence of the ankylostoma in the human intestine is described as ankylostomiasis. The infection due to this parasite ought rather to be described as "ankylostom-anaemia", but it is known under the most varied terms in different countries; the anaemia or chlorosis of Egypt, miners' anaemia, brickmakers' anaemia, etc. (see also p. 134: DANGERS AND STATISTICS). The term "uncinariasis" is also often used.

**THE PATHOGENIC AGENT**

There are two kinds of ankylostoma: *A. duodenale*, or European, and *A. Americanum* or *Uncinaria Americana* or *Necator Americanus* — both of them being nematoda of the genus *Strongylidae*.

Among the different species of *Necator* the following should be remembered: *N. Americanus*, originating from the gorilla and spread over tropical and sub-tropical regions; *N. caecidens*, a parasite of the chimpanzee (Africa); *N. Congoensis*, also a
parasite of the chimpanzee (Belgian Congo); and *N. suisius*, parasitic in the pig (Island of Trinidad, where the infected pigs vary from 60 to 100 per cent., with a quite special symptomatology). Curiously enough, experiments made to infect the pigs with *N. Americanus* have so far proved negative. *A. duodenale*, discovered in 1838 by Dubini, and studied especially by Perroncito and Raillet, is a pale flesh-coloured red worm, cylindrical, sexual; the male measures 8·10 mm. in length and 0·46 mm. in breadth, the female respectively 10·16 mm. and 0·95 mm.

The mouth, a real cupping glass with a chitinous armature, has two pairs of curved hook-like teeth on the ventral aspect and two small dorsal teeth which are the rounded edges of the "dorsal gap" of the chitinous capsule. The canals of two cephalic glands open into the buccal cavity. The oesophagus dilates into a muscular stomach and ends in a lateral anal orifice. The vulva is situated at the posterior third while the seminiferous tubules end in two spicules. This unusual arrangement explains the Y form assumed by the worms during copulation, the short end of the Y being represented by the male.

In the small intestine of its host the adult female lays her eggs, which scarce develop at all in the intestinal canal owing to lack of oxygen and do not develop until they have been expelled with the faeces and so reach appropriate surroundings (heat, humidity, relative darkness).

The two kinds of *ankylostoma* have the same life history, cause the same pathological troubles, and differ only in certain morphological characteristics, of which the most important are the following: the head of *uncinaria* is narrower than that of *ankylostoma* and is always bent dorsally. The buccal capsule is smaller. While *ankylostoma* shows two pairs of strong teeth curved downwards, *uncinaria* has only two cutting chitinous plates terminating in two large spines pointing towards the cephalic apex and a conical tooth projecting from the bottom of the buccal capsule towards the dorsal side far into the lumen. The bursa copulatrix opening is larger than in *ankylostoma* and the sides are of a more sober colour; the vulval opening in the female is in the middle of the body, while in *ankylostoma* it is at the posterior third. (For eva, see Diagnosis, p. 140.)

The complete cycle of the *ankylostoma* comprises, as in the case of all nematoda, three main or stages. During the 24 hours following its arrival in suitable surroundings, the ovum undergoes segmentation and develops, more or less rapidly according to the temperature, into an embryo or larva which pierces the shell of the egg, and escapes in the form of a rhabditiform larva (bulba oesophagus) (measuring 250 microns). After three days the first moult (larva of 300 microns) occurs and two days later the larva, which measures 480 microns, loses its oesophageal bulb and assumes the strongyloid or filiform appearance. In the second phase the strongyloid larva, measuring 560 microns, undergoes the second moult, in which a cyst is formed around the larva. It finds itself then protected and more able to resist forces in its surroundings likely to injure it. This is the stage at which it is ready to enter man. The *ankylostoma* cannot attach itself or develop in man except when in the larval condition. At this third stage the larva has not yet acquired a buccal capsule; after five days comes the third moult. Then follows the fourth phase: the larva has a provisional buccal capsule and on the fourteenth day occurs the fourth moult. In the fifth and last phase the larva has a definite buccal capsule, and in 21-28 days the adult form is reached with coupling of the two sexes and reproduction of the cycle.

The cycle can be sketched as follows: Human infection — contagion of the surrounding favourable ground — infection of the ground — man — human infection.

1 According to Wilson G. Smillie, who based his data on the studies of Clayton Lane, the microscopic differentiation between the two parasites can be made from the following characteristics:

**Ankylostoma duodenale**

*Female*

- **Length:** a little longer than *Necator* and much larger.
- **Form:** assumes always a position reminiscent of the letter "C" more or less accentuated.
- **Posterior extremity:** ends in a large and blunt point.
- **Colour:** white, sometimes a black spot near the oesophagus. Very frequently the fresh blood can be seen through the body of the worm.
- **Resistance:** analogous to that of cartilage (under a dissecting needle).

**Additional characteristics:** apply also to the male, for which, however, the following additional characteristics must also be borne in mind:

**Ankylostoma duodenale**

*Male*

- **Length:** longer than *Necator*; diagnosis can generally be made on this point alone.
- **Form:** very like a nail; sometimes slightly curved like the letter "C".
- **Posterior extremity:** terminates in an open fan-shaped bursa.

**Necator Americanus**

*Female*

- **Length:** rather shorter and thinner than *A. duodenale*.
- **Form:** assumes the form of an "S".
- **Colour:** white, sometimes a black spot near the oesophagus. Very frequently the fresh blood can be seen through the body of the worm.
- **Resistance:** analogous to that of cartilage (under a dissecting needle).

**Additional characteristics:**

*Male*

- **Length:** much smaller than *A. duodenale*.
- **Form:** always in the form of an "S" with the characteristic dorsal curvature at the cephalic extremity.
- **Colour:** white, sometimes a black spot near the oesophagus. Very frequently the fresh blood can be seen through the body of the worm.

**Pathological characteristics:**

- **Marked brownish colour; the red colour of the blood is hardly ever visible through the body.**
- **Soft worm (under dissecting needle).**
- **Always in the form of an "S" with the characteristic dorsal curvature at the cephalic extremity.**
- **Terminates in a closed bursa like the bud of a flower.**
From the arrival of the ovum outside the organism to the laying of eggs by the females in the human intestine, the cycle lasts from 45 to 56 days, i.e. 5-7 days outside the body and the rest inside.

The ova are killed by a temperature of 5° C., but show prolonged resistance to chemical agents. They do not develop in water, a temperature of 18° C. being needed. The temperature most favourable to their development is 25-30° C. The larvae also show considerable powers of resistance. Ova and larvae are easily killed by the sun, dryness, or frost; on the other hand, chemical disinfectants have only slight action in the conditions under which it is practical to apply them. Formalin notably is without action (see further under PROPHYLAXIS, p. 141).

In the organism the larvae resist the action of the gastric juice.

The larvae are reported to be able to migrate vertically in the ground; under certain conditions they come to the surface even if they have been buried with infected faeces at a depth of 90 cm. to 1 metre. Transmission of the larvae is not effected solely by the earth, mud, water, etc., but also indirectly by insects, flies, etc., which are said to be, however, only intermediate and purely accidental hosts acting as simple agents of transmission (Italy, Japan). The pig is also said to be the intermediate host for the dissemination of ova of ankylostoma (Trinidad), but apparently of a distinct species, the Necator suis (Rockefeller Commission Enquiry, John Hopkins University, 1922). Having reached the skin, the larva throws off its cyst and penetrates as far as the lymphatic spaces along the sheaths of the hair follicles, even if the skin is intact, but more easily if this is broken. The irritation set up by the larva favours its penetration. In 30 to 40 minutes the larva penetrates the skin and reaches the bloodstream. By way of the veins it passes into the right side of the heart and so passing through the pulmonary circulation it arrives at the alveoli; it ascends the respiratory tract as far as the trachea and descends from there along the oesophagus to the alimentary canal. Probably associated with this route, sufficiently complicated but definitely proved, there is another shorter and surer path followed by the larva from the skin to the small intestine where it attaches itself.

At all events, during this transit, the larva develops very little; it
arrives at sexual maturity only when it reaches the intestine, where the cycle recommences.

The parasites in the human intestine can number several thousands (from 4,000 to 6,000; apparently 2,000 is the average figure in warm countries). Some writers, Italian especially, assert, however, that they have not found more than an average of 200 and even numbers considerably less (from 12 to 14).

The life of the adult parasite in the intestine is limited: if new infections do not occur the ova cannot develop in the digestive tract and the worm dies (spontaneous cure).

DANGERS AND STATISTICS

The problem is a world-wide one — the menace of an obstacle to civilisation which demands international measures and efforts. The infection is confined in the earth over a range of 66 degrees of latitude (from 36° north to 36° south) inhabited by 940,000,000 persons exposed to risk (58 per cent. of the world's population), of whom at least 20 millions are infected. It should be remembered that the ankylostoma has been found at 57° latitude north (in Scotland), which proves that the danger is even greater than is generally conceded.

The Rockefeller Sanitary Commission to Combat Ankylostomiasis, organised in October 1909 (with its headquarters in Washington), proposed to determine geographical distribution of the disease, to undertake the treatment of the affected, to eliminate the causes of infection and to hinder the contamination of the ground. The remarkable work this Commission has accomplished and is in process of accomplishing in the countries chiefly infected is described in the annual reports of the Commission.

Below is the number of persons examined and treated during the period 1910-1923 by the Rockefeller investigators:

The proportion of persons infected, therefore, to the total population examined varies from a minimum of 36.7 for the middle States of the United States, to a maximum of 88.2 for the East (of which 75 per cent. relates to China; 93.2 per cent. to Borneo (1921); 97 per cent. to Ceylon from 1916 to 1921). Very high figures have been reported also in Natal (30 per cent. of the coolies on the sugar-cane and tea plantations); in German Guiana (80 per cent. in certain zones), and 90 per cent. of the workpeople in Porto Rico in 1904.

The mortality from anaemia was so remarkable in Porto Rico from 1890-1897 (15 to 15.5 per cent. of all the deaths: 22.13 per cent. in 1898) that the federal authorities were led to take up the matter, believing that poverty and wretchedness could not alone account for it. The committee of investigation reported that ankylostomiasis was the cause, and Dr. Ashford believed the parasite to be Ankylostoma Dubini. Later investigation by Stiles (1902) led to the conclusion that another species was the cause, to which he gave the name Neuctor americanus and which is now known as ankylostoma of Stiles. The propaganda organised among the medical men by the members of the committee — which had now become permanent — led to the creation of dispensaries and sanitary measures which rapidly brought about improvement. At the end of June 1910, 300,000 persons had been treated (a third of the population) and the proportion of the infected, which had been 44.90 per cent. and in certain provinces 50 per cent. fell rapidly.

An enquiry in the Philippines (1922) showed that 85 per cent. of those examined were carriers of intestinal parasites, a half of them being either A. Dubini or Stiles. Most of these carriers, however, were in a good state of health.

In the U.S.A., during the war, examination of 507,000 recruits showed 10 per cent. affected with ankylostomiasis. The Southern States showed the highest figures (Georgia 23 per cent., Florida 32 per cent., Alabama 29 per cent. of the recruits); the Northern States showed the lowest (1 per cent.); the majority of the infected in the North had previously been in the Southern States. In this Argentine Republic infection is rife over a great part of the country, especially among the children. Every day new districts, hitherto free, become infected (T. Tonina, 1923).

The campaign against the infection is of extreme urgency inasmuch as even the minor cases represent an important loss collectively. An American enquiry has reckoned the output of an infected workman as one-half or even one-sixth of that of the normal output, and Dr. Gunn has calculated that the annual loss in output of infected miners in California amounts to 30 per cent.

**Occupations exposed to Infection.**—All occupations affording contact with warm and humid earth are liable to infection from the larvae: agricultural labourers (use of stable and byre manure), planters of coffee, sugar, bananas, cocoa, tobacco, tea, labourers in rice fields, brick-workers (the first case was notified in 1882 in Cologne), pottery workers, tile makers, kitchen gardeners, and peasants.

Tunnelling operations are also a frequent cause of contamination in the absence of necessary precautions. Thus, while the St. Gothard tunnel has gained notoriety for a widespread epidemic affecting thousands of workmen (it has been estimated to have caused 10,000 deaths from anaemia — Perroncito), not a single case occurred among the 25,000 workmen employed in tunnelling the Simplon.

Cases of ankylostomiasis can also occur among excavators, workmen making bridges, canals, etc., but it is of principal interest in coal-mines, where the conditions are most favourable to the life of the parasite. It affects only the deep miners, in whom contamination occurs readily in consequence of the grime on their skin (a mixture of sweat, coal dust and mud).

With regard to dissemination of the disease, the carriers (without any morbid conditions) are the most dangerous. One carrier can contaminate a whole mine. The families of the infected usually remain immune.

The frequency and gravity of the infection vary greatly according to the locality. The number of persons affected also may vary from time to time. When ankylostomiasis attacks a mining area for the first time the symptoms are usually severe, but as time elapses the miners seem to suffer less (diminution of the virulence of the parasite and increase in the resistance of the miner). Infected shafts have been observed close to others unininfected in the same mine, especially where men work in a sitting posture (St. Etienne, France).
Infected Coal Mines. — Australia: In the campaign against this infection, out of 5,063 coal-miners in Queensland and New South Wales, 644 were found to be infected with ankylostomiasis by the special commission appointed. Contagion was due to defective installation of pits and consequent contamination of the water and the faeces. The measures taken, combined with education of the miners, reduced the number of infected persons from 31.5 to 6.1 per cent. (W. C. Sweet, Congress of the British Medical Association, Australian Section, 1923). The metalliferous mines are practically free from it. In fact, amongst 10,228 workers occupied in 156 mines in six States, only 644 contaminated persons were found (6.3 per cent.).

Austria: Generally speaking, the mines do not present the local conditions favourable to the development of infection. Cases usually come from abroad. Ankylostomiasis has been rapidly eliminated by strict observance of the measures laid down in the Ministerial Decree of 4 September 1904 (see under Legislation, p. 142).

Belgium: The mining basin of Liège was, thirty years ago, the most infected in Belgium; successive commissions of enquiry revealed upwards of 50 per cent. of carriers of ankylostoma in certain mines. The general average of carriers for this area in 1900 was 26 per cent. among about 30,000 miners.

The basin of Charleroi was much less affected. In that of Mons, ankylostomiasis rages intensely in certain mines, there being as many as 70 per cent. carriers, but, on the whole, there were fewer affected than in the district of Liège.

The campaign was concentrated principally in two organisations at Liège and Mons — the "Miners' Dispensaries to Combat Ankylostomiasis". Here microscopical examination of the dejecta of the workers engaged was made, and anti-parasitic treatment applied. Further, several firms organised a service of their own, comprising examination and treatment provided to medical men attached to their mine. The activity of these organisations has reduced, year by year, the percentage of carriers to such a point that, in the Liège basin, where the results are the most striking, in 1923 only one carrier was found among 26,000 examinations of dejecta of workmen in different coal-mines. The actual danger lies in the engagement of numerous foreign workmen, among whom carriers of ankylostoma (workers from North Africa) and of other intestinal parasites are found.

Bulgaria: Bulgarian miners were immune up to 1910.

Chile: In 1910 Fernandez, after examination of 950 miners, found that the percentage of workers affected varied from district to district. He found, in fact, percentage varying from 6 per cent. to 72.5 per cent. of those examined.

France: At the moment there is no ankylostomiasis in French coal-mines. An enquiry made in 1905 by Dr. Potelet, at the instigation of Dr. Calmette, on 17,153 of the 77,396 men employed in the mines of the Nord (nearly 23 per cent.) showed that 527 (3.07 per cent.) were found to be carriers. The men drawn from 23 coal companies were also found to be immune. In other firms the percentage infected varied from 0.11 per cent. to 60 per cent. Among these 23 firms thirteen cases, that is, 32 per cent. were infected, the infection having been imported. In other firms the number of mines is considered.

Morbidity is practically absent from mines of the North of France because of their dryness. The carriers did not become infected at the cutting face, but, even if this had been the case, it would have been impossible to take any of the ordinary precautionary measures because of the arrangement of the approaches as soon as the seams are reached. In the passage-ways used by the miners in reaching the coal-face, however, there is nearly always some water trickling down the walls. The gutters for carrying this water ought to be replaced by covered drains. In the St. Etienne region the enquiry of Briacon (1904), relating to 1,200 miners, showed the fact that though the workers in certain shafts were contaminated up to a proportion of 92 per cent., other shafts were immune. Altogether, he found that about 5 per cent. of the miners were carriers and that there had never been a real epidemic, although infection was permanent among them.

Germany (Rhenish area): In 1902 the average number infected did not exceed 9 per cent. In two years the numbers of parasites had fallen by 85 per cent.; this success was due to prophylactic measures applied with requisite energy and discipline and the disposal of adequate financial means to impede microscopical examination of dejecta on engagement, compulsory treatment, etc.).

Hungary: The mines of Selmezchanya and Kormabanya were infected (1882-1892), but ankylostomiasis has completely disappeared thanks to the installation of
pails in the mines and prohibition of defaecating elsewhere than in them.

India: In the coal-mines of Bengal 70 per cent. of the miners are carriers without apparent sequelae (Tomb, Indian Medical Gazette, October 1923).

Italy is affected as regards its sulphur mines (Romagna and especially Sicily), where at the time of the health enquiry (1899) 80-90 per cent. of the miners were infected. (See article "Sulphur").

Netherlands: The first general enquiry took place in 1904 in the mines of South Limburg, carried out by Drs. Girms and Backer, the second in 1907 by Drs. Kranenburg and Kuijjer. The enquiry yielded the following results:

<table>
<thead>
<tr>

<td>54</td>
<td>2.068</td>
</tr>
</tbody>
</table>

In 1907-1908 Dr. V. Putten examined the brickmakers in South Limburg. The carriers here were ascertained to have worked in Belgium and Germany; 14.5 per cent. were found to be infected.

The sulphur mines of Central Russia and of the Balkan States are also infected (no recent data).

In general, mines in which the infiltrating water contains salt, even merely the small percentage of 1 grm., are immune (e.g. St. Just, in Cornwall).

In the tin-mines of Cornwall and Devon (in 1894 and 1902) 38 per cent. of the workers were affected. Here also portable pails and compulsory treatment (from 1905) have proved very successful. In 1908 not a single case of sickness was reported although 80 per cent. of the workers were still carriers. In other mines infection was less serious without cases of sickness.

Other infected mines are gold and silver mines in Hungary, and lead mines in Spain (reported as the most infected mining centre — 80-90 per cent. of the workers). (For metalliferous mines, see Australia.) No case has been reported from any quicksilver mine.

Only one detailed study of the geographical distribution according to country exists — that of Siccardi in 1909. In this an analysis of 571 Italian papers is given showing that 45 out of 69 Italian provinces were infected.

**PATHOLOGY**

The disease is extremely protean, varying according to the predominance of one or another symptom. Carriers showing no effects must be distinguished from the really sick, suffering from anaemia. This is of prime importance in regard to prophylaxis.

From the clinical point of view the infection can be slight, moderate, or severe. After an incubation period varying from three weeks to one or two months, there follows the period in which severe anaemia is the most marked symptom, due, it would appear, rather to the secretion by the salivary glands of the worm of a haemolytic toxin, than to mechanical factors.
action following on the mucous haemorrhages provoked. Though abdominal pains, nausea and vomiting are rare, the following general symptoms are common: feeling of fatigue, malaise, lassitude, dyspepsia, sometimes diarrhoea.

The skin is hard, dry, rough, sometimes atrophied. A trained medical man can at this stage recognise the existence of cutaneous lesions situated generally on the feet and legs and on such parts as come into contact with infected matter (e.g. the forearms).

At the period of onset there is frequent vertigo, dyspnoea, precordial oppression, in most cases slight fever (38°-38.5°), continuous or intermittent

**Digestive Tract:** The appetite is increased (in serious cases hyperoreia), perverted taste (ingestion of earth: Indian and negro earth eaters); epigastric pains with nausea and vomiting, increasing salivation; obstinate constipation alternating with diarrhoea; foetid stools, distension of the abdomen (dilatation of the stomach), slight ascites, rarely jaundice.

**Circulatory System:** No cyanosis (except in cases of cardiac insufficiency); signs of overwork of the heart. In severe cases slight hypertrophy. Dyspnoea and palpitation, either spontaneous or as the result of slight effort, vertigo, buzzing in the ears, headache, tendency to syncope,

![Fig. 15. — Larva of ankylostoma during passage into the lung. (Prepared by Dr. Lambinet, Liége.)](image)

(not returning to normal between the attacks) and not related to the number of parasites but rather to the severity of the anaemia; ceasing often after expulsion of the worms.

The tint of the skin is typically yellowish green (dirty especially among the mulattoes). Sweating is diminished and in serious cases even suppressed.

The face shows definite puffiness especially marked on the eyebrows and cheeks.

**Respiratory Tract:** Sometimes there is bronchitis with frothy mucous expectoration, in which the larvae can be found. Sometimes epistaxis. In severe cases the cardio-vascular symptoms seem to dominate the gastric. Oedema of the legs and feet is generally late in appearing (although it may be early).

No marked emaciation occurs; the muscles are flaccid, weak, simulating paralysis, and there is profound asthenia.

**Nervous System:** Mental activity is reduced; there is an expression of melancholy. The patient loathes his work, is indifferent, idle, prone to fall asleep. In the worst cases there is depression, mental confusion, knee jerks, exaggerated or diminished,
sensitiveness to cold, tickling sensation or sensation of deadness in the feet. Sometimes there is pseudo-maniacal or pseudo-melancholic psychical state, hystero-epilepsy, etc.: nevertheless, the state of nutrition generally remains good.

Special Senses: Visual acuity is diminished and pupils dilated; cataract is rare. Diplopia, optic neuritis, retinal haemorrhages. In miners the anaemia predisposes to nystagmus.

Blood: Examination shows a diminution in the haemoglobin and in the number of red cells (2,500,000 to 2,000,000 or less), morphological changes in the red cells (microcytosis especially), macrocytosis, myelocytosis and numerous megaloblasts.

After a varying period all the signs of pernicious anaemia appear. The blood loses its colour and consistency in proportion as the anaemia progresses. In very severe cases it is pale, thin, and has the appearance of being washed. The leucocytic count is very variable and without characteristic value. There is no marked leucocytosis, and sometimes even leucopenia. On the contrary, marked eosinophilia (10-17 per cent. or more instead of 1 to 2 per cent.). The eosinophils are larger than normal, and fragile with tendency to degeneration; they persist after the expulsion of the worm and have no relation to the number of these; they can exist even with other worms. In several cases eosinophilia is not present and the small number of eosinophils may not indicate increased severity of infection.

Efforts to find a specific precipitin in the serum of persons suffering from anaemia due to ankylostomiasis have been fruitless.

Urine: A trace of albumen may be present, also cylinders, urobolin, peptone and indican according to the degree of infection. The amount of urea is often less than normal (severe cases with malnutrition).

Faeces (see under Diagnosis, p. 140): The presence of the intestinal anguillula at the same time as ankylostomiasis is exceptional; that of the ova of ascaris is more frequent, also that of the ova of trycocephalus.

Skin lesions: Infected persons always say they have sensations of itching or burning on some part of the skin. The skin shows at an early stage an erythema which becomes papular, then vesicular, most frequently papulovesicular, and terminates in a form of eczema, tuberculous urticaria. These lesions carry names varying according to locality: "bunches" in Cornwall, "mazzamora" at Porto Rico, "pitirru" in Sicily, "gourme des mineurs" in France, "panighao" in the tea plantations of Assam, and still other names in America such as "toe itch", "ground itch", "water itch", "water pox", etc.

Spontaneous cure results at the end of a period more or less long, but rapidly under suitable treatment. Certain localised ulcerations above the ankle are resistant to all symptomatic treatment, yet always heal after antihelminthic treatment.
From the social point of view, ankylostomiasis should command attention by its pernicious influence on the physical and mental development of children affected and even on the progeny of infected persons: late appearance of puberty, of the menses, impotence in men, amenorrhoea, sterility, and miscarriage in women. Young persons infected for years show the typical appearance of infantilism or dwarfishness; feminine look, arrested development of the sexual organs, evidence of disthyroidism, with hypertrophied thyroid more or less degenerate or sclerosed.

Course: Left to itself ankylostomiasis goes on for years. It can last for 4, 5, 8, and even 15 years without complications. Rapid cure results after suitable treatment. Sometimes the anaemia persists even after recovery. Relapses are frequent. Though a fatal termination is rare in Europe, it is less so in tropical countries where ankylostomiasis complicates other diseases peculiar to these countries. It is a debilitating malady which diminishes resistance to other morbid influences (especially tuberculosis). The *Necator* or *Ankyl.* of *Stiles* has obviously a worse influence on the development of infection than the *Ankyl.* *Dubini.*

Immunity: Apart from an immunity in certain persons with long-standing infection, there is relative immunity in the black races. Very important is the relative immunity of certain carriers who show but the slightest trace of infection or even none at all.

**Diagnosis**

Examination of the faeces is indispensable because the symptoms in many of the cases may lead the untrained physician to form a wrong diagnosis. The existence of a progressive grave anaemia, the special pallor in persons exposed to infection, ought to direct the attention of the doctor to the necessity of looking for the ova of ankylostomiasis in the faeces as the only positive evidence. The faeces should be examined within 24 hours of evacuation because microbial fermentation alters the ova (a saturated solution of sodium chloride preserves them). By direct examination the ova only show if they are very numerous. Although the method of examination gives an immediate result, it does not suffice for discovering all the carriers. It is necessary to have recourse to processes of enrichment. Teleman's method (to treat the stools with ether and hydrochloric acid and centrifuging) allows of accurate diagnosis in the case of 55 per cent. of the carriers and gives an immediate and satisfactory result. By the method of bringing to the surface (diluting the faeces with sodium chloride, agitating and then allowing them to stand), the ova float on the top and attach themselves to a coverslip placed in contact with the surface of the liquid, etc. The sedimentation method or the method of culture (proposed by A. Looss) reveals 99 per cent. of the carriers, but is not practical for all medical men as it requires at least five to six days.

A gramme of faeces can contain 15,000 to 20,000 ova, which represents one thousand parasites. It has been shown, however, that the number of worms in the intestine is not always so high (see above). Recently, Stoll (1923) calculated that a female parasite produced approximately 9,000 ova per day, so that in certain cases the number of ova might reach several millions. But it should be added that only about a quarter of the ova produced are viable.

The characteristic appearance of the ova prevents likelihood of confusion with those of other parasites.

The following data will serve for differentiation of the two types of ova:

*Ankylostoma Dubini.*

- **Length:** min. 44 microns.  
  max. 67 
  **Average:** 52-64
- **Breadth:** min. 22 
  max. 42 
  **Average:** 40
- Double outline apparent.
- Shell thicker.
- Generally at the commencement of segmentation 12 to max. of 4 blastomeres.

*Necator Americanus.*

- **Length:** min. 62 microns.  
  max. 82 
  **Average:** 72
- **Breadth:** min. 38 
  max. 56 
  **Average:** 55-56
- Double outline very close and very difficult to bring out.
- Shell thinner — more easily broken under the coverslip.
- More frequently in an advanced stage of segmentation (8-16 blastomeres).

**Direct examination for the parasite** should be made after administration of a vermifuge; examine three differ-
ent stools; dilute the faeces with water, sift carefully.

In 1916 White proposed to examine for traces of blood in the faeces. This indirect method takes as long as examination for the ova, and naturally has only a very relative value. Examination for the crystals of Charcot-Leyden and cholesterine has only a complementary value.

Examination of the Blood: A leucocytes count has no positive value. Eosinophilia at the same time has been the only guide for diagnosing exactly the anaemia of Porto Rico (Dr. Ashford), but exaggerated importance ought not to be attached to it; it is only a complementary element in diagnosis.

Deviations of the complement, the monistagminique reaction, etc., are not necessary if so simple and neat a method as that of examination for the ova is employed.

Examine for larvae in specimens of earth (method devised by Nocht (Java) in 1917).

Prophylaxis

Prophylaxis has several aims: (1) to prevent dissemination of the ova of the parasite (most important, especially for mine and tunnel work); (2) to prevent the development of the larvae and destroy those that are already adult; (3) to prevent all transmission of infection by water, earth, mud, etc.

The necessary measures should never be employed separately or the campaign will be long, difficult, and perhaps unsuccessful.

The Rockefeller Foundation has inaugurated since 1915-17 a campaign against ankylostomiasis in the island of Antigua with 7,200 inhabitants. Infected persons numbered 29.8 per cent. of the population; 1,972 persons have been declared cured. A portion of these, examined in 1925, showed 21.2 infected. The improvements made had declined. Treatment alone, therefore, is not enough; it requires to be completed by a whole series of sanitary measures, by education, etc., effectively organised.

1. Commence with two kinds of measures.

(a) Note the sick and treat them.

(b) Prohibit defaecation on the ground.

All measures taken are dependent on the co-operation of the population, and unless the workpeople recognise the danger and have been educated in the steps which it is necessary to take, these are unfortunately likely to be of very little practical use.

If the industrial situation permits it, and if financial means are available, it would naturally be advantageous on the practical side to stop work for some weeks and undertake sanitary measures both in relation to the workers and their surroundings.

(i) Examination of the workers: no workman should be engaged for mine work unless he is immune (Germany, England, Austria, Belgium, etc.). Further, provision should be made for unexpected developments by periodic examination of the personnel of the undertaking; the examination should extend to every well in the mine shaft and to the defecation of 20 per cent. at least of the personnel. If a single carrier is found, the examination should be extended to all the miners. Prohibit the infected from mine work until they are completely cured.

Treat the sick and carriers by the methods now recognised as the most effective. They should be treated in dispensaries or hospitals, as domiciliary treatment is not to be recommended, supervision being impossible.

The most efficacious method to combat the infection is undoubtedly to treat all the infected subjects, because in this way the source of infection can really be attacked, even in circumstances where it is difficult to limit infection of the soil. The efficacy of this method is greatly heightened if the treatment is repeated with a view to the reduction of re-infections and be putting it into operation whenever practical during the cold or dry season, that is, when the infection of the soil is at its minimum. The application of this method minimises in a few days' time the number of embryos reaching the ground.

(ii) Place in the galleries numerous serviceable metal pails at the most likely points. Special attention should be paid to types which are in keeping with the workmen's habits. Water-tight pails must be carefully and regularly removed and disinfected by a personnel specially charged with the task. One pail for four workers was the rule in the campaign organised in Westphalia. See that penalties are exacted in the case of persons who fail to use them. They are compulsory in Germany (in the Dortmund district since 12 March 1900), in Austria (since 1900), Belgium (in Liège since 4 November 1904), etc.

In mines where the galleries are numerous, narrow, and low, or where
the roads are confined (e.g. in the coal-mines of the North of France) they may be difficult to employ, but in such cases a truckle system is possible.

Commendious latrines also, sufficient in number, may be placed near the approach to the mine or tunnel, and efforts made to habituate the workmen to use them before descending the shafts or entering the tunnel.

2. The contamination of the ground can cease in two or three days as a result of the action of rain and insects (especially the larvae of Drosophila and other flies). But under favourable conditions the larvae develop in five to fifteen days.

Covering the faces with clay, cinders or coke and burying them at a depth to about 30 cm. is not sufficient to prevent the development of the larvae, which can rise to the surface of the soil. They develop in a sandy soil at a depth of 90 cm. and work their way up from there, but the number of larvae which rise is proportional to the depth. On the other hand, pure clay does not allow the larvae to rise even from a depth of only 18 cm. below the surface.

Numerous measures are applicable in special cases according to circumstances. Thus the problem of dealing with the subsoil water arises; in mines active ventilation of the galleries is necessary; drying of the galleries and passage ways (arrange for the water to get away, prevent stagnation, remove mud, etc.), good maintenance of the ways, suppression of dripping of the water by drainage, etc. Diminution of the temperature with less humidity would mean the creation of conditions unfavourable to the development of the ova and larvae.

Disinfection of the galleries of the mine or of pathways is also useful. Carboic acid 5 per cent., milk of lime 10-20 per cent., caustic potash or soda 5-10 per cent., ferrous sulphate and cooking salt 10 or 20 per cent. have been suggested, but the results are not very satisfactory; the substance used, even if very concentrated, is rapidly diluted by the water in the galleries or subsoil or undergoes chemical change resulting in less efficacious products. The duration of the disinfecting action is, therefore, limited. Lime was recommended in 1900 by Van Ermengen and Thenolt (Belgium), and studied by Lambinet, of Liège, and by Previtera in Italy. Milk of lime (5-10 per cent.) has some action on very young larvae; for ova and adult larvae a 20 per cent. solution acting for three hours at least is required.

Cooking salt was suggested as a disinfectant for the first time by Perroncito, and first practically applied in a 2 per cent. solution by Manouvrier in 1905. Previtera lays stress on the fact that a 3 per cent. solution is necessary to kill young larvae rapidly. Use of salt, however, makes the galleries slippery, and this greatly interferes with the work of the miners who push the trolleys; the undissolved crystals, moreover, injure the feet and cause a burning sensation, especially if the skin is abraded. Crushed salt or saltina 20 per cent. solution is thrown on the ground: it is very useful against young larvae and ova but without effect on encysted larvae.

3. Prevention of the transmission of the parasite is effected by good drainage of waste water, especially provision of good drinking water (so that there is no chance of contamination). Installation at the surface of douche baths, cloakroom and washing accommodation, etc., in order to facilitate as much as possible cleanliness of the workmen on their arrival at the surface or on leaving the tunnel (Germany since 1900, Belgium, etc.).

At the place of work basins should be provided with salt water (5 per cent.) for washing the hands and the tools and articles which have been in contact with the ground. Similarly, provision of foot-baths on leaving the lifts are useful (this is difficult of application).

Avoid, as far as possible, contact of uncovered parts of the body with earth (especially the hands and face): this is a pious expression of opinion, as in hot climates and in mines the workers are often naked (e.g. sulphur mines of Sicily).

Compel the workmen to wash their hands before meals: part of a general hygienic health propaganda.

Emigrants. — Compulsory examination of emigrants from infected countries should be considered as indispensable as also treatment of carriers. The length of the transatlantic voyage allows of the application of these measures being more easily effected than at the port of disembarkation.

Treatment belongs to the medical man.

Legislation

Compulsory notification: Germany, Bavaria, etc. Belgium, Brazil (agricultural labourers). Great Britain (since 1900), Hungary, Illinois, Netherlands (since 1911), New Zealand.
Compensation on the same lines as accidents, but only for cases of ankylostomiasis among miners: Alberta, Argentina, West and South Australia, Germany, Illinois, New York, New Brunswick, Nova Scotia, Ontario, Great Britain, Russia.

Compensation also for carriers: Great Britain, Queensland, Western Australia (mines, quarries, stone breaking and dressing).

Compensation is provided without specifying the occupation in Argentina, Bolivia, and New York.

Special Legislation.

**Austria:** Circular of 4 July 1904 of the Minister of Agriculture to the Inspectors of Mines at Vienna, Klagenfurt and Gracow prescribing the prophylactic measures: examination on commencement of employment, pails, prohibition of depositing stools on the floor of the galleries, etc.

**Belgium:** Numerous Royal Decrees as regards preventive measures in the coal-mines. A Decree of 24 October 1904 requires the provision of pails; another of 4 November deals with infected mines in the neighbourhood of Liège (douche baths, etc.). In 1906 a Decree affecting Hainault groups the mines, following on the result of an enquiry made. If they are free, notification of any case that may occur in the future is required; water closets at the surface (1 to every 25 persons) as near the shafts as possible; movable pails below ground, capable of being closed, provided with deodorants, and to be steam-disinfected once every 24 hours. If the mines are infected, the Decree requires medical examination of all the workmen.

It was, however, only after 1919 that the Minister of Labour organised by a series of Royal Decrees (30 June 1919, 31 December 1920, 7 March 1921, 17 October 1921), measures applicable to limited localities, but to all the five coal mine areas of the country. The principal measure is microscopical examination of the stools of every workman on commencement of employment and six weeks later. The Ministry of Mines can require examination of every underground workman if there is danger to fear from contamination of the waxes; the coal-mines have to undertake at their own cost the anti-parasitic treatment proposed for carriers. All these measures are applied at the prescribed time whether, as in the Liège district, the microscopical work necessary (about 30,000 examinations a year) is centralised in the central dispensary for examination and treatment of the carriers, or, as in the other districts, the microscopical work is carried out by medical men attached to the coal-mines, provided that the latter, after attendance at the special course in parasitology, have received the approval of the Minister of Labour as to their competence.

**Brazil:** Decree of 18 June 1919, No. 5010.

**France:** The Decree of 17 June 1913 prescribed the compulsory treatment of infected mines.

**Germany:** Act of 12 March 1900 requiring provision of movable pails in galleries, douche baths, cloakroom and washing accommodation, etc. Penalties for not applying to mines in the district of Dortmund requires a medical certificate on commencement of employment stating that the workman is free from ankylostomiasis, with examination within six weeks following and compulsory treatment of carriers.

**Great Britain:** The measures were already provided for in section 27 of the Metalliferous Mines Regulations for Devon and Cornwall.

In the Dominions: Ceylon Acts of 8 June 1917, No. 6879, and 2 September 1917, No. 6897.

**Italy:** Circular of 30 March 1901, No. 20300, of the Minister of the Interior and the Act of 14 July 1907, No. 357, on the subject of the compensation to workmen suffering from ankylostomiasis employed in the sulphur mines.

**Netherlands:** The preventive measures against the spread of infection among the miners date from 1906 (Ztrbl. No. 248, Art. 207, e.v.), but modifications of the regulations are at the moment in preparation. They relate to medical examination, washing and bath accommodation, sanitary conveniences, drinking water and overalls.

**Spain:** Measures decreed in 1912.

**Anthracene**

**French:** Anthracène. — **German:** Anthracen. — **Italian:** Antraceno. — **Spanish:** Antracena.

**CHEMICAL PROPERTIES**

Anthracene is a hydrocarbon found in small quantities (0.25-0.45 per cent.) in coal tar and derived from the less volatile part by fractional tar distillation above 270° C. i.e. from anthracene oil (also called green oil). Anthracene oils contain about 2.5-3.5 per cent. of anthracene in conjunction with naphthalene, diphenyl, pyrene, etc. If the
fractional distillation be carried further, purified anthracene or anthracene at 50 per cent. is obtained.

Raw commercial anthracene, known as technical anthracene, is in the form of a crystalline mass — yellow to brown in colour, with an odour similar to that of naphthalene — and contains 30-90 per cent. (mostly 60-50 per cent.) of pure anthracene. Pure commercial anthracene C14 H10 is in the form of brilliant white crystalline flakes with violet fluorescence. It boils at about 360° C., melts at about 213° C., and sublimates easily, giving forth an irritating odour; it is insoluble in water, slightly soluble in alcohol, ether, and benzene, and easily soluble in boiling benzol.

**INDUSTRIAL USES**

Purified anthracene is mixed with potassium and distilled in iron retorts. Impurities (chiefly carbazole) are thus eliminated and a non-volatile compound of potassium is obtained. The distillate consists essentially of anthracene and phenanthrene which are separated by means of toluene. By repeated crystallisation, using benzene, pure anthracene is obtained.

Anthracene is used in the preparation of anthraquinone, which again is used in the production of alizarin and other dyes (aniline colours). Crude anthracene oil is sometimes employed for giving a preserving coat to wood and it is also used as an agglomerating agent for briquettes. Anthracene oil is often added to sulphonated machine oils because of its lubricating properties and cheapness, forming an ingredient of the so-called "soluble oil" or "screwing mixture".

**SOURCES OF POISONING**

The following categories of workers are exposed to the effects of anthracene: workers engaged in the production of anthracene and of anthraquinone, workers handling certain artificial organic dyestuffs — alizarin dyes, vat dyes, mordant colours, so-called tar colours — workers using an anthracene preparation for coating wood, makers of briquettes, makers of lubricating compounds containing anthracene, and workers in engineering shops using such compounds.

**TOXIC ACTION — SYMPTOMS**

Anthracene acts as a strong irritant of the skin and the mucous membrane, and the injury to the skin caused during the production and use of anthracene often results in serious skin diseases with eruptions usually on workers' hands, forearms and feet, which may later develop into cancer.

This action may be produced even on contact with products containing minimal percentages of anthracene. Doubt exists as to whether injury is the result of the anthracene itself or of impurities contained in it. Grandhomme denies that it exerts an injurious influence. Other authorities pronounce it harmless when free from phenol, cresol or carbazole, while certain authorities are of the opinion that the irritation produced by briquette making is due to a mixture of anthracene and not in the anthracene oil itself.

Cases of dermatitis and of cancer caused by anthracene have been noted particularly amongst workers tending machines lubricated with this product. In certain factories where more expensive mineral oil was replaced by anthracene oil numerous cases of skin eruption occurred. Oliver cites cases of dermatitis on the hands and arms of workers employed in making "coal grease", a mixture of heavy crude oil and anthracene oil, with the same quantity of resin and lime. Amongst those workers who had received hot splashing on the hands, forearms and face, two cases of epithelioma of the forearm were reported. Amongst 25 workers handling anthracene, cases of epithelioma were also recorded (3 cases affecting face, hands and wrists). An overgrowth of epithelial tissue has been produced experimentally in rabbits by injecting an anthracene dye.

Data relating to the frequency of cutaneous lesions due to anthracene are not of recent date. In 1904 the management of a large factory of chemical products in Germany conducted an inquiry into the health of workers engaged on the manufacture of anthracene. During ten years 22 out of 30 workers employed presented an erythematous dermatitis localised on the hands and arms, and neck; 3 had to be operated upon for cancerous ulceration of the scrotum. They had worked in the anthracene department from six to eight years.

A German inspector in the Arnsberg district in a survey (1906) of 9 establishments for the production of anthracene found very few cases of eczematous affections.

According to O'Donovan, workers handling the "crude cake" are most affected, those dealing with the purified product being but slightly involved.

Besides dermatitis (eczema) and epithelioma, lesions such as acne, kera-
tosis, telangectasis and pigmentation are common. Growth are unlike those of tar cancer, being solitary with no metastases.

According to numerous observations made, anthracene fumes are capable of causing a lesion of the delicate and sensitive skin of the eyelids rather than of the conjunctival mucous membrane. Certain experts consider, however, that this action is due to acridine rather than anthracene.

**Hygiene**

The use of anthracene oil in cutting compounds should be discontinued unless in such reduced proportions as to be harmless. In all other industrial operations where the product is handled, workers should have their hands and faces protected from contact with it.

**Legislation**

Cancerous dermatitis due to anthracene is included in the German list of diseases assimilated to accidents for the purpose of compensation. (See also articles "Tar", "Paraffin", "Tumours").

---

**Anthraquinone**

Anthraquinone [formula, \((C_4H_2O_3)\)] is obtained by oxidising pure anthracene by means of sodium bichromate and sulphuric acid. One hundred parts of anthracene (95 per cent. strength) yield 110 parts of crude anthraquinone, which is purified by sublimation by steam or by dissolving it in hot concentrated sulphuric acid and precipitating again with water. In this way 80 to 85 per cent. of pure anthraquinone is obtained.

The substance can be obtained also by electrolysis of anthracene in the presence of sulphuric acid and salts of cerium or manganese, or by oxidising anthracene by nitrous fumes, or iron salts, in acid solution.

Anthraquinone occurs in the form of clear yellow crystals or as a white powder (if finely ground). They melt, when the product is very pure, at 284° C., while commercial anthraquinone melts at 273–277° C. It also sublimes readily. Insoluble in water, and very slightly soluble in alcohol, ether and benzene, it dissolves readily in boiling benzene, glacial acetic acid and strong sulphuric acid.

By sulphonation, nitration and chlorination, etc., anthraquinone yields several useful derivatives for the preparation of synthetic organic colours.

It is *used* in the preparation of artificial alizarine, which is a dioxyanthraquinone, and other anthraquinonic colours (quinizarine, purpurine, anthraquinone red, etc.), as a catalytic agent, etc.

Some of the ill-effects recognised from use of ursol (" paraphenylene-diamine", see that article) are attributed to the action of anthraquinone. Other ill-effects occurring in the course of the manufacture of the substance have been attributed to pyridine (see that article).

Similarly, in the case of the group of substances of the fluorescent azines, having the property of damaging the cells of the higher organisms where exposed to light, while remaining inactive in the dark, e.g. the series of acridine, anthracene, xanthone, anthraquinone show the same effects.

Lewin has described how workmen in a cardboard-box factory, using a cement made from pitch, suffered from an itching or burning sensation of the skin and face, neck, arms, etc., and showed diffuse redness of all these areas.

Of 103 men affected, 85.4 per cent. only suffered discomfort when they exposed the parts to the action of the sun or light; 25 showed lesions both in light and shade. Blond persons were most affected (86.4 per cent.). According to Lewin, acridine was the cause of this dermatitis, but neither anthraquinone nor certain products of the series could be excluded as playing a rôle.

---

**Anthrax**

(French: Charbon. — German: Milzbrand. — Italian: Pustola maligna. — Spanish: Carbunclo.)

An infectious disease common to animals and man, due to a specific microbe, the anthrax bacillus, anthrax affects certain kinds of animals particularly: sheep, goats, oxen, horses, and, less frequently, swine.
The anthrax bacterium is an immobile rod, cylindrical, homogeneous, and transparent, from 3 to 8 microns long, and 1 to 1.17 micron broad. The ends are a little swollen and slightly concave, so that, when two bacilli are joined, a space between them is left.

The bacilli are sometimes united to one another in chains of two or three. In culture it assumes a filamentous wavy appearance such as it never has in the living animal.

Elimination is by way of the urine, the faeces, and the nasal secretions. It spreads on the soil and in manure, where conditions favourable to sporulation are present. The offal of anthrax-infected animals and the skin, hair, horns, etc., infected with spores can keep their power of growth for a very long time.

The bacilli can be found in abundance (especially some hours before death) in the blood and tissues of infected persons.

The bacillus multiplies by fission, but when the conditions of the medium are unfavourable it changes, generally in a few hours, into the resistant form of the spore. Sporulation, however, never occurs in the living animal nor in the body of animals that have died of the disease. Under such conditions the death of the infected animal prevents access of oxygen to the bacillus, with which it cannot dispense. But if the body is opened or — as frequently happens — if death is accompanied by spontaneous haemorrhages, sporulation formation is rapid. Outside the body the bacillus can exist in a state of suspended animation for a very long time even in media entirely deprived of nutritive elements (earth, water, surface of the body, etc.) and preserve their virulence up to the time when conditions become favourable for their development and the spread of infection.

Kuylenstierna has shown that the bacilli begin to produce spores at an atmospheric pressure of 150 mm. of mercury; at 600 mm. mercury the quantity of spores produced is nearly the same as at 760 mm.

It is noteworthy that agricultural work, running streams, worms, insects, and especially snails, favour conveyance to the surface of the ground of spores which have escaped from the body. Flies, insects, etc., are also means by which infection is spread to a distance. Recently (1924) Tabusso has proved that birds of prey, and particularly the Cathartesex atratus, play in Peru an active roll in spreading the disease, through their faeces, which contain the pathogenic germs in high virulence.

As regards susceptibility to infection, the human subject holds a position between very refractory species (dogs, birds, carnivorous animals) and those very susceptible (sheep, oxen). This susceptibility also varies much in different subjects.

Natural immunity does not exist in man, but a first attack does confer it in considerable measure. Generally anthrax does not recur. Artificial immunity can be conferred by treatment with serum (see below).

The virulence of the bacilli increases by successive passage through animals more and more resistant, and diminishes, with preservation of its power of growth, by exposure to different physical and chemical agents (unfavourable temperatures — too high or too low — sunlight, antiseptics, compressed oxygen, etc.). The bacillus is not more resistant than any other microbe to the action of physical or chemical agents. It requires three conditions for its growth and development: (1) suitable nutrient media either neutral or slightly alkaline; (2) presence of oxygen (the bacilli multiply the more rapidly the greater the proportion); (3) a temperature varying between 18° and 45° C. with an optimum (especially for sporulation) of 35° C.

**DANGER OF INFECTION**

In the majority of cases the malady is occupational in origin, either from contact with infected animals and their products, or by handling the products derived from them.

(a) Agricultural anthrax is by far the commonest form. Generally it is due to direct infection from the bacillus, rarely the spore, and attacks persons engaged in looking after diseased animals and manipulating the products of animals that have succumbed to the disease: shepherds, cultivators of the soil, veterinary surgeons, knackers, butchers, gutscrapers, meat carriers, workers in slaughterhouses, etc.

(b) Industrial anthrax is an infection, indirectly caused by the spore—rarely by the bacillus. This kind of infection is less frequent than the former, but is nevertheless sufficiently widespread. According to some estimates, danger is greater than is admitted to-day because, as a consequence of the difficulties of diagnosis, the number of notified cases is less than those which actually occur.

Among the industries liable to infection are:

1. The hide and skin industry. Especially affected are the workers employed in warehouses and tanneries (contamination through abrasions). The other operations involve less risk. Even after finishing, hides and skins can still be dangerous (cases among bootmakers, saddlers, and furriers).

The effluent from tanneries is a very important means of spreading anthrax spores in fields near the factory (infection of cattle at pasture, and even indirectly infection of cattle from hay). Hides and skins from China, Russia, etc., are notoriously dangerous.
2. Wool industry. Among workers engaged in sorting, carding, combing, and spinning wool coming from Turkey, Asia Minor, Persia (Alpaca, etc.), contamination takes place especially from infected dust (occurrence of the clinical form of internal anthrax was frequent in the past). (See below: Pulmonary Anthrax, p. 149.)

3. Hair industry. Very dangerous in so far as hair of horses and cows is concerned. Risk of infection is by way of the respiratory and digestive tracts (pulmonary and intestinal anthrax), to persons employed in sorting, heckling, carding and carding in factories for the manufacture of brushes and brooms. Even manufactured hair as delivered to the public (shaving brushes and ordinary brushes) can cause infection.

4. Industry for the working up of horns, hoofs, bones, blood, etc. Horns come mostly from India and China. Of the three operations they undergo — blunting, splitting, and planing — the last, consisting in scraping and smoothing the horn previously sawn in two is the most dangerous owing to the dust produced. Dry horns are said not to be dangerous but become so after undergoing a maceration of three weeks to remove the crust.

5. Transport industry. Risk is run by those charged with the transport of the bales of skins at the ports (dock labourers, wharfingers), warehousemen, on the railway and on arrival at the factories, and those engaged by sailors doing similar work on board ship. Contagion from man to man is very rare. In 1922, however, a case was described in Germany affecting the mother of two young boys who had contracted external anthrax from slaughtering an animal. The mother contracted the disease from infecting her sons. She fell ill seven days after them and died of pulmonary anthrax on the fifth day of the disease.

Statistics

Statistics collected in relation to animal anthrax are as follows:

1. Number of stables infected.

In Austria cases of animal anthrax numbered 10 in 1919, 38 in 1920, 68 in 1921, and 104 in 1922. In the Argentine Republic, 10,140 cases were reported in 1918, 4,132 in 1919, 813 in 1920, 1,123 in 1921, and 884 in 1922.

Canada has published no statistics; France reported 248 cases in 1918, 397 in 1919, 398 in 1920, 632 in 1921, and 549 in 1922; South Africa reported during 1921-1922, 292 infected localities in the Cape Provinces, 49 in Natal, 357 in the Orange Free State, 560 in the Transvaal, and 298 in Transkei. In Great Britain during the period 1911-1920, 6,550 cases were reported — an average of 635 a year; in 1921 the cases numbered 647. New Zealand has had no definite case since 1907, but in 1922 some suspected though not confirmed cases were reported from one farm. In Rumania animal anthrax seems fairly common, but details are wanting. In Sweden fatal cases numbered 847 for the period 1912-1914, 538 for 1915-1917, 229 for 1918-1920, and 225 for 1921-1922. Poland reported 288 cases during nine months of 1920, 912 in 1921, and 1,479 in 1922. Czechoslovakia gives the following figures for the provinces of Bohemia, Moravia and Silesia: 388 (1911), 498 (1912), 398 (1913), 332 (1914), 293 (1915), 214 (1916), 231 (1917), 210 (1918), 119 (1919), 144 (1920), 199 (1921), and 241 (1922).

In Italy, statistical returns contain from 1920 onward the number of stables infected, instead of the number of cases amongst animals. In 1924 the number of stables infected amounted to 1,504, in 1925 to 1,369, in 1926 to 1,634, and in 1927 to 2,532. The inspectorate is of opinion that the difference between the number of stables and that of the cases of infected animals is not in practice very great, for the animal is generally isolated and slaughtered and in consequence does not cause infection to spread to other animals in the stable and to the pasture.

The kind of animals most frequently attacked are oxen and sheep. As a matter of fact, of 10,258 anthrax-infected animals in Italy during the period 1915-1919, 5,702 were oxen and 4,336 sheep; of 3,747 in Czechoslovakia, 3,350 were oxen; and of 1,765 in France between 1918 and 1923, 1,139 were oxen and 590 sheep.

In Great Britain, 69 per cent. of the cases of anthrax among animals were said to be due to the importation of contaminated foodstuffs and fodder, 15 per cent. to infected soil, and 18 per cent. to causes unknown.

The statistics relating to human anthrax, so far as they are obtainable, are as follows:
Uruguay reported 186 (31 fatal) in 1923. ed 1 fatal case in 1919, 5 (3 fatal) in 1920,
to 1913; 12 (1 death) from 1916 to 1919;
Southern Russia, etc. the majority from Pennsylvania (22).

In Argentina 1 case was reported in 1911,
1912, 9 in 1913, 9 in 1914 to 1918, 1
in 1919, 11 (with 3 deaths) in 1921, 13 (with
1 death) in 1922, and 8 in 1923.

Denmark reported 44 cases from 1910 to
1918, 2 cases (both fatal) in 1920, 1 in 1921.
From the United States 89 cases (with
42 deaths) were reported in 1922, the
majority from Pennsylvania (22). During
the first quarter of 1924 31 cases were
reported (of which 12 occurred in the State
of Missouri). In New York State during
the period 1919-1923 61 cases (19 fatal) of
human anthrax were reported (of which
32 were caused by shaving brushes, 16 by
hides and skins and 42 by horsehair, etc.).

In Canada no cases have occurred in
Alberta, New Brunswick, Prince Edward
Island. In Nova Scotia 2 cases were
reported (1917-1919); in the Province of
Quebec 51 cases (1 fatal) between 1896 and
1917; in Ontario 23 cases (7 fatal) between
1882 and 1919, etc. In South Africa there
were 46 cases in 1921-1922 and 48 in 1922-
1923. France publishes no statistics for
agricultural anthrax but reported 200 cases
(25 fatal) of industrial origin from 1910 to
1913, 157 (19 fatal) from 1914 to 1919, 48
(5 fatal) in 1920, 21 (5 fatal) in 1921, and
17 (1 fatal) in 1922. In the Netherlands
cases of anthrax number about 50 a year.
Fatal cases have been: 1 in 1919; 3 in 1920,
1 in 1921, and 2 in 1922. Poland reported
45 cases (9 fatal) in 1920, 66 in 1921, and
56 (10 fatal) in 1922. In Roumania there
were 704 cases (62 fatal) in 1922. In Russia
the reported cases of anthrax numbered
3,904 in 1921 and 7,801 in 1923. The districts
most hit are the Ukraine, middle Volga,
Southern Russia, etc. Sweden shows the
following figures: 156 (4 fatal) from 1997
to 1913; 32 (1 death) from 1916 to 1919; 1
(fatal), in 1922-1923. Czechoslovakia returned
1 fatal case in 1919, 5 (3 fatal) in 1920,
49 (6 fatal) in 1921, and 81 (5 fatal) in 1922.
Uruguay reported 186 (81 fatal) in 1923.

In Italy, cases of anthrax notified amounted
to 2,205 in 1923, 2,728 in 1924, 2,989 in 1925, and 1,753 in 1926.
So far as occupational groups are concerned, agricultural anthrax affects
especially labourers, butchers, slaughter house hands, and veterinary surgeons.
In industry anthrax is most prominent (except in Great Britain) in the hides
and skins industry, after which comes that of horsehair and bristles. The statistics of
three great industrial countries give the following figures:

For Germany and Great Britain the most recent statistical data are as follows:

<table>

Note. — The raised figures refer to fatal cases. Very detailed particulars are given in the
articles dealing with the industries in question.
the upper limbs; twice on the lower limbs; twice on the back. Once only there occurred a case of internal anthrax.

External anthrax (malignant pustule) is the most frequent clinical form. Thus in France, of 431 symptoms 386 were malignant pustule, 38 anthracemia, 8 malignant pustule associated with anthracemia, and 4 internal.

External anthrax occurs most frequently on the head, the neck, and the upper arms. From statistics collected in France and Germany relating to 1,550 persons the pustule was situated on the head in 601 cases, on the neck in 219, on the upper arms in 630, on the legs in 36, and on the trunk in 42.

According to statistics of cases in Great Britain prepared by Legge, a relation can be made out between the mortality from anthrax infection, certain particular conditions of which time a general reaction takes place: a rise of temperature of the patient's surroundings, the general symptoms at first very ill-defined vertigo, somnolence, nausea, prostration, shivering, violent cramps in the chest, dyspnoea with violent oppression, etc., very often difficult to interpret. Then follow the signs of congestion and pulmonary oedema, dry frequent cough coming in spasms, or an atypical pneumonia with frothty,

A fatal issue ushered in by an exacerbation of the symptoms and hyperpyrexia, generally occurs on the ninth or tenth day, sometimes more rapidly. Recovery, rarely spontaneous, most frequently follows early intervention and shows itself in improvement in the local and general symptoms. In 90 per cent. of the cases the pustule is situated on the uncovered parts (face, neck), the position affecting moreover the seriousness of the lesion (more dangerous on the face).

Anthracemia (malignant oedema), which is less frequent, is usually situated on the eyelids, more rarely on the neck, arms, and thighs. It always begins with a diffuse painless oedema often extending widely. The condition develops much more rapidly and is more serious than malignant pustule and often leads to a fatal issue. Infection internally (pulmonary or digestive) gives rise to internal anthrax (pulmonary or intestinal) in which general infection dominates the clinical picture. In such cases diagnosis is difficult so that death often supervenes before anthrax has been even suspected by the medical man. Recently (1924) Sanarelli has said to have demonstrated the impossibility of the development of anthrax in the intestines. Research, therefore, was necessary to ascertain how internal anthrax could develop in animals and man. Sanarelli has shown that internal anthrax can be contracted through the respiratory tract. Anthrax spores coming in accidental contact with the buccal mucous membrane can easily pass into the lungs. If they are very numerous (a rare event) they set up anthrax pneumonia and death. But if they are scanty they are engulfed by phagocytes and, through the systemic circulation, are deposited in various organs. They remain there a long time in a latent condition, incapable of growth. Provided, however, that they are not digested by the cellular ferments the anthrax spores can at any moment give rise to a fatal anthrax infection, certain particular conditions only require to present themselves, as for example, a rise of temperature of the patient's surroundings, a diet poor in water, etc. Among spore carriers anthrax infection can be started by the injection of cytolytic substances like quinine, arsenic, lactic acid, and even distilled water.

Pulmonary anthrax commences with general symptoms at first very ill-defined vertigo, somnolence, nausea, prostration, shivering, violent cramps in the chest, dyspnoea with violent oppression, etc., very often difficult to interpret. Then follow the signs of congestion and pulmonary oedema, dry frequent cough coming in spasms, or an atypical pneumonia with frothty,
sometimes bloodstained, expectoration. Fever is absent or moderate accompanied by cyanosis. Death ensues with collapse and hyperpyrexia in the course of four or five days. Sometimes the form of the disease is fulminating.

Recovery is very rare. When it does occur convalescence is long with the possibility of relapse even after three months.

Gastro-intestinal anthrax is very rare, coming on acutely with symptoms generally analogous to those of a severe infective gastro-enteritis, colic, bloody diarrhoea, abdominal pains, irregular pulse, cyanosis, choleraic aspect, etc. Death occurs in from two to five days.

In accordance with recent experiments (1925) carried out by Sanarelli, the bacilli are quickly killed by the gastric juice and even by the intestinal juice. The spores pass through the stomach without undergoing change, but, contrary to the opinion of certain authors, conditions there do not favour their proliferation. It has been found in vitro and in vivo that anthrax spores do not develop there. On the basis of these experiments, Sanarelli is not inclined to admit the clinical picture of intestinal anthrax.

Like any severe infective condition anthrax exercises a baneful effect on the cardiac muscle, showing itself in a marked increase in the rapidity of the pulse — more remarkable in very severe cases. If the pulse frequency has a tendency to increase progressively the prognosis is bad.

In animals anthrax is generally intestinal, septicemogenic in character, without notable local phenomena. It is possible however to find in oxen of certain regions (America, India, China, Australia) a form of anthrax localised, at first, to the tonsils and attended by oedema of the glottis and suffocation (gargantilha or garottilha of South America). A real pustule analogous to that present in man is only found when the animal has been bitten by an insect on the most delicate part of the skin (udder, anus, etc.). This is the form known in Brazil under the name of Olho preto.

**Diagnosis**

The lesions are often so characteristic that the diagnosis of anthrax is easy, especially if the history and precise knowledge of the occupation come in to assist.
The necessity for bacteriological examination in the diagnosis of malignant pustule is apparent in doubtful cases and especially in internal anthrax where the diagnosis otherwise is very difficult and often impossible. Search for the bacillus should be made in the exudation from the pustule, in the expectoration in the pulmonary form, in the faeces in intestinal anthrax, and in culture from the blood. If agglutination has no value, search for the specific sensitiser can be helpful in diagnosis. The reaction of the precipitins of Ascott allows anthrax to be diagnosed in carcases dating some time back when the bacilli may have disappeared from the blood and viscera.

**Prophylaxis**

Intervention is necessary in every case, even when only suspected, without waiting for confirmation by laboratory diagnosis. A negative result does not permit of the conclusion that the case is not anthrax.

**A. Animal Anthrax**

The sources of animal anthrax may be in (1) soil foci (kept up by spores that have lived for a period more or less long in the pasture lands of infected localities), (2) water foci (that is, areas fed by spores carried with the effluent from factories manipulating infected raw materials).

The prevention of animal anthrax comprises a number of measures now accepted in the legislation of the majority of countries which have codified sanitary measures dealing with contagious disease among cattle:

1. Compulsory notification of cases suspected to be anthrax or diagnosed as such.

2. Isolation of affected animals and sometimes compulsory slaughter. Isolation of animals which have been in contact with sick or dead animals.

3. Destruction of the carcase without opening it (by burning or deep burial in quicklime); prohibition of the use of products emanating from animals that have died of anthrax.

4. Disinfection of infected localities and destruction of the dejecta. Campaign against insects which can have come into contact with sick animals or their secretions, carcases, etc.

5. Prohibition of the import of suspected animals or of those coming from suspected areas.

Several countries require by law compulsory vaccination and provide a free supply of vaccine or grant subsidies. Others indemnify the owners of slaughtered animals attacked by the disease. The indemnity in some countries is limited to half the value of the animal and is withheld if notification has not been made within the period specified by law.

**Vaccination.** — Toussaint was the first to realise the possibility of vaccination against anthrax, which Pasteur, assisted by Chamberland and Roux, made practicable in 1881. It is carried out by the two following methods:

(a) The Pasteur method rests on the principle of immunisation of one subject by inoculation of attenuated virus, giving rise to slight symptoms only and enabling the organism to resist a stronger virus or the different kinds of natural infection. This principle is attained by the use of two viruses, the one weak, the other strong. The Pasteur vaccines are made by culture at unfavourable temperatures but others are in use in which attenuation is obtained by heating or by the action of antiseptics or by chemical methods, or compressed oxygen (Chauveau).

(b) The second process of Cienkowsky (vaccination by immunising bodies containing the attenuated spores) is a modification of Pasteur's method. Two series of immunising bodies are used consisting of cultures much attenuated by the action of high temperatures. To obtain a constant virulence the test animal used is *spormophyllus cystilus* (souslik). A good supply of spores is obtained on killing the cultures, after the formation of the spores, with a solution of glycerinated serum added in such a way that the vaccine No. 1 is one-tenth of vaccine No. 2. The virulence of the two vaccines is such that 0.2 grm. of vaccine No. 1 kills the mouse and souslik and the same dose of vaccine No. 2 kills the guinea-pig, but not the rabbit. The advantage of this process lies in the stability of the immunising bodies used and the possibility of their dosage.

In other countries vaccines Nos. 1 and 2 are different in degree. Thus in Italy vaccine No. 1 kills mice and not guinea-pigs, while another kills mice and one or two out of five guinea-pigs. For vaccine No. 2 a vaccine may be used which kills 50 to 70 per cent. of the guinea-pigs and another 100 per cent. None of these vaccines otherwise is sufficiently virulent to kill rabbits or give a localised reaction at the point of inoculation.
Cienkowski's method was the one most used in Russia. From the information supplied the losses in the course of immunisation were said to be very limited (among horses from 0.1 to 0.3 per cent.; cattle from 0.02 to 0.07 per cent.; sheep from 0.1 per cent). The same is the case also in Hungary, where this method has been introduced quite recently — horses and oxen, 0.03 per cent.; sheep, 0.01 per cent.

Good results have also been obtained in North America and in Japan, where Cienkowski's method has entirely taken the place of Pasteur's. Vaccination to-day costs very little and gives a relatively lasting immunity. Nevertheless the immunity gradually lessens after several inoculations; hence necessity, generally disputed by those interested, of repeating the vaccination, so as to maintain resistance to infection.

Experience really shows that vaccination of flocks and herds ought to be practised at least every three or four months by repeating always inoculation of a double dose of vaccine No. 2. In Italy it is generally done every 6-12 months when it is a question of the usual livestock, and every 4 months with high-class animals and dairy cows.

Where vaccination has not been repeated, anthrax has sometimes occurred three months after the last inoculation. The procedure enables the animals to become resistant to more virulent vaccines fatal to rabbits and confers a great immunity to forms of very virulent vaccine. It gives, 1042 hours later, a third injection of a very virulent culture which is raised (41°-41.5°-42° C.), or if the animal shows signs of a grave general infection, recourse is had to high doses of serum intravenously (200 c.c.) because smaller doses, even if repeated at short intervals, are found to be insufficient.

Eight days after the first injection of serum (20 c.c.) in the case of sero-vaccination a second inoculation of vaccine is given, and 12 days later, both with vaccination and sero-vaccination, inoculation with serum No. 2 is done using a double dose of that ordinarily given (0.5 c.c.) in order to intensify the active immunity.

This method, as used in Italy, has never given rise to any accidents, and in comparison with other methods has given a stronger and more lasting immunisation.

**Immunisation by sero-vaccination** is a combination of active (vaccination) with passive (inoculation with serum) immunisation and has been popularised by Sobernheim. He uses anti-anthrax serum and a culture of anthrax bacilli the virulence of which is analogous to Pasteur's vaccine No. 2.

This method obviates all the objections to vaccination. After an injection of serum and vaccine Sobernheim gives 10-12 hours later, a third injection of a very virulent culture which gives the animal such a degree of active immunity as could never be obtained by other methods. This method, applied systematically during the war when hides and skins from foreign countries, used in tanneries, disseminated anthrax in a more fatal form than previously, has given really excellent results.

In conclusion, sero-vaccination alone is insufficient and expensive (in Italy the per animal of sero-vaccination is 0.60-70 L., while that of vaccination is 0.30 L.), but is useful during times of epizootic spread. The most serviceable preventive measure, therefore, seems to be vaccination.
B. Human Anthrax

Although treatment rests with the physician, the use of serum at the earliest period possible is not sufficiently insisted on even in suspicious cases and before any bacteriological examination has been made. The harmlessness of the method being recognised, with the object of insuring early intervention, premises in which there is risk of anthrax should make a point of seeing that a supply of serum is available for first-aid treatment. A slight expense of this kind will thus avoid delay in treatment, which otherwise might be fatal to the victim.

In every suspected case make a subcutaneous or intramuscular injection of 20-30 c.c. of serum at different points of the body if necessary. In a case of external anthrax (first stage) inject subcutaneously (abdomen or thigh) 40 c.c. of serum at intervals of 20-30 c.c. every 24 hours until there is improvement in the general condition or diminution of fever. In the most severe or late cases inject 40-50 c.c. in the muscles and 20 c.c. in the veins. Repeat the intravenous injections on the days following with doses of 10-20 c.c. (or intramuscularly of 10-30 c.c.) until there is noticeable diminution of the pulse. In cases of internal anthrax inject without any delay 20 c.c. of serum intravenously and 40-50 c.c. into the muscles. Repeat the intravenous injections at intervals of some hours until the danger is past. Apply caustic energetically to the pustule, put a bandage over the lesion and prescribe digitalis. Exclude absolutely anything in the nature of surgical interference which might help the spread of the bacilli in the organism.

The use of neosalvarsan proposed by F. Becker is now currently practised at the Pretoria hospital (South Africa). The anthrax patient receives an intravenous injection of neosalvarsan (0.6-0.9 grm.), the exact dose depending essentially on the state of the patient, being increased in proportion to the severity of the case. The injection is repeated next day; generally it is followed by a marked rise of the temperature. On the fourth day in certain very exceptional cases a third injection is given.

In the case of sick persons, or such as have been exposed to contagion, the measures followed might take the form of serotherapy with a view to cure, or of prophylaxis in the case of wounds, etc.; in the case of persons coming in contact with animals suspected to be suffering from anthrax, or which have contracted it, they would include protection of the hands and skin, exclusion of persons with skin lesions, disinfection of the hands with 2 in 1,000 dichloride of mercury and personal cleanliness.

For *industrial anthrax*: General measures would include (a) cleanliness, dust extraction, etc., disinfection of raw materials; (b) working clothes or overalls, caps, gloves, etc., personal cleanliness, etc.; (c) organisation of a health service; close medical supervision of those exposed to risk; notification of cases of anthrax, instruction to workers to repair immediately to the doctor or ambulance room in the case of skin lesions, however slight; (d) provision of first-aid requisites if there is no permanent ambulance staff; provision of antianthrax serum in premises exposed to risk of anthrax; (e) warning placard of the regulations in force.

The preventive measures in the case of human anthrax should cover the particular dangers in each industry: wool, hides and skins, horsehair and bristles, horns, hoofs, etc. (see these articles).

From the international standpoint prevention of anthrax among animals will ultimately be studied by the International Institute of Agriculture in Rome, which in this matter will keep in close touch with the International Labour Office. The problem of disinfection of hides and skins contaminated with the spores of anthrax has been confided to a mixed International Committee consisting of members of the Council of Hygiene of the League of Nations and of the International Labour Office—a Committee which will direct all the enquiries made in this direction in the various countries (laboratories and tanneries).

The question of disinfection of anthrax-infected wool having been dismissed by the International Labour Conference of 1924, any action taken must be limited for the time being to horsehair, hoofs, and horns. Details as to the problems to be solved will be found in the articles relating to the industries in question. Measures should be taken to protect transport workers and to provide adequate ambulance provision for dock labourers. For the protection of flocks and herds against anthrax, even before an International Convention is agreed to, it would be in the interests of agriculture and of the different States to engage in a more and more active campaign against animal anthrax.

Lastly, the attention of those concerned should be urgently directed to the
difficulties of diagnosing the disease and to the necessity of enabling doctors to acquire the necessary knowledge.

**Legislation**

Compulsory notification of animal anthrax has been required by legislation in most civilised countries: Germany (Law of 26 June 1909 and Regulations of 7 December 1911); Austria (Law on Epizootic Diseases of 29 February 1880); Denmark (Laws on Veterinary Police of 24 August 1894 and 14 April 1920); in South Australia, Tasmania, and Victoria by the laws on epizootic diseases; in the Argentine Republic by the Law 3,959 of 8 November 1906 (Veterinary Police); in Canada by the Law of 1906; in France by Article 29 of the Rural Code; in Great Britain by Order No. 7,939 of 1910 of the Ministry of Agriculture; in Italy by the Sanitary Law of 1917 and Veterinary Police System of 10 March 1914; Netherlands (Law of 26 March 1920); New South Wales (Law of 1901); Poland (1901-1909, formerly Austria); Queensland (Law of 1915); Rumania (Law of 20 November 1913); Sweden (Royal Decree of 9 December 1898 and Law of 1 May 1903); Switzerland (Federal Law of 13 July 1917 on Epizootic Diseases and Executive Order of 30 August 1920); Czechoslovakia (Law of 6 August 1909); Tasmania (10 June 1927); U. S. S. R. (Circular No. 214/390, dated 8 May 1924 and No. 396/460, dated 13 September 1924, on anthrax prevention).

Human anthrax is required to be notified:

(a) As an infectious disease: in Germany (Law of 30 June 1900 and Order of 28 November 1909); in the Argentine Republic (Decree of 1 April 1911); in Belgium since 1917; in Austria since 1907; Prussia, Baden, etc.; in Canada (Public Health Law); South Africa (Art. 18, Law of 1919, Regulations of 1923); Austria (Law of 14 April 1913); United States (in 25 States under 1906 Act and 1912 Act); Italy (Sanitary Regulations of 3 February 1901); Poland (25 July 1919); Rumania (Regulations of 8 December 1881, September 1894, June 1897, July 1905); Sweden (will be made at once obligatory); Czechoslovakia (Law of 14 April 1913); Uruguay (May 1916); Tasmania (10 June 1927).

(b) As an occupational disease: in Austria (Order of 1 August 1912); Argentine Republic (as an accident) by the Law 9,688 of 10 June 1927 and particularly by Art. 149 of the Regulations which gives the victim the right of compensation; South Australia and Victoria (1902); New Zealand (1905); Great Britain, not obligatory in agriculture but in industry under section 73 of the Factory and Workshop Act, 1901 (which does not apply to docks or the transport industry), but the local authorities can add anthrax to the diseases notifiable under the Infectious Diseases Notification Act; France (anthrax is not among the list of infectious diseases notifiable under the 1902 Act, nevertheless a Circular dated 20 July 1910 calls for notification of cases of industrial anthrax to the inspectors of factories and calls for a special enquiry in each case); India (Act of 5 March 1923, section 3 (2)); Netherlands (since 1905 by Art. 21 of the Law of 1911); Queensland (compulsory when the infection is contracted in the course of certain industrial operations, e.g. combing, wool-sorting, handling of skins, bristles, hairs, wool, carcasses of animals; in these cases the diseases are treated as occupational (Law of 1916-1921) and accident compensation is paid); Rumania, notifiable and treated as an accident (Law of 17 June 1916).

Generally the law regards industrial anthrax as an accident, and compensation is granted accordingly. In a number of countries, however, anthrax is included in the list of industrial diseases, giving a claim to compensation: South Africa, Alberta, South Australia, New Brunswick, British Columbia, Nova Scotia, Nova Scotia, New South Wales, Great Britain, India, Manitoba, Ontario, Queensland, New Zealand, Saskatchewan, Victoria, Western Australia, U. S. S. R., in Canada by Article 29 of Circular 214-390, dated 8 May 1924, and in the United States of America (Minnesota, New York, Ohio); lastly the Argentine Republic and Japan.

The Draft Convention on Occupational Diseases passed by the International Labour Conference at Geneva, 1925, contains in the list appended to the Convention infection from anthrax described in the following terms: "Anthrax infection: work in connection with animals infected with anthrax; handling of animal carcasses or parts of such carcasses including hides, hoofs and horns, loading and unloading or transport of merchandise."

**First-Aid Boxes.**—The French Decree of 9 October 1913 prescribes that the first-aid box should close easily and contain 30 grm. of tincture of iodine (official) in one bottle with a wide neck, closed by a ground glass vaselined stopper; a paint brush placed in a closed glass tube; two separate dressings, each dressing being kept in an impermeable and hermetically sealed envelope containing a gauze pad, a pledget of cotton wool, a strip of lint, a closed glass tube; two safety pins, the whole aseptic; two closed packets of 30 grm. of absorbent cotton wool; a strip of gauze 6 cm. wide and 2 m. long; a pair of nail scissors, and instructions.

**Placards.**—The French Decree of 9 October 1913 has drawn up a warning placard as to the dangers of anthrax infection. Similar placards have also been drawn up by the Medical Inspectors of Factories in Austria, Great Britain and the Netherlands, by the Health Officers in Germany, Belgium, Italy, etc., by private associations, such as those for the prevention of accidents, in France, Italy, Belgium, etc.

**Bibliography**

Antimony

Antimony is a metal of silver white colour with a bluish tinge; its structure is crystalline (rhombohedral) with a strong metallic lustre; its symbol is Sb, and density 6.85. It melts at 630° C. and volatilises at white heat (boiling point 1440° C.). It is very brittle and is easily pulverised.

At ordinary temperatures it is not affected by air, but becomes rapidly oxidised in the melted state. It burns with a bluish white flame without volatilising, but at about 900° C. gives off, in the presence of traces of oxygen, exhalations which have a smell resembling garlic, and dense white poisonous fumes.

It dissolves in boiling hydrochloric acid with liberation of hydrogen. Nitric acid changes it into oxide in the form of a yellowish white powder insoluble in water. It dissolves in aqua regia, from which it is precipitated by the addition of water in the form of a beautiful white deposit.

It is found occasionally in its native state (Sweden, Brazil, Mexico), but generally in the state of sulphide combinations the principal of which is stibine, Sb, S, or trisulphide of antimony. It is contained also in a great number of ores: sulphides of iron, copper, nickel, lead, silver, and in the form of metallic antimonides.

These ores are found especially in China, France, United States, Mexico, Australia, Asia Minor, Hungary, Japan, Portugal, Spain, Germany, Canada, Bolivia, Peru, Borneo, and Italy.

Compounds of antimony are very numerous. Those most used in industry are the trioxide, the chloride, the trichloride (tartrate of antimony and potassium), and the golden sulphide. All the oxides have the property of forming metallic antimony when heated to melting point at about 700-800° C. with cyanide of potassium.

Industrial Operations

The ore (stibine) is roasted in reverberatory furnaces where it becomes transformed into oxide (Sb, O₃) which, by calcining with charcoal, is then reduced to the metallic state. In the course of this process, fumes of antimony are formed (volatile dioxide of antimony) which should be recovered. Smelting of the ore in tall furnaces accomplishes simultaneously both roasting and reduction. Stibine can also be melted with iron (precipitation process), when the antimony which gathers upon the hearth of the furnace is collected.

In the electrolytic process a solution of sulpho-antimoniate of sodium (Sb, S, 3Na, S) is used in iron pans, fitted with iron cathodes and lead anodes. Antimony is deposited upon the cathodes, which are scraped with steel brushes.

Antimony obtained by these different processes is not pure and should be refined, which is effected by successive melting in the presence of nitrate and carbonate of soda. (See also articles "Lead" and "Silver").

Use

Antimony is used especially as an alloy with other metals and in parti-
cicular with lead, tin or copper, either with them singly or mixed. Arsenic (0.2 to 0.8 per cent.) and antimony (8 to 14 per cent.) are often added to alloys to harden them. Alloys with lead and tin are used for making type, antifriction metal, metal trimmings on furniture and decorative objects, in the pottery industry, some chemical products (colours), and in pharmacy.

**Toxic Action**

It is not yet clear if antimony is a cause of industrial poisoning, and the opinion of authorities on this point is particularly divided. Löwy, according to whom antimony, from the toxicological point of view, belongs to the same group as arsenic, supports Rambousek, Köelsch, and other experts in attributing any toxic action to arsenic, which is a frequent impurity of antimony. It is, therefore, sometimes difficult to know in any particular case if the poisoning is due to antimony or to arsenic. On the contrary, certain authors claim to have established by experiments (Boveri) or by clinical observation (Ferrannini, Scalia, Schrumpf, and Zadel) the toxic nature of antimony, while others do not consider the matter proven (Berterelli).

Seitz (1924) has reported among type-founders blood deterioration similar to that which he obtained experimentally with cats. A subcutaneous injection of antimony produced a diminution in the number of red and white blood cells (about 50 per cent.), whilst if the antimony was given by the stomach, a diminution of the white cells and an increase of the red cells were noticed. The results of experiments on guinea-pigs were not so pronounced. However that may be, medical literature reports instances of poisoning by antimony and Ramazzini was the first to describe the effects of antimony upon chemists.

It seems doubtful if all the compounds of antimony are injurious to the health of operatives who handle them; only the antimoniates and tartar emetic act differently both in regard to their local and general toxic effect. Whereas certain salts of antimony cause, when in large quantities, symptoms of poisoning, chronic poisoning by tartar emetic leads to serious degeneration of the internal organs without it being possible to explain this action.

In the chronic form brought on by certain antimonial preparations it is noticed, as distinct from arsenic, that there is not only a diminution of the white cells, but also in time, and with an increase of the doses, an increase in the relative and absolute strength of the absorption. It is not possible to obtain immunity against the local action of tartar emetic either by long administration of the substance or by preliminary treatment by salts of antimony or arsenic.

**Sources of Poisoning**

1. *In the course of manufacture* during the roasting of the ore, the great danger lies in the presence of arsenic, which exposes the workers to the absorption of this product and of its compounds, arsine oxide or arseniuretted hydrogen.

Some cases of poisoning have been observed among miners and smelters of stibnite (Biondi), especially when the working of the furnaces is defective, and during pulverising stibnite or pure antimony (Roth); and also among workers employed in putting into sacks the oxide drawn from condensing chambers, as well as among those employed in cleaning these chambers (Biondi and his pupils).

2. *In the course of its use*. Poisoning occurs, in the making of alloys as
well as of tartar emetic, from the inhalation of fumes of oxide of antimony (Erben). Lehmann is, however, inclined to think that the damage caused should be attributed to arsenic. The manufacture, as well as the manipulation, of type causes symptoms among the workers (smelthers, typesetters, etc.). These symptoms have up to the present been attributed to lead, but they may, on the other hand, be due to antimony (Schrumpf, Zabel). A. Hamilton, Carrozzi, and others, however, have not found any evidence of any special clinical entity attributable to antimony among hundreds of printers who were examined. Hamilton has only reported two cases of troublesome eczema of the hands and forearms among workers employed at the melting pots used for type.

Antimony in a finely divided state is used as "iron black" (noir de fer) for bronzing metal objects, colouring varnishes, glazing terra cotta, and preparing aniline colours (instead of arsenic).

3. In the course of other industrial processes. Fumes of antimony are set free in the lead industry during the reduction of oxides by charcoal (Patinson process of crystallisation); in zinc smelting, where the fumes may sometimes contain traces of arsenic, cadmium, lead or manganese; in copper and zinc refineries, where the fumes may contain other metallic impurities which cause dermatitis and an ulcerating rhinotrachitis, the former of which must be distinguished from the itching caused by copper and the latter from zinc asthma; in the desilvering of lead wherein risk occurs of poisoning by lead, arsenic and antimony during the roasting of ores; in electro-plating where the same danger as in the preceding case exists in the course of the electric deposition of gold, silver, copper, nickel, and zinc; in recasting old metal and scraps of metal, and in retrieving old rubber, due to setting free blue fumes of antimony during the crushing.

4. In the course of the use of its compounds. Hydrogen is set free during the burning of cannons, of rifles and steel objects by means of trichloride of antimony (Eulenberg, quoted by Lehmann). Hydrogen antimonide, like chloride of antimony, is not poisonous, but is very irritating. The golden sulphide is used to make antimony colours (bismuth, Cassel, and Naples yellow, cinnabar of antimony). The red (pentasulphide of antimony) and the yellow are used in the rubber industry. Although according to Carlson (Chicago), 8 per cent. of antimony in the red sulphide and 3 per cent. in the yellow sulphide are soluble in gastric juice, and are sufficient to cause injury to the workmen who use these mixtures in great quantities, yet industrial poisoning seems to be fairly rare (Hamilton). Further, it must not be forgotten that generally workers handle at the same time litharge and lead sulphate, so that the symptoms which arise are more probably to be attributed to lead. Other writers consider that the cases of dermatitis which have for a long time been attributed to antimony are for the most part due to the accelerators employed in vulcanisation (see article "Rubber").

For some time past it has been proposed to use oxide of antimony, either alone or mixed with zinc white, as a substitute for white lead. Sulphide of antimony is used in the painting trade as a mordant, and also for making the paste for safety matches. Tartar emetic and the fluorides of antimony are used in the dyeing of cotton and printing of cloth. Some cases have been recorded of local lesions caused by materials so dyed and used in the making of garments which are worn next to the skin (Kaysen, Sandtner). The trisulphide of antimony is used in the making of fireworks, and fulminating primers. According to an expert in the American artillery service, certain cases of poisoning reported during the war were possibly caused by antimony. Hamilton is of opinion that it is impossible to distinguish the effects of antimony from those of fulminate of mercury, as certain symptoms which have been noticed, e.g. local irritation of the skin and respiratory passages, are characteristic of fulminate.

**Symptoms**

Locally, antimony and its compounds cause very irritating eruptions of the skin, characterised by peculiar small pustules (eczema of antimony) which resembles those of smallpox, often accompanied by marked sweating.

Cases of keratitis have also been noticed, caused by the fumes of the chloride or trichloride of antimony; also cases of irritation with erosion of the mucous membrane of the mouth and throat; some of burning pains in the mouth and pharynx with swelling of the lips, the formation of vesicles, and increased salvation (Koelsch).

Acute poisoning which is very rare as an industrial disease has a symptomatology similar to that of arsenic, i.e.
cramp in the lower limbs, convulsions, and collapse.

Chronic poisoning, brought to light by Schrumpf and Zabel, is met with especially among workers exposed to dust containing antimony. It is characterised by a peculiar expression of the features, watering of the eyes, eczema, nervousness, irritability, insomnia, fatigue, vertigo, frontal and occipital headache, muscular pains, neuralgic pains in the extremities, nausea, vomiting, loss of appetite, constipation, intestinal colic, gastro-intestinal trouble of every kind, fatty hypertrophy of the liver, inflammation of the mouth and pharynx accompanied by burning sensations, bleeding from the nose and difficulty in swallowing. Stomatitis caused by antimony is not common; even though some inflammations of the mouth of mixed origin have been described, due to the association of antimony with lead or tin, it seems nevertheless that there is no reason for admitting that there is a stomatitis solely due to antimony. Symptomatology, of the stomatitis found does not differ at all from that of stomatitis caused by lead, arsenic, etc. But whilst in lead stomatitis the gumline is distinctly brown and often slaty-black, in that caused by antimony it has a special reddish brown colour tending to deep violet (Koelsch). Salivation is as abundant as with mercurial stomatitis. It should, moreover, be noted that alcohol and tobacco increase the effects of antimony. Thus Biondi has seen antimony smelters show a drunken gait after having drunk a glass of white wine or smoked a cigar.

Antimony causes a slighter anaemia than arsenic, but exceptionally it produces a serious anaemia and a secondary cachexia (Eulenberg, Scalia). Associated with this anaemia, variations of the blood picture have been reported, accompanied sometimes by complex and numerous morphological changes which depend on the susceptibility of the individual as well as on the duration and intensity of the poisoning. The blood changes in men affected with industrial poisoning agree with those obtained by laboratory research. In addition to the diminution in the number of red blood corpuscles (Scalia, Ferrannini), in their amount of haemoglobin and cytological strength (Ferrannini), and in the number of leucocytes (Schrumpf and Zabel, Scalia) and of blood platelets (Seitz), the appearance has been noticed of sudanophilic granules in the polymorphonuclears and the large mononuclears (Biondi and Galassi, Ferrannini), of eosinophilia often marked (Schrumpf and Zabel), of anisocytosis and polychromatosis and of polychromatophilia (Ferrannini), and also of a diminution in the alkalinity and the carbon dioxide in the blood.

In the serious cases there are cardio-renal changes with albuminuria, glycosuria, feeble heart action, lowering of blood pressure, giddiness, fainting, loss of strength, marasmus, and cachexia. Diminution of sexual desire, sensation of oppression, dyspnoea with cough and pains in the chest have also been reported (Löwy).

Antimony like arsenic may cause neuritis (recurrent and optic neuritis), difficulty of speech, athetotic movements, epileptic positions, melancholia, etc. (Löwy).

Unless they are very serious the symptoms rapidly disappear when the source of poisoning is removed. In the cases of Schrumpf and Zabel, the symptoms disappeared at the end of two or three weeks after suspension from work.

The diagnosis depends upon the medical history and knowledge of the trade of the person affected.

Detection

Antimony can be detected qualitatively in urine and faeces by means of Marsh's apparatus, or that of Naquet (reaction of antimonuretted hydrogen with silver nitrate), or even by precipitation by sulphuretted hydrogen. Antimony is detected in urine by the following reagent: antipyrine 1 grnn., iodide of potassium 2 grnn., water 30 c.c. After the destruction of organic matter the residue is dissolved in 1 or 2 c.c. of hydrochloric acid (at 1:5), it is filtered and then 0.5 c.c. of the nitrate is added to the reagent. If antimony is present there is formed a characteristic precipitate of a golden yellow. The investigation is sometimes carried out for arsenic and antimony at the same time. It is far from easy to effect detection, which is a matter for toxicologists.

Legislation

Generally speaking, regulations issued for the exclusion of women and young persons from metallurgical processes and processes preliminary thereto for ores containing lead, zinc, etc., are applicable also for the ores and smelting of antimony.

In Great Britain the regulations for the chemical industry of 11 July 1922 cover also the manufacture or the preparation of carbonates, chromates, chlorates, oxides and hydroxides of antimony.

The Greek law excludes boys of less than 16 years and young girls of less than 18 years from works dealing with antimony and its compounds.
Apothropine
(Atropamine)

This product is atropine with one molecule of water less (formula, C₃H₁₈NO, and is obtained as a secondary product of the mother liquor in the course of preparing atropine. It is obtained also by dehydrating sulphate of atropine by means of sulphuric acid or acetic anhydride.

Severe cutaneous eruptions, localised at first on the hands, are found in persons manufacturing apothropine. The lesion appears in the form of yellow ulcers which spread to all parts of the body. Marked conjunctivitis has also been described in a chemist who was in the workroom but not directly engaged in producing the substance.

In one case the dermatitis lasted for several months and the worser eventuallly had to be dismissed.

Arsenic (Poisoning by)
(Arsenicism)

Chemical Properties

Arsenic (As) is found in the natural state (native arsenic), although impure and with small quantities of iron, cobalt, antimony, silver and gold. But it is most often found combined with sulphur (red arsenic or realgar), As₂S₃; yellow arsenic or orpiment, As₂S₃; with iron sulphoarsenate of iron or mispickel, Fe₅As₅; with cobalt (sulphoarsenide of cobalt, CoS₃As); with nickel (nickelglance), Ni₃As₂. Some minerals, such as zinc, cobalt, copper, nickel, silver, iron and lead, contain arsenic among their impurities, and it can even be obtained as a secondary product by metallurgical treatment (in the form of arsenious anhydride).

The specific gravity of arsenic is 5.725 at 15°C. It is a good conductor of electricity. When heated to 450°C it gives off a vapour without melting at ordinary pressure (sublimation); under pressure it melts at 500°C. It emits a very characteristic allaceous smell. It dissolves in concentrated nitric acid, becoming converted into arsenic acid.

In dry air at ordinary temperatures arsenic undergoes no change, but it oxidises in moist air. At a temperature of 180°C, it burns with a bluish flame, giving off a smell like garlic and forming arsenious anhydride (As₂O₃). At high temperatures it combines directly with numerous elements.

Arsenic generally appears in crystalline forms of greyish white appearance, with a metallic lustre. There are three allotrop forms: a grey or black variety, which appears when arseniuretted hydrogen gas is heated: a dark brown variety obtained by reducing arsenic compounds; a yellow kind obtained by cooling ordinary arsenic by means of liquid air in the dark.

As a description will be given only of those compounds of arsenic of importance from the point of view of industrial hygiene.

Arsenicous anhydride (As₂O₃ or arsenic trioxide, white arsenic, arsenious acid) is a white solid substance occurring in the form of octahedral or prismatic crystals (in Claudetite) or in an amorphous or vitreous form. Its density is from 3.7 to 3.8. Only slightly soluble in water, it dissolves readily in acid or alkaline solutions.

The anhydride is found in nature; industrially it is obtained as a by-product from certain metallurgical processes. It is prepared on a large scale by roasting arsenical pyrites. The impure vapours are led along channels of masonry or are precipitated as a white powder (flowers or flour of arsenic) which is purified by sublimation into a transparent mass (arsenic glass).

Reduced easily to the state of arsenic, it oxidises just as readily, forming arsenic anhydride (As₂O₅), a white vitreous substance which dissolves slowly in water, becoming converted then into arsenic acid (As₂O₅HO). Heated with charcoal, arsenic anhydride is reduced to arsenic; at high temperatures it decomposes into oxygen and arsenious anhydride. (For arseniuretted hydrogen see that article.)

Arsenic acid (H₃AsO₃) is obtained in watery solution from the corresponding anhydride in the state of the salt.

Orpiment (arsenic trisulphide As₂S₃) can be obtained industrially by melting arsenious anhydride with sulphur. It still contains arsenious anhydride, and is therefore toxic.

Arsenic colours are represented principally by emerald green. Schweinfurth green (Cu₃(C₂H₃O₂)₃+Cu₂(As₂O₅)₁), which contains about 50 per cent. of arsenic and is very toxic, is an aceto-arsenate of copper. It is also known under trade names such as Patent green, Original green, Swiss green, Parrot green, Imperial green, Mitis green, etc. Scheele's green or Paris green (little employed) is an arsenite of copper (Cu₂As₂O₅) and contains about 52 per cent. of arsenious acid. Vienna green is an arseniate of
copper. Brunswick green is a mixture of Scheele's green, sulphate of lime, and hydrocarbonate of copper, etc.

These greens are now replaced for certain purposes by commercial arsenate of lead, which is a mixture of basic arsenate (As₂O₃). H₂O and hydrous arsenate of lead (PbH₂AsO₄). Formerly, it was made by reaction between the acetate and nitrate of lead and arseniate of soda; now replaced by the Luther Volck method — a reaction of lead oxide with a solution of arsenic acid together with a small quantity of nitric or acetic acid which acts as a catalyst.

By reducing the mono- and di-methyl arsenic acid by means of a zinc amalgam and hydrochloric acid, the primary and secondary arsines are obtained. The best known of the alkyl derivatives of arsenic are the cacodyl compounds, which are violent poisons. The aromatic arsentical compounds, it should be remembered, correspond with the nitrated nitric and aminoderivatives, as for example, arszenobenzene (see that article), etc.

**INDUSTRIAL OPERATIONS**

Arsenic is mainly obtained from mispickel (Fe₃As₂, arseno-pyrites) which, when heated in cast-metal retorts in the absence of air, gives off free arsenic which is sublimated and condensed in iron pipes. The preparation gives rise to arseniferous dust. Arsenic is also obtained from arsenic acid with charcoal.

The fumes given off in the course of the smelting operations at the Anaconda Copper Company of Montana (United States), consist mainly of arsenious oxide and sulphurous anhydride. As they pass through the piping they are deposited in the form of dust containing 20 per cent. of arsenic. The solid particles are precipitated by Cottrell's method and the dust thus recovered is sent to a second furnace, then through another Cottrell apparatus which yields a product containing from 75 to 90 per cent. of arsenious oxide that can be still further purified.

Schweinfurth green is obtained by mixing a boiling solution of copper acetate and arsenious-acid; the operation should be carried out in a closed vessel. Drying as well as sieving and barrelling must be done under a hood with locally-applied exhaust ventilation to remove the toxic fumes. The manufacture of this product, according to Hamilton, is the most important arsenic industry in the United States (Brooklyn and Chicago). As much as 0.093 grains of arsenical green per cubic metre have been found in workrooms where the salt is made.

It is very high incidence of tumour of the lung is, however, attributed to arsenic or arseniate of copper sulphate by arsenious acid in the presence of potassium. The preventive measures described above in regard to Schweinfurth green should be applied here also. Vienna green is made by precipitating copper sulphate in excess by means of arseniate of soda. Mitis green, used in painting, is an arseniate of copper.

**Uses**

Arsenic compounds are used in the chemical industry and preparation of various green colours. These are used (although in diminishing quantity) for painting, wallpapers, lampshades, playing cards, artificial flowers, toys, etc.; but it can be said that danger from this source is now chiefly of historical interest. These colours, on the other hand, are still used in dyeing. The arsenic compounds serve for mordanting, preservation of furs, feather and skins; stuffing animals; stripping hair from skins; manufacture of artificial stones, malachites and certain enamels; to decolourise glass and crystal; for black bronzing (arsenic sulphide) or green (copper arsenite); for preparing the "carrotting liquid" (Teleky); to destroy the larvae of mosquitoes (arsenic trichloride: United States), canker-worms, vegetable and animal parasites ("sheepdip") is a mixture of arsenic, flowers of sulphur, potassium carbonate and soap), etc. Arsenic is given off as compounds or arsenical vapours in the course of metallurgical processes with arseniferous minerals; in the melting of lead (the "fume", for example, and dust in the lead smelting works of Utah and Colorado contain more than 60 per cent. of arsenic), of silver, zinc, antimony, nickel, cobalt, iron, brass, in the manufacture and manipulation of sulphuric acid, hydrochloric and nitric acids; in galvanotechnical operations, etc.

**Sources of Danger**

Workmen engaged in the extraction of the metal run risk only of accident in the roadways. A very high incidence of tumour of the lung is, however, attributed to arsenic or arseniate of
cobalt (Schwarz, 1922) among the Schneeberg miners (see article "Cobalt"). Those employed in crushing and grinding are exposed to the risk of arsenic if the work is done dry or by hand. The roasted, sublimation, and raking of arsenious anhydride is particularly harmful.

Cases of arsenic poisoning have been reported among dock labourers in the Port of London (1912) employed in carrying birds' skins preserved with arsenical compounds; during the war among persons manufacturing arsenic trichloride (Great Britain), e.g. dermatitis and ulceration of the skin, especially of the face and hands, irritation of the mucous membranes of the nose, mouth and throat, etc., were reported; among chemists (lesion of the septum of the nose affecting an American chemist and his assistant, who during a period of six months had ground 10 to 15 kg. of trichloride of arsenic daily); among workmen handling birds' feathers; in glass factories (Ohio); among painters (Great Britain) handling paint in shipbuilding — in one instance one point; among lacquerers (use of lacquers containing arsenical compounds; the greatest damage occurred among American airmen scattering arsenic in the colours, liberating diethyl arseniuretted hydrogen gas). According to Biondi, the existence of arsenical green (Illinois), with irritation of the bronchial tubes, digestive disturbance, and ulceration of the intestines; among workmen handling arsenic acid. For practical purposes arsenic containing a certain proportion of the oxides should be considered as harmful.

The fatal dose of arsenious acid varies between one and twelve cg. (Lehmann). He concludes that one must be prepared for such effects as intolerance, acclimatisation, age, state of the digestive tract, the presence or absence of fatty matters in the food, etc.

When pure the sulphides of arsenic are insoluble and consequently are not toxic. But the commercial products always contain important proportions of arsenic acid.

Arseniuretted hydrogen gas is very toxic, an atmosphere of 1 per 4,000 being rapidly fatal (see article "Arseniuretted Hydrogen").

Arsenic in small or even in fairly large doses in people accustomed to it exerts its action especially on the haematopoietic organs (blood poisoning), giving rise to a hyperaemia which excites activity in these organs and those of the tissues. The bone marrow and perhaps also the other haematopoietic organs throw into the circulation a larger number of red blood corpuscles with some erythroblasts, which is evidence of medullary regeneration. According to the experiments of Bettmann, the blood changes set up by arsenic are not qualitative but exclusively quantitative. Sudanophil leucocytes have also been reported (Biondi); increase in the globular tension (by arseniuretted hydrogen: Giordano); increase of the coagulability of the blood (Silbermann and Heinz) and a slight increase of the viscosity of the blood (Farmachidis). Arseniuretted hydrogen gas, on the other hand, destroys the red cells and causes haemoglobinuria.

According to Biondi, the existence of arsenical erythrohaemia could not be sufficient to prove an embryonic effect and function of the haematopoetic organs. But the erythrohaemia, according to this authority, serves to explain why arsenic eaters can carry heavy weights without dyspnoea at high altitudes. The experiments of Delépine in 1922, following on an acute fatal case of poisoning by arsenic trichloride affecting a workman who had upset a vessel containing this substance over his leg, have shown that arsenic can be found in the hair and urine of persons and animals exposed to toxic vapours. Delépine attributed exclusively to the belief that the trichloride if applied to the skin could set up poisoning. The air of the workrooms where this product is prepared and handled may
arsenic poisoning, brought out the fact that one sample of coal contains 0.75 grm. of arsenious acid per kilogram and another 3.6 grm. Gifts, of Boston, had already enunciated the same view in 1891.

As to the action of arsenic compounds on the bladder, see article “Aniline”.

The localisation of arsenic is of great importance for the toxicologist; it must, however, be remembered that the data now available are anything but concordant on the point of the localisation of the poison in the different tissues of the body. Ludwig, for example, found, in the body of a man poisoned by arsenic, 0.00515 grm. in 100 grm. of kidney substance, 0.0038 grm. in 100 grm. liver, 0.0012 grm. in 100 grm. muscle, and 0.0004 grm. in 100 grm. brain. On the other hand, in a case of slow poisoning, Kohn-Abrest found on the whole in each organ analysed 1 mg. in the intestines and liver, 0.4 mg. in the kidneys, 5 mg. in the brain, and 0.1 mg. in the lungs, etc.

**Statistics**

Arsenical colours have set up dermatitis and poisoning especially in Germany. In a German arsenic factory the cases of illness presented themselves as follows:

<table>
<thead>

The majority of cases were dermatitis and irritation of the mucous membrane (of the eyes, throat, and respiratory passages); there were also numerous cases of boils and ulcerations. During the period 1914-1918 14 cases of arsenic dermatitis were reported from Bavaria, of which 10 were due to Schweinfurth green; 5 cases due to Schweinfurth green occurred in 1921, 11 cases in 1922, besides 10 cases of dermatitis. Arsenate of soda was responsible for numerous cases of poisoning in a factory in Hanover which had taken up the manufacture without the necessary authorisation and without adopting the indispensable precautionary measures.

Finally, cases of poisoning from arseniac lead were reported in the United States among aviators engaged in scattering this substance in order to destroy parasites among vegetables.

In Great Britain the number of cases of poisoning by arsenic compounds contain appreciable traces of arsenical compounds.

The researches of certain experts (Bayet, Sloose, etc.) it should be recalled, serve to show that arsenic has a cancerogenetic action. In workmen coming into contact with pitch (see that article), suppurating lesions, warts, and cancers are frequently found; and samples of the coal examined by Bayet were all arseniferous to the extent of 1-5 mg. of arsenic per kilogram. Arsenic was also trace in the products of distillation such as the soot of the chimney, the ammoniacal effluent from the factory gas, the pitch, the oils, etc. Arsenic finally was found in the hair, the blood, and the urine of the workman employed (1921-1922). This view, however, is not accepted by some German and English authorities.

Biot, a Belgian medical inspector of factories, has determined the amount of arsenic in the different kinds of pitch used in the manufacture of patent fuel (1921). Of the 31 samples analysed, 17 coming from England contained from 10 to 130 mg. of arsenious oxide per kilogram of tar, 11 of Belgian source contained from 10 to 60 mg., while 3 of unknown origin contained only 10 to 30 mg. per kilogram (see article “Pitch”). The English view is that the arsenic present in the tar does not play a role in the production of epitheliomatous ulceration among tar and pitch workers.

According to the English pathologist, Jonathan Hutchinson (1887), small doses of arsenic acting for a long time may favour the development of epithelial neoplasms. Bland Sutton, Leuenberger, and others cite arsenic as one of the auxetic substances. Dubreuil, in 1910, described four cases of arsenical keratosi and collected 19 cases of epithelioma, but not one was of industrial origin; the three cases of Geyer (1900) were so only indirectly. On the other hand two industrial cases set up by the use of sheepdip have been described by Nutt, Beattie, and Pye Smith among 31 cases collected up to 1913.

The cause of soot pitch and paraffin cancer (see these articles and the article “Tumours”) has been closely studied, particularly cancer occurring among chimney sweeps, which generally is attributed to the arsenic present in the coal, chiefly English coal. It is due to this account that this morbid condition occurs more frequently in that country than on the Continent. The enquiry by Délépine carried out in 1903, to find an answer to the question set by the English Royal Commission on
Local Action

At the point where the caustic derivatives of arsenic are applied ulceration occurs; this is why the finger ends of workers who habitually handle arsenical compounds are specially selected as the site. The ulceration also becomes localised often at the angles and folds of the mouth and on the genital organs (carrying the caustic material thither by dirty hands).

Erosion of the septum of the nose is frequent. The dust coming into contact with the moist mucous membranes gives rise to arsenic acid which sets up well recognised ulcerations. The mucous membrane may be protected by pads soaked in iron hydroxide and magnesia oxide or by a mixture of camphor and petroleum menthol.

As regards cancerous lesions see above.

General Action

The different symptoms depend on the organs affected by the poison.

(a) Gastro-intestinal symptoms. — These are mainly vomiting and diarrhoea. Fits of vomiting follow habitual ingestion of the poison. They are intense and recur at each fresh ingestion of a liquid or solid. A large part of the poison is thus got rid of.

Diarrhoea also acts as a defence of the organism in eliminating the arsenic. It comes on some time after the commencement of the acute intoxication: abundant stools like those seen in cholera. In sub-acute cases the stools are yellowish and of foetid odour; diarrhoea may be absent in chronic forms.

These digestive troubles are accompanied by epigastric pain and colic, which is associated with the stools.

The gums at the same time become red and inflamed; sometimes erosions and even maxillary necrosis and loss of teeth, etc., occur. Pharyngitis and coryza are frequent.

(b) Skin eruptions. — These are frequent in the various forms of intoxication. But they take on different appearances. In the acute forms the eruption may be morbilliform, scarlatiniform or urticarial. Sometimes purpura is said to occur. Sometimes, too, the eruption may be papular, vesicular or pustular.

In the chronic forms, the skin is pigmented (melanoderma) — frequent in the Tyrolean arsenic eaters — on sites that are subject to friction (the neck, abdomen, and flexures). This pig-
mentation lasts long after the disappearance of the poisoning. Keratosis of the palms of the hands and soles of the feet is not uncommon; the nails and hair may fall out. A case of scleroderma is described by Ayres (1918).

(c) Kidney and heart affections. — These are less important than in mercury poisoning. For the most part they consist in diminutions of the quantity of urine passed, with presence of albumen lasting until death or until a cure has been effected. Certain terminal uraemic symptoms are said to appear in association with these symptoms in cases of slow poisoning.

The heart can be affected especially in acute cases; heart failure, lipothyramia, syncope even is not unknown (due to fatty degeneration of the heart muscle).

(d) Nervous symptoms. — Sensory nerve symptoms are characterised especially by severe headache and sometimes intense pains in the bones. In acute poisoning spasms of the sphincters occur as in cholera. Numbness, tingling and itching are extremely common. The painful anaesthesia of Mark should be borne in mind. Vision may also be affected: the patient complains of giddiness, failing vision (without obvious lesions of the fundus oculi), etc. Eczema of the eyelid, conjunctivitis (especially in susceptible persons) characterised by lachrymation, photophobia, with oedema but generally resulting in recovery; more rarely optic papillitis (case of Moleen, 1913; of Hass, 1919) with retinal oedema, diminution of sight, scotomas either relative for colours or absolute; arsenical lesions of the ocular muscles, ptosis, nyctagmus, etc., are rare.

Motor troubles consists of peripheral paralysis — toxic peripheral paralysis; generally they start in the lower limbs from whence progressively they proceed upwards. The paralysis is generally symmetrical and in one-half of the cases subsequently involves the upper limbs.

Tendon reflexes are abolished; the extensor muscles are particularly affected and a precocious atrophy is often marked. Anaesthesia remaining localised in the extremities accompanies it.

Such is the form seen in acute cases; the duration is usually short.

In chronic poisoning, on the other hand, the course is slow and sometimes takes on an incurable polyneuritic form localised in the small muscles of the hands and feet; tendinous retractions may develop, necessitating surgical interference.

The motor affections are rarely seen industrially. In Mark's statistics, which go as far back as 1891, they do not appear. Brouardel was the first to describe arsenical paralysis in a case of sub-acute industrial poisoning.

Clinical Form

The symptoms described show themselves more or less frequently and variously according to the amount of the poison, the channel of absorption, and the compound concerned. There are thus two distinct clinical types.

(a) Very acute form. — This is evidently exceptional industrially. It arises from massive ingestion of arsenic acid. Gastric symptoms are severe, vomiting incessant. The patient has a feeling of dryness in the mouth and thirst. After some hours diarrhoea supervenes, and death advances rapidly, the patient being pale, cyanosed and aneuric — the appearance closely resembling cholera.

(b) Acute form. — This is much the most frequent and that seen habitually in the majority of cases of suicide, accidents, and after medicinal doses. Occasionally it is seen industrially.

The necessary dose requires to be high and death usually supervenes six, eight or fifteen days after the accidental taking of the arsenic. But because of the early vomiting the poison may be rejected in part and a cure may follow.

Vomiting and diarrhoea, habitually very frequent, cease at the end of 24 to 48 hours. When this happens, improvement sets in with a feeling of well-being. Then a day or two the general condition becomes worse, the pulse small, the extremities cold, the patient cyanosed, breathing becomes laboured, the urine diminishes in quantity and is found to be loaded with albumen. Death follows in a state of syncope. It is important to recognise that this remission occurs in arsenical poisoning. It seems to be pretty general and it is after its appearance that the cutaneous lesions described show themselves.

If a cure takes place convalescence is long. The patient complains of gastrointestinal troubles. Chronic nephritis sets in, often also paralysis, and, even after a long time, fatal syncope may occur.

(c) Chronic form. — This is much the most frequent form industrially. It follows on daily doses of the poison,
sufficient to cause death, but sufficient to produce organic changes.

The first signs are more or less marked digestive troubles; salivation, vomiting, diarrhoea, and signs of paralysis in the lower limbs with sensations of numbness and tingling.

The patient also suffers from, though to a slighter degree, similar symptoms to those observed in acute poisoning — eruptions, paralysis. If the poisoning continues palmo-plantar keratosis will appear, as well as melanoderma.

But the symptoms may not all be present together; in some patients certain pathological symptoms predomi-

nate which in others are absent: the digestive troubles and paralysis seem to be the most frequent.

Finally, the cerebral symptoms must be referred to. These are almost all confined to the chronic cases: thus there is a toxic delirium, that is, mental confusion. In some cases Korsakoff’s syndrome or association of mental changes with symptoms of polyneuritis are present.

**Diagnosis**

Diagnosis has to be made in very different conditions according as whether the poisoning is acute or chronic, and whether in reference to a patient or in the case of an autopsy.

**Acute Poisoning**

In many cases knowledge of the possibility of poisoning helps much in diagnosing the case. Failing this diagnosis must be based on cumulative evidence as to agreement of the symp-
toms, remembering always that acute poisoning can appear in different forms and that some symptoms may be lacking; the most constant are the gastro-intestinal symptoms, eruptions, and nephritis.

In fatal cases often sanguineous effusions of the mucous membrane of the digestive tract are striking, by reason of fatty degeneration of the viscera with ecchymosis.

Here again search for arsenic often results in detecting it, since analytical methods, which have been brought to a high state of perfection, enable as little as one-hundredth of a milligram of arsenic to be found in a hundred grammes of viscera.

**Chronic Poisoning**

Diagnosis here is particularly delicate; but again knowledge of the poisoning (occupation in which arsenic of no

matter what kind is manipulated) allows certain diverse symptoms to be referred to their proper source. The possibility of an error in diagnosis should always be borne in mind in regard to cases where local ulcers are present round the corners of the mouth and on the genital organs (diagnostic from syphilitic ulcers).

Post-mortem diagnosis must be based on detection of arsenic in the viscera — but the presence of normal arsenic in the body must not be forgotten (this is only found in appreciable quantity in the thyroid and mammary glands) and the arsenic which may have entered the body after death (rain water in arseniferous localities): an analysis of the earth ought to be made at the same time. The possibility of the patient having been under medical arsenical treatment must also be taken into consideration.

**Demonstration**

This is work for the toxicologist, but it may be useful to refer to the subject in passing.

The reagents must be very pure: they are submitted therefore to a rigorous control before each research: acids must not contain more than one part in 10 mil-

lions of arsenic. In methods depending on hydrogen reliance must not be placed on the reaction of zinc on acid, as zinc always contains a little arsenic. The processes applied vary according as the arsenic is present in ponderable amounts or only in traces.

The first thing to do is to destroy the organic matter: this is done by heat and requires great precaution because arsenic is volatile and loss by evaporation is almost inevitable.

The best method of dosage consists in precipitating the arsenic as arsenic tri-
sulphide (As₂S₃) and weighing the precipitate. To destroy the organic matter the material is heated with hydrochloric acid and potassium chlorate. Thus the excess of chlorine is driven off by boiling. The residue is diluted with water and filtered. Hydrogen sulphide is next bubbled through the solution for three days: the precipitate of sulphide is filtered and dried. The precipitate and filter are then treated with sulphuric and nitric acid. Careful incineration follows. The carbon is removed with hot water and filtered and the filtrate is reduced by a current of sulphurous anhydride, which is elim-

inated next by boiling. The solution, after having been acidulated with hydrochloric acid, is again treated for three days with hydrogen sulphide, the excess being then driven off by a current of carbonic an-

hydride. The arsenic sulphide is filtered on a tared filter, washed and dried at a temperature of 110° C. and weighed.

The only impurities which can be present in the precipitate are copper and
mercury. They are removed, if present, in the following way: the precipitate is dissolved in sulphide of sodium or sulphide of ammonium if mercury is present. Filtration follows and arsenic passes into the solution. If this filtrate is acidulated with hydrochloric acid, arsenic trisulphide is reprecipitated. Saturation with hydrogen sulphide follows in order to complete the precipitation: filtration on a tared filter follows and washing with water containing hydrogen sulphide, alcohol, ether and carbon bisulphide. The operation is completed by fresh washing with ether and drying (S. Roche Lynch, 1922).

Thorpe's method resembles Marsh's, differing only in that the arseniuretted hydrogen gas is produced by electrolysis of the arsenical solution in a special apparatus.

This apparatus has been criticised by many because the platinum electrodes are said to lose their sensitiveness.

The Gutzeit method or its modifications is also recommended. With this method electrolytic hydrogen has to be used. All the same Marsh's method is to be preferred.

The Reinsch method is purely qualitative; it is an excellent means of ascertaining the presence of arsenic and ought always to be used. Its sensitiveness is somewhere between the gravimetric methods and those of Marsh and Gutzeit. The Reinsch method requires only two reagents: hydrochloric acid and copper leaf.

Heim and Hébert have proposed the use of the method recommended by them for the demonstration of antimony (see that article).

Kohn-Abrest uses the following method: about one gramme of dust is treated with dilute nitric acid; evaporation to dryness follows in a bain marie; some ten decigrams of magnesia and some cubic centimetres of a 20 per cent. aqueous solution of nitrate of magnesia are added; evaporation and calcination to a dark red then follows. The resulting ash is treated with dilute sulphuric acid and introduced into the Marsh apparatus.

It has been suggested to substitute for the Marsh method microscopical examination of the crystalline bodies formed with silver nitrate, magnesia liquor and the molybdic reagent with arsenic compounds. This last method is the most delicate for revealing arsenic in the form of arsenic acid; sensitiveness equals 1/20,000 of a milligram (Piutti and Boggio-Lera, 1922).

**HYGIENE**

The floor of the workrooms should be of cement so as to ensure impermeability; the passage ways should be paved and capable of being flushed with water.

The workroom should be well ventilated; large hoods should be placed over apparatus and connected up with a chimney with good draught; the poisonous fumes should be absorbed by passage through coke wetted with nitric acid. Every toxic emanation should be condensed and any dust caught removed. Complete airtightness must be ensured by use of cover for piping and entire apparatus for dust removal. In factories for the manufacture of compounds of arsenic hot processes should be done under glass hoods and manipulation of powders in glass cabinets hermetically closed. Protection of the workers against dusts of arsenical greens, especially the very light Scheele's green, which flies about readily, is very difficult to secure. Automatic packing is not possible and the ordinary means of protection (e.g. by respirators) favour sweating and consequently ulceration of the skin. Persons with moist skin and those who sweat readily are unsuitable subjects for the work and should be excluded.

In an American factory A. Hamilton found 0.093 grm. of arsenic per cubic metre of air.

The effluent waters should be neutralised before being led to a drain or sewer (see article "Hides and Skins"). Care should be taken as to how the rain water that has come into contact with material or dust, etc., containing arsenic is disposed of.

Mechanical and automatic methods should take the place of hand labour. Apparatus and receptacles require to be very strong to avoid breakage. In all operations where arsenic dust is likely to arise, the tables on which the work is done should be provided with downward exhaust ventilation. Special working clothes and head-gear, washing accommodation with hot and cold water and towels to enable the workers to wash face and hands before meals and before leaving work should be provided.

Neither food nor alcoholic drinks should be allowed in the workroom and smoking and snuff-taking should be prohibited.

**LEGISLATION**

Employment of women is forbidden in any room where arsenic is found free in the air unless workpeople are prohibited from introducing food into these rooms and unless a good potable water is supplied to them: Canada (Alberta and Ontario). In the manufacture of arsenic acid by means of arsenious acid and nitric acid; in the manufacture of arseniate of potassium by means of salpetre, and in the manufacture of arsenic sulphide: France. Wherever arsenious dust, fumes or gas are evolved: Japan. In the manufacture of arsenic and its compounds,
in that of verdigris (Spanish green), in the preparation of certain products having regard to their delivery or use: Netherlands, Russia, etc.

Employment is prohibited in the case of young persons under 14 years of age in Belgium in calico printing generally, in the manufacture of wallpaper, waxed taffetas or varnished cloth, in colour printing on cloth, and in workrooms where coatings or materials containing toxic substances are prepared, under 15 years in Delaware in the manufacturing or packing of colours and the manufacture or use of toxic dyes; in Japan in works manipulating arsenic or its compounds and in workrooms where arsenical dust, fume or gas is evolved; in Italy, in the case of boys under 15 years of age in factories where colours or materials containing arsenic are made, in the manufacture of arsenical alloys, in the smelting of ores containing arsenic (calcinatory chambers, etc.), and above all of arsenical copper, and in paper factories where colours containing toxic dyes are prepared for impregnating wallpapers are used: young persons of less than 16 years in all the States of North America in which the manufacture and packing of lead colours is prohibited (prohibition applies also in the case of the manufacture or packing of arsenical colours and manufacture and use of toxic dyes: Alabama, California, Connecticut, Maryland, New Jersey, North Dakota, Oklahoma, Pennsylvania, Wisconsin); in the manufacture and use of poisonous dyes in Argentina; in Belgium in the manufacture of arsenical compounds; in currying leather; in workrooms in which skins are treated with lime and sulphide of arsenic; in Canada (Quebec) in the manufacture of arsenical white; in packing colours and Scheele's green; in Greece in factories for the preparation of arsenic and its compounds; in Spain in the painting and decorating of toys, calico printing when arsenical colours are used, and the manufacture of arsenic and arsenical preparations of arsenic and arsenious acids; young persons of less than 18 years in the Netherlands as also of women; in South Africa in grinding colours; in France in the industry of painted cloth and workrooms in which poisonous substances are used; in Switzerland, etc.

Employment of female young persons under 18 years of age is prohibited in Canada (Quebec); in Greece, together with boys under 16; under 21 years of age in Belgium and in Spain as in the case of young boys under 15, and in Italy and in the case of boys of less than 15; for young persons under 18 in Switzerland, etc.

In France the Decree of 1 October 1913, as to the special precautions to be taken in factories for the manufacture of emerald green, known as Schweinfurth green, (arsenic-arsenide of copper), prescribes frequent washing of the floors and walls of workrooms, where solution of the product and the precipitation and filtering of the same is done, as well as washing of external walls of the vats and other vessels used for the process. They must also be kept constantly moist. Vessels in which the material is brought or placed are covered or closed under ventilating hoods. The drying of the green is to be done in a stove hermetically closed except for ventilating pipes. Workers are forbidden to enter rooms where the product is processed before it has cooled. Means for personal protection (respirators, moist sponges, cloth gloves, powdered t alc of Fuller's earth, working clothes, etc.) are to be placed at the disposal of the workers and the washing of these frequently effected by the management.

In Great Britain the Chemical Regulations of 11 July 1922 (No. 731) apply to all operations involving the manufacture or extraction of chromates, oxides and hydroxides of arsenic, arsenic acid and arsenious anhydrides. (For details see articles "Chrome", "Chromates", "Nitro and Amido Derivatives").

In Western Australia the Factory Act, amended in 1923, controls the factories in which compounds of lead, mercury and arsenic, are prepared and manipulated. The Government has the power to prescribe the conditions under which periodical medical examination shall be made in these industries.

In Illinois the Act of 1911 and in Missouri that of 1915 prescribe the same measures in factories for the manufacture of arseniate of lead and Scheele's green as for white lead.

In the Netherlands the factories for compounds of arsenic giving off fume are subjected to the same measures as those laid down in the case of fumes of mercury, and factories evolving dust to the same regulations as those applied in the case of white lead.

Production of arsenic compounds is included in the Russian Regulations of 10 April 1922 on industrial safety, which prohibits young persons of both sexes and women from this industry, regulates the length of the working days and lays down the precautionary measures to be taken as regards lighting, heating, ventilation, protective devices, sanitary and medical treatment, washing and cloak room accommodation, accident prevention, etc.

Use of arsenic in the printing trade, dyeworks, etc., is forbidden or regulated by the Order dated 19 September 1924.

Poisoning by arsenic and its compounds is compulsorily notifiable in the Grand Duchy of Baden, in Bavaria, France, Great Britain, Western Australia, Poland, Russia, Saxony, and the U.S.A. (California, Connecticut, Maine, Maryland, Michigan, Mississippi, Missouri, New Hampshire, Pennsylvania and Wisconsin). In the Netherlands notification is obligatory for cases reported in the following industries: glass-works, chemical works and chemical laboratories; industries for making, altering or repairing ladies' hats; artificial flowers; manufacture of waxed cloth; stuffing of animals; shot factories; wallpaper factories; sheep and wool washing places; dyeing, printing and bleaching of stuffs; weaving; tapestry; and coal mining.
Poisoning by arsenic and its compounds is brought within the Workmen's Compensation Acts in the following countries: Argentina, Australia (Queensland, South Australia, Victoria, and Western Australia), Bolivia, Brazil, Canada (Alberta, British Columbia, New Brunswick, Manitoba, Nova Scotia, and Ontario), Finland, Germany, Great Britain, Japan, New Zealand, Switzerland, and the U.S.A. (Illinois, Minnesota, New Jersey, New York and Ohio; in New Jersey and Illinois the products covered are arsenic lead and Paris green, as well as poisonous dusts and poisonous chemical products).

(Paris).

**Arseniuretted Hydrogen**

French: Hydrogène arséné (Arsine). —

**Properties**

Arseniuretted hydrogen (formula AsH₃) is a gas which cannot be obtained directly by the combination of its elements, but is chiefly formed from arsenical compounds when they come into contact with nascent hydrogen; in this case it is diluted with hydrogen. It is obtained in the pure state when sodium arsenide reacts with dilute sulphuric acid.

A litre of arsieniuretted hydrogen weighs 3.49 grm.; so that this gas is heavier than air. It liquefies at -40° C. and even at -110° C. it does not solidify. It has an extremely unpleasant smell like garlic, but in strong concentrations the smell is absent (Koelsch, Jaeger). It is neutral in reaction, and very unstable; its formation is accompanied by a considerable absorption of heat; it is easily decomposed into its constituent parts, either by heat or an electric spark, and explodes when acted upon by fulminate of mercury.

It is not readily soluble in water, five parts of which only dissolve one part of arsieniuretted hydrogen, or in alcohol or ether; but it is very easily dissolved in oil of turpentine and much less easily in pure fat oils. These chemical properties explain its action on living protoplasm (Zangger).

In the presence of a sufficient quantity of air, arsieniuretted hydrogen burns with a pale flame giving off water and arsine anhydride. Without a sufficient quantity of air, or if the flame is cooled, there is a deposit of black arsenic powder. It is absorbed and completely decomposed by a solution of silver nitrate, especially if a little nitric acid is added.

**Sources of Poisoning**

Arseniuretted hydrogen is very little used in industrial technique. It is used in chemical laboratories for separating arsenic after the volatilisation of arsieniuretted hydrogen; in medico-legal investigations; at chemistry lectures when preparing the gas for the purposes of demonstration; in researches on aniline dyes and arsenical compounds. The persons exposed to the poison are thus chemists, physicians, physiologists, and medico-legal specialists (Glaister, Zangger).

It must be borne in mind that the dark-coloured deposit observed when arsenic is deposited after the volatilisation of the arsieniuretted hydrogen is either arsenic or sulphide of arsenic, and this also applies to the brown deposit which is noticed when the flame is directed on to a cold china saucer (Zangger).

Arseniuretted hydrogen is liberated chiefly as a by-product in the course of certain industrial operations when hydrogen is formed in the presence of traces of arsenic in either metals or acids, which react on each other; whether it is the metals or the acids which contain these traces of arsenic or both together, the result is the same. Hydrogen when generated contains arsieniuretted hydrogen, for metallic ores, as well as some metals in the raw state, often contain considerable quantities of arsenic. This is why industrial sulphuric acid contains arsenious acid from 0.001 to 0.014 per cent., and commercial hydrochloric acid contains it from 0.0014 to 0.691 per cent.

Zangger points out that the presence of antimony facilitates the production of arsieniuretted anhydride and also that, as long as this substance is being liberated, no antimonious hydrogen is produced. The production may be accelerated by the addition of salts of copper or platinum.

Arseniuretted hydrogen may be given off in the course of a few operations carried out in the chemical and metallurgical industries.

Some of these operations are enumerated below.

**Chemical Industry**

There may be noted in the chemical industry all those factories which manufacture or make use of sulphuric acid, produced from arseniferous ores (pyrites); and those which utilise or manufacture hydrochloric acid, manufactured from arseniferous sul-
Phosphoric acid. Here the cleaning out of acid tanks is particularly dangerous; and cases of poisoning have been reported by Legge. Arseniuretted hydrogen is also given off: in the course of treating lyes with sulphuric acid; in the manufacture of artificial soda; in the preparation of chlorine by Deacon's process; in the preparation of hypochlorite of lime, of chloride of phosphorus, of the chloride and sulphate of zinc (1 case reported by Bannister), of chloride of methyl, of dimethylsulphate, of guncotton, of sulphate of iron (from scrap iron), etc.; in the manufacture of cement when treating the "sediment" (Bodensatz) with sulphuric acid; in all aqueous electrolytic reactions, for recent research has shown the constituents contain arsenic which with hydrogen becomes volatile; moreover, small quantities of oxide of arsenic may be transformed into arseniuretted hydrogen; arseniuretted hydrogen is also given off when sulphuric acid is used in electric batteries composed of bichromate of potassium, or in charging accumulators. Hot sulphuric acid contains traces of arsenic; this danger is especially connected with submarine accumulators (cases mentioned by Giordano, Belli, Dudley); during galvanising in an arsene bath and in numerous processes of organic chemistry; in the manufacture of aniline dyes, due to the use of arsenious acid as a reducing agent; in the manufacture of rosiniline, and of fuchsine by oxidising an aniline mixture of ortho- and para-toluidine ("rotol") by means of arsenic acid; during the manufacture of glucose in the treatment of fecula with sulphuric acid; during the treatment of such ferment residues in soda and glucose factories, etc. It is also found as an impurity of acetylene and as such causes frequent attacks of illness especially when it is generated in a confined space.

Poisoning by arseniuretted hydrogen, known by the name of the "gulf disease" or "Haff disease", which in 1924 attacked the fishermen of Frisches Haff, a lagoon on the coast of East Prussia, deserves special mention. Long and searching enquiries carried out on the spot made it necessary before it was possible to make an etiological diagnosis of the disease.

Bacteriological, epidemiological and toxicological experts established a series of facts which made it possible from the start to put on one side the supposition that the epidemic was an infectious disease. Clinically, it concerned an apyretic disease, without enlargement of the spleen and non-contagious; cultures from the blood and urine were negative; and no parasites were found in the blood or faeces. The possibility of poisoning by food could also be excluded, for the families of the fishermen were not affected. Only persons exposed to the morning mist while washing nets and seeking bait on the shore, or who had disturbed the mud of the gulf were attacked by the disease. In the first place it always affected the fishermen whose work with lines or crab pots caused them to lean over the surface of the water; on the other hand passengers crossing the gulf were only very rarely affected, or persons who bathed there, or even those who navigated the boats, or the net fishermen who use boats with higher sides.

Further, the part of the gulf attacked varied according to the direction of the wind, which led to the conclusion that the disease was due to a poison emanating from the gulf itself.

The fishermen blamed the sulphurous waste from two large cellulose factories, which discharged their waste waters with the sewage of Königsberg. It was also noticed that since the war, the gulf was often contaminated in an unusual manner during the summer of 1924, forming quite close to the surface of the water, in enormous masses and often in a purifying condition.

Investigations made by Lewin in the factories in question elicited the following very important facts: in order to prepare the sulphuric acid required for making cellulose, they used up to 1924 Norwegian pyrites which did not contain arsenic. By contrast, Spanish pyrites which, starting from the said year, replaced the Norwegian pyrites, contained 0.3 mg. of arsenic per 1 kg. of arsenic. Waste water analysed by Gay contained 28 mg. of arsenic per litre, or 56 kg. of arsenic for the 2,000 tons of waste discharged daily.

The hypothesis that this arsenic, transformed by the vegetation of the gulf into arsiniuretted hydrogen, could cause the poisoning found among the fishermen is open to the following objection: the factories had before the war used Spanish pyrites without causing any evil effects. But another factor which had recently come into play supplied the solution of the problem. The construction of a dyke in 1916 at the mouth of the most important river flowing into the gulf had resulted in the transformation of what had hitherto been practically fresh water into water very similar to sea water — which further was continuously polluted by the 30,000 cubic m. of sewage water discharged daily by the town of Königsberg. This change in the water, formerly used as drinking water but
since rendered totally unfit for any domestic purpose, explains why the arsenical waste in 1924 underwent checks that the fresh water before the war could not cause. As a matter of fact it is known that salt water facilitates the production of arseniuretted hydrogen.

The substitution for the arsenical pyrites of pyrites weak in arsenic and the establishment of a passage allowing again the access of fresh water into the gulf soon removed the cause. As a result no case of the illness has been reported for several months (1925) (see also article "Hides and Skins").

In the same way volatile arsenical compounds, and arseniuretted hydrogen in particular, arise from arsenical manures, due to the action of fungi, e.g. Penicillium breviculae, as well as from substances containing oxides of arsenic (Zangger).

It must finally be pointed out that ferrosilicon which always contains traces of phosphorus and arsenic, decomposes in moist air with the formation of arseniuretted hydrogen and phosphoarsenic hydrogen (see article "Ferrosilicon").

**Metallurgic Industry**

Arseniuretted hydrogen is set free during the extraction of arsenic by roasting such arseniferous ores as mispickel or arsenical sulphide of iron; when roasting ores of cobalt and manufacturing cobalt blue; when fusing zinc ores, as well as during work with arseniferous zinc; during the manufacture of all combinations with zinc, with crude sulphuric and hydrochloric acids; during treatment with hydrochloric acid of arseniferous or arsenical sulphide of iron; during the galvanic bath containing sulphate of iron, and concentrated sulphuric or nitric acids; during the reduction of sulphides of arsenic; from electrolysis of arsenious solutions; and from the action of water or dilute acids on metallic arsenides.

Further, it may be set free during soldering due to arsenical impurities in the composition of solder or in the cleansing solution, or to dissolution of zinc in the hydrochloric acid; during corroding or cleansing metals by impure acids; during burnishing silver in imitation of old silver; during the galvanic precipitation of arsenic on unpolished articles in solutions containing arsenic (4 per cent.), antimony, green vitriol and concentrated hydrochloric acid; during plating or blackening silver objects by means of an acid arsenical bath containing sulphate of iron, and concentrated sulphuric or nitric acids, the reaction of which is accelerated by the addition of a few pieces of zinc (the process of Bayer quoted by Koelsch); during the bronzing of metals by immersion in nitric acid containing arsenic; during the cleaning of jewelery by impure hydrogen.

In conclusion it may be said that arseniuretted hydrogen is always about during industrial operations which give off impure hydrogen. In order that hydrogen may be chemically pure it must be prepared by the electrolytic process.

The above explains why poisonings are reported during the manufacture of hydrogen from zinc and hydrochloric or sulphuric acids for filling toy balloons and airships, and during the preparation of explosive gas, and of gas used for the oxyhydrogen blowpipe, etc. Out of 59 cases of poisoning reported by Rambousek, 11 were due to filling toy balloons, 3 to military balloons, and 13 occurred among chemists.

These cases of poisoning arise in consequence either of the presence of arseniuretted hydrogen in the hydrogen, or in consequence of the action on metals containing arsenic of an excess of hydrogen (Zangger).

The frequency of the liberation of arseniuretted hydrogen is explained by the fact that arseniuretted hydrogen can arise from the reduction of arsenious and arsenic acids and their salts by means of nascent hydrogen in an acid or alkaline medium; from the reduction of sulphides of arsenic; from electrolysis of arsenious solutions; and from the action of water or dilute acids on metallic arsenides.

**Toxic Action**

Arseniuretted hydrogen enters the body by the respiratory passages with air contaminated by the gas.
It is very poisonous in all concentrations. According to Zangger it is so in a dilution of 1 in 100,000, but after an absorption of long duration.

According to Erben a few puffs are sufficient to cause death. Schindler obtained symptoms of poisoning with quantities of gas corresponding to a strength of arsenic of 0.01 gmm.

Dubitzki, by means of experiments on animals, found that arsenuresetted hydrogen is 10 to 20 times more poisonous than carbon monoxide, sudden death certainly occurring with a dose of from 7 to 10 mg. of poison per kilo of animal. Doses from 2 to 9 mg. to 4.2 per kilo were tolerated, but it seems that about 5 mg. per kilo of animal represents the minimum fatal dose. If these figures are applied to man, the fatal dose will be 0.3 gmm. (66.1 c.c. of arsenuresetted hydrogen — Koelsch). Jochimoglou, in his researches on the haemolytic action of this poison, has fixed 0.1 gmm. to 0.15 gmm. as the fatal dose for man, whilst Wignall considers that stronger doses are necessary. Lehmann considers that a dose of arsenuresetted hydrogen corresponding to 0.01 gmm. of arsenic represents the smallest toxic quantity. (Schindler has seen a case of poisoning with this dose.)

But it must be admitted that the concentrations encountered in practice rarely reach these figures, which is no doubt due to the great instability of these products. In the case of the death of a chemist named Brittan, the fatal issue supervened after the absorption of 381 c.c. of impure hydrogen, made with arseniferous sulphuric acid, which represented 0.776 gmm. of arsenious anhydride (As2O3) or 0.612 gmm. arsenuresetted hydrogen. In another case, quoted by Taylor, death occurred at the end of six days after the inhalation of 150 c.c. or 0.7 gmm. arsenious acid. In the fatal case of Professor Gehlen (quoted by Loewy) death was caused by a dose corresponding to 0.55 mg. of arsenic. On the other hand, Rambousek has seen a serious case of poisoning arise after the inhalation of a hundreth of a milligram.

It is certain that concentration plays an important part. Dubitzki considers as dangerous a strength of arsenuresetted hydrogen of 0.05 per thousand.

The time spent in the contaminated air is sufficiently long, 0.03 per thousand suffices to cause trouble. According to Jochimoglou, a strength of 0.2 to 0.12 c.c. (0.94 to 0.38 mg.) per litre of air causes in the case of cats serious symptoms at the end of an hour’s inhalation; concentrations below 0.1 c.c. cause serious haematuria.

Hebert and Heim found that with mammals breathing an atmosphere containing 3.5 per thousand of arsenuresetted hydrogen caused in some instances general and fatal poisoning; a stay of a quarter of an hour, repeated three times at intervals of twenty-four hours, in an atmosphere containing 0.05 per thousand of poison, caused equally fatal poisoning, through successive doses. The sensitiveness of birds is still greater; the minimum general toxic dose is for them 0.09 per thousand and the dose when taken successively 0.02.

After absorption by the respiratory passages, arsenuresetted hydrogen passes through the lungs without causing damage; but it is not clearly known what this poison becomes in the body. It is probable that a very great part of it is expired, but it is equally possible that, by phenomena of oxidation, it becomes transformed into arsenious acid and that there is a system of storage in the tissues and organs.

Zangger points out that the action of this poison is quickly over, and that in the body it disintegrates quite rapidly into less poisonous products. According to Hamilton, the elimination of arsenic is very slow.

Arsenuresetted hydrogen is above all a blood poison, a powerful haemolytic agent; but it does not involve the formation of methaemoglobin. The haemolytic action is moreover not finished when the poison leaves the blood. Certain corpuscles are destroyed immediately, others have their life shortened; which explains the progressive decrease in the amount of haemoglobin found on the days following the poisoning.

Lehmann and Dubitzki think that the action on the blood is not always the only or chief one.

The poison as a matter of fact acts on the central nervous and peripheral systems (see later).

**Statistics**

**Great Britain.** — The cases of poisoning notified to the Chief Inspector of Factories were from 1900 to 1918, 53, classified as follows: chemical industry, 28; galvanising, 7; bronzing of metals, 5; dyeing operations, 4; other operations, 9.

From 1920 to 1924 inclusive, 14 cases were reported, of which 6 were fatal, classified as follows: 1920, 5 (of which 3 were fatal); 1921, 1 (fatal); 1922, 4 (of which 2 were fatal); 1924, 3; 1925, 2 (of which 1 was fatal); 1926, 1.

Dudley reports 30 cases of poisoning among a submarine crew, due to corrosion of lead plates in the accumulators by sulphuric acid containing 0.2 per cent, of arsenic.
Glaister in 1908 collected reports on 127 cases of poisoning by arsениуретті hydrogen, as follows:

Chemical operations in laboratories 30
Industrial operations 73
Military aeronautics 16
Wallpapers 6
Unknown etiology 2

Germany. — In the factories at Breslau the factory inspectors observed in 1902, 5 cases of poisoning, of which were fatal. In fifteen years Bachfeld has only seen a dozen cases, of which only one was fatal.

Koelsch in 1920 reported 130 cases of which 36 (27.7 per cent.) were fatal. He deals first with 11 cases (one of which was fatal), which occurred in 1915 in metallurgy during the making of vanadium steel, owing to washing arseniferous ores with sulphuric acid; then with 3 cases reported in 1916 by the Industrial Association (Chemische Berufsgenossenschaft), and with 116 cases reported in 1918 by Heffter and distributed as follows:

Laboratories 14
Chemical and metallurgical industries 64
Aeronautical industry 29
Making of toy balloons 16

According to the reports of factory inspectors cases of arsenical poisoning for the period 1920-1924 occurred in the following industries: in the manufacture of metal articles in galvanising (one case, very rare, was that of a workman operated in colouring a grey steel colour some iron ash bins lined with brass; the ash bins were plunged into a mordant made up of 1 per cent. arsenic, 2 per cent. hydrochloric acid, sulphate of iron and water; precipitation of arsenic occurred when a small stick of zinc was plunged into the mordant, the action of the acid on the zinc liberated hydrogen which combined with arsenic); in a copper foundry at Hamburg; in the district of Wiesbaden during the reduction of a nitrated compound by zinc powder in an alkaline solution; in Bavaria, affecting a person occupied in pouring sulphuric acid into a zinc bucket, etc.

In 1911, Dubitzki could only find 53 serious cases in laboratories, of which 16 were fatal. It is certain that slight cases must be much more common.

In 1914 Prößs reported 39 cases, of which 19 were fatal in 3 to 24 days, classified as follows:

Chemists 12
Filling toy balloons 17
Aniline workers 7
Lead industry 5
Aeronautics 3
Unknown etiology 1

In 1939, 12 cases reported at the Institute of Industrial Diseases at Milan originated in workshops for galvanising and photo-engraving.

The mortality is fairly high, but it is not as high as is ordinarily accepted. Heffter found a mortality of 28.4 per cent. (33 deaths in 116 cases); Geigl, 30.18 per cent. (16 deaths in 53 cases); Bachfeld, 8.3 per cent. (1 death in 12 cases); Koelsch, 9.1 per cent. (1 death in 11 cases), and 27.7 per cent. (36 deaths in 130 cases); Rambousek, 63.3 per cent. (19 deaths in 30 cases); and Glaister, 31.3 per cent. (37 deaths in 118 cases).

Symptoms

The early symptoms are due to anoxaemia, and the later ones to the presence in the blood stream and in the circulatory system of the products of the disintegration of red cells.

In very slight cases, there is simply lassitude, cephalalgia and malaise, sometimes a little dyspnoea and sometimes fainting; but generally work is very little interrupted, or not at all. There is a weak, quick pulse, a fall in arterial pressure, sometimes a yellowish coloration of the skin with the presence of arsenic in the urine (5 cases reported by Wignall).

In average poisoning cases, some hours after the inhalation (4 to 6 hours, Legge; 9 hours, Kunze-Krause) are noted lassitude, vertigo, shivering, syncope; the tongue is furred; there is oppression, heaviness in the gastric region, sometimes distress, nausea, vomiting, gastric, renal or hepatic pains and diarrhoea. Haemoglobinuria appears at the end of 4 to 6 hours; the urine is reddish brown, and for several days, contains blood and bile pigments. At the end of two to three days jaundice appears.

In serious cases, the onset is as in the preceding: the feeling of malaise which occurs at the onset increases in a few hours (three hours generally). There are shivering, fatigue, cephalalgia, pains in the hepatic and epigastric regions, dryness in the throat and thirst; kidney tenderness, breath smelling of garlic, hiccup, bilious vomiting which is sometimes blood-stained; a dull feeling of weakness, somnolence, semi-unconsciousness, giddiness accompanied by restlessness and insomnia; pulse rapid, weak, and regular at first, then feeble and thready; cardiac weakness revealing itself by diminution of the sounds of the heart; palpitations, and syncope; pronounced dyspnoea with cyanosis; haemorrhagic and congested conjunctivae; contracted pupils, slow to react; increased respiration (24 a minute); exaggeration of reflexes (foot clonus), muscular and nervous pains in the upper and lower limbs.

After eight to twelve hours haemolysis supervenes as well as haemoglobinuria.
The urine is blood-stained, and contains dissolved haemoglobin, hyaline casts, filaments of haemoglobin, and "shadow corpuscles." The urine is thick, slightly acid and contains albumen; it becomes very small in quantity, until the oliguria may develop into complete anuria, accompanied by pains in the kidney area.

Towards the second day a severe jaundice of the skin and mucous membranes makes its appearance of a coppery bronze colour, due to a mixture of the yellow colour of jaundice and that of cyanosis. On palpation the liver, and sometimes also the gall bladder, is found swollen and enlarged, signs of hyperactivity of the organ overburdened with its duty of destroying haemoglobin set free by haemolysis. The formation of bile is increased as much as up to twenty times the normal quantity. The spleen is also perceptible.

As regards the kidneys, there is sometimes a blocking of the urinary canalici by cellular debris, which explains the oliguria passing on to anuria. At the same time deep-seated changes take place in the structure of the protoplasm of the parenchymatous elements of the kidney. In some cases they may be nearly completely destroyed, only a small cellular focus remaining intact; it is from this focus that the complete regeneration of these organs is carried out (Zangger). Apart from these lesions, more ordinary symptoms may occur — for example, inflammation — which sometimes persist for a long time during convalescence.

The pathological conditions observed are then connected directly or indirectly with the effects of the poison on the blood.

Haemoglobinaemia brings in its wake jaundice and haematuria. Other troubles arise from the action of cell debris thrown off into the system. The kidneys and liver are overpowered by the increase of work, which elimination of the products of destruction of the blood cells necessitates. This in particular explains the increase in bile, which can no longer be excreted and invades the liver. The jaundice is definitely haemo-hepatogenous.

The blood picture is interesting: diminution in the number of red blood cells and of the haemoglobin index. In a week three-quarters or four-fifths of the cells are destroyed. Their number may fall to one and a half, or two millions, at the same time as the haemoglobin index diminishes from 16 to 20 per cent. (Koelsch). "Shadow corpuscles" appear. According to Hamilton baphile granulations, poikilocytosis, and anisocytosis are found. The blood is of a dark colour and laked; its alkalinity is diminished. Anisocytosis can, however, be considered as a sign of tumultuous regeneration rather than the index of a toxic condition (Biondi).

In addition to these lesions, there are to be detected signs of regeneration of the red blood cells which, as a matter of fact, go on for several weeks after the end of the poisoning; and also the presence of erythroblasts, of nucleated cells, of polychromatophiles, and of granulobasophiles. The myeloblasts are more numerous than the normoblasts. There is an increase in the thrombocytes.

A myelogenic reaction is also found with a modification of the leucocyte count. Hyperleucocytosis exists without there being any parallelism with the intensity of the poisoning. Whilst generally there is an increase in the number of neutrophile leucocytes, it may be said, from the point of view of the various groups of leucocytes, that there are individual reactions.

In one fatal case studied by Délépine the autopsy showed hypertrophy of the liver, which was in a state of fatty degeneration, the tissues adjacent to the big vessels being strongly coloured black from altered blood pigment. Under the microscope the hypertrophied tissue appeared in great measure to be atrophied and pigmented with necrosed areas. The kidneys were also hypertrophied, with commencing necrosis of the epithelium.

Clinical course. — In very slight cases, cure is effected in a few days.

In medium cases, the disease follows a favourable course and the symptoms subside. The blood and bile pigments disappear from the urine, but troublesome albuminuria persists and convalescence is fairly long, and strength is only slowly regained.

In serious, but not fatal, cases, convalescence occurs very slowly. More often than not the symptoms get worse; there is great weakness, dyspnoea, cyanosis, multiple haemorrhages, clonic spasms, unconsciousness, delirium, coma, and oedema. The pulse, hard at the onset, becomes quick and small; respiration slows; hiccup appears; and death occurs towards the second or third day at earliest, at the end of a week generally. The patients retain consciousness generally up to the end, although in the final period unconsciousness may occur with or without delirium. Sometimes death occurs more slowly; a case has been recorded of death on the thirtieth day (Koelsch)
which was due to anaemia (Bachfeld),
to action on the nervous system,
uraemia, and to cardiac failure.

In general, acute poisoning by
massive dose — such as is met with
in the manufacture of arseniuretted
hydrogen as a war poison gas — death
occurs rapidly without haemolysis
having time to show itself.

In very acute, and immediately fatal,
cases, the original cause of death is
haemoglobin and consequent cellular
asphyxia: in cases which are not
immediately fatal, death arises from
lesions of such organs as kidneys and
liver (secondary cause of death).

In serious cases when death does not
occur, sequelae may appear, the effects
of the poison on the nervous system
making themselves felt in various ways
and chiefly in the acute period.

An early sensitiveness of the nerves
which should not be confused with
polyneuritis, disappears in five to six
or eight cases on after an
interval; it depends on the toxic effects
of arsenic making themselves felt when
the poisonous arsenical albuminoid
combinations are decomposed (Zangger).
Toxic polyneuritis in some cases
develops two to four weeks after the
poisoning; it is shown by pains in the
nerves, especially in the extrem-
ities and between the ribs. A diminu-
tion of sensibility is also noticed, but no
motor disturbances. This polyneuritis
disappears in seven to ten days and
the patient returns to a state of health,
but slowly.

A typical picture of poisoning by
arseniuretted hydrogen was drawn in
1924 among the fishermen of Frisches
Haff, characterised by a special haemo-
globinuria. During the late hours of
the night, or the early hours of the
morning, after their work, at a time
when the fishermen lived in the lagoon, the fishermen were attacked by
a feeling of malaise and stiffness in the
joints. A little later a crisis developed
with full intensity: muscular pains
affected the neck, back, and loins, and
so severe that they fixed the patient in
absolute immobility, most often in his
boat, incapable of the slightest move-
ment for hours and even days until
someone came to his assistance.

The pains were often accompanied by
dyspnoea, cold extremities, and sweats.
Following retention of urine, at first
defeated unfruitful passing of a brown and
even black urine, which contained
haemoglobin, methaemoglobin and uro-
bilin, with four to five per cent. of
albumen and an abundant sediment,
made up chiefly of casts of haemoglobin.
The pulse was rapid and feeble, then

it slowed; the temperature was normal;
spleen not increased in size; mentality,
reflexes, and cutaneous sensibility re-
mained unaltered. The muscular pains
disappeared at the end of twelve to
twenty-four hours; the urine gradually
became clearer, but the albuminuria
often remained for two to three weeks.

Some atypical cases had myalgias
without haemoglobinuria, or haemo-
globinuria without myalgias.

The mortality was very low; for out
of 450 fishermen affected from the last
days of July up to the middle of
November 1924, 6 died. Four of the
fatal cases, however, occurred in sub-
jects who had incurable organic dis-
eses.

The fishermen who had been affected
once seemed more liable to fresh attacks,
as many as eight successive attacks
being observed; each time the attacks
developed in similar circumstances.

Chronic poisoning is a doubtful ques-
tion. If it exists, it does not give rise
to specific symptoms; but repeated, from
day to day it causes a chronic patho-
logical condition, perverting the physi-
ological functions of the blood-forming
system. Workmen, and more especially
chemists, who are exposed to chronic
inhalation, apart from the occurrence
of definite haemolysis, generally ex-
perience lassitude and an overpowering
sense of fatigue, without depressing
influences and loss of energy from
other causes entering into account.
Cardiac palpitation on the least exer-
tion is also noticed, the cause of which
may be sought in a whole series of other
causes. As headaches often occur,
"anticephalics" are prescribed sys-
tematically. In other cases there may be
cardiac instability, or digestive troubles
with anorexia and sometimes diarrhoea.

In these different cases it should be
noted that anaemia is not very pro-
mocious, apart from the occurrence
when the blood picture, however,
shows signs of regeneration, but not
very definite.

**Prognosis**

The prognosis of acute poisoning
depends first and foremost on the pre-
sence of oliguria; it is bad when the
quantity of urine passed diminishes.
Apart from lack of oxygen and asphyxia
of the tissues, consideration must be
paid to the part played by uraemia, to
decrease in the activity of the renal
functions, and to invasion of the blood
by urinary products.

**Diagnosis**

A positive diagnosis should be based
on the chief signs at the onset: cephal-
algis, weakness, nausea, vomiting, and blood-stained urine, appearing suddenly. The presence of jaundice confirms the diagnosis. However, at the onset of slight or average cases, which are the most important cases in practical industry, it is fairly difficult to make a diagnosis and it is necessary to eliminate gastric catarrh and catarhal jaundice.

In the most marked cases the absence of methaemoglobin enables a distinction to be made between acute poisoning due to nitro-compounds, such as nitrobenzene, which forms methaemoglobin, and to amido-compounds with their marked cyanosis. In poisoning by chloride of calcium, there is no jaundice. Poisoning by aniline is characterised by a livid colour, by methaemoglobin in the urine, and the absence of jaundice.

However, jaundice and haemoglobinuria are met with in a certain number of poisonings, and it is necessary to exclude all toxic haemalytics; the inorganic, e.g. Iyes of soda and potash, alkaline carbonates, and chloride of calcium; the organic, e.g. alcohols, ether, glycerine, Soaps, and cynamide of iodine; the animal, e.g. biliary salts and snake poisons; the vegetable, e.g. saponin, menthol, acconitine and piincoline; the animal, e.g. biliary salts and antimony; the organic, e.g. antimony and iodine; the animal, e.g. biliary salts and antimony; the vegetable, e.g. saponin, menthol, acconitine and piincoline; the animal, e.g. biliary salts and antimony.

Arseniuretted hydrogen, on the other hand, is the only one which is gaseous and capable of developing, at the expense of methaemoglobin. There is no jaundice, but all these poisonous substances must be absorbed per os, or penetrate by a break in the skin or mucous membranes. Arseniuretted hydrogen, on the other hand, is the only one which is gaseous and capable of developing, at the expense of methaemoglobin.

In addition, arsenic was found in the urine of patients (0.1 mg. per litre), in the stools (0.001 mg. per 5 grm. of stools) and even in the blood (0.05 mg. per 7 grm. of blood).

It must, however, be added that further researches (1926) of Matheis on the sequelae of the disease, of Meerwein on the water of the gulf, the air and gases of the schtanmi (mud), or Rohde, who experimented on animals, of Selter and Palewka on the sewage water, and finally pathological anatomical researches of Kaiserling, have not been able to confirm the results stated above, nor to justify the acceptance that the epidemic was due to arsenical poisoning; so the etiology of the disease of the gulf, according to these experts, still awaits solution.

**DETECTION**

This gas having a smell of garlic, the tendency is to consider that when this smell does not exist, arseniuretted hydrogen is not present. But recent work and a certain number of instances show, on the one hand, that the garlic smell is a poisonous substance, such as ethylarsine and diethylarsine, exist which have a smell of garlic (Biginnelli, Kunz-Krause, Arnold, Kober), and that, on the other hand, poisoning may occur without arseniuretted hydrogen being perceptible by its smell. Heffer thinks that the smell disappears in strong and fatal concentrations, and, as a matter of fact, Jaeger reported, in 1925, 41 cases of poisoning, of which 19 were fatal, in connection with which no odour was present. He must then be concluded that no relation exists between the concentration of arseniuretted hydrogen and the diminution of the garlic smell; that this poison in its nascent state is quite inodorous, and that the garlic smell is due to a change in the arseniuretted hydrogen which contains derivatives analogous to ethylarsine. The pure product is no less toxic than its derivatives, but the danger it presents is increased by the absence of smell.

Hebert and Heim have established a method of detecting arseniuretted hydrogen and have constructed a "hydr arseniometer", which depends on a yellow colour reaction between the poisonous gas and mercuric chloride. As a preliminary the gas for analysis is made to pass into a hydrochloric solution of cuprous chloride at 15 per cent. with the object of eliminating sulphuretted, phosphoretted and ammonium hydrogen, which may accompany arseniuretted hydrogen. The gas is then passed into a tube containing test papers soaked in mercuric chloride at 5 per cent. which turns yellow under the influence of the poisonous gas. The paper prepared beforehand can be kept in small strips, which only require to be slightly moistened by some drops of water at the time of using. The reaction is sensitive at 1 in 100,000.
These same writers advise also placing in workshops small birds, whose sensitivity to the poison is such that they can play the part of indicators just as they can in the case of carbon monoxide. In any case they are poisoned by doses which are harmless to man.

The quantitative method of Dubitzki utilises as absorbent materials silver nitrate, hydriodic acid, or chloride of calcium.

The test for arsenic in urine can be carried out by means of Marsh’s apparatus. (For the method of Gosio see the footnote on page 170.)

**Prophylaxis**

**First aid.**—In case of acute poisoning, the earliest etiological indication is to ward off asphyxia by administering oxygen under pressure; by blood transfusion; by bleeding and injecting physiological serum or Ringer’s solution; and by giving heart tonics and liquids which encourage diuresis.

Of course any liberation of arseniuretted hydrogen must be avoided.

When employing commercial hydrogen, Wentzki’s method of purification should be used. The hydrogen is passed through a cylinder containing a mixture of two parts of dry chloride of lime and one part of moist sand; it gives off any arseniuretted hydrogen and takes up a little chlorine which is retained in its turn by slaked lime.

In operations involving the liberation of hydrogen, only materials which are free from traces of arsenic should be used, or at least a preliminary examination should be made of their strength in arsenic. The strength of arseniuretted hydrogen in the atmosphere depends on the strength of arsenic in the raw materials, on the quickness of the reaction, on the quantity of the materials brought into contact with each other, on the cubic capacity of the place where the operation is carried on, and on the frequency and intensity of the ventilation.

Sight must never be lost of the possible liberation of arseniuretted hydrogen during certain operations which should be carried on either in closed apparatus, or in apparatus provided with a good exhaust.

Coal can also be a cause of arsenical poisoning.

Further, good general ventilation is needed; notably of places where ferrosilicon is stored. Dry warehousing prevents the development of vapours and poisonous gases.

Workers should be instructed in the dangers to which they may be exposed.

**Legislation**

The Regulations laid down for poisonous gases are applicable (see that article). In Prussia the Ministerial Ordinance of 5 October 1887 (revised 22 October 1902 and 8 January 1921) draws attention to danger from liberation of arseniuretted hydrogen. A series of instructions have been prepared by the Industrial Association of the Chemical Industry (1 January 1912).

Injuries caused by arseniuretted hydrogen are subject to compulsory notification in the State of Missouri, U.S.A. (see article “Gas and Fumes”), and in the Netherlands. Compensation is provided by the legislatures which compensate for poisoning by poisonous gases and is included in the schedule drawn up by the British Government, in the British Dominions where the law provides for cases of poisoning by arsenical compounds, and in Switzerland. Acute cases are generally treated everywhere as accidents.

**Bibliography**

For literature dealing with gulf or Half disease, see the *Bibliography of Industrial Hygiene* published quarterly by the *International Labour Office*.

Prof. H. Zanger (Zurich).
Artificial Flowers

BIBLIOGRAPHY

Artificial Flowers

Under this name are comprised artificial flowers, leaves, and fruit used for decoration, for funeral wreaths for trimming ladies’ hats, for wearing in the hair and on ball dresses, etc.

The raw material for this industry is silk, cotton, paper, gold beaters’ skin, celluloid and other artificial substances. For making up the flowers, caoutchouc or waxed cloth, glue (glues with a para basis dissolved in acetone, benzol, etc., in the rubber industry), starch paste, cotton, seeds, pistils, etc. The hearts of the flowers are made of cotton covered with rubber solution and dusted with coloured powders. The woman worker fixes in the pistil and petals with glue, covers the stalk with a tube, and mounts the little bouquet by means of very thin wire.

SOURCES OF RISK

The work is generally done in the workers’ homes or in badly lighted, overcrowded workrooms. It demands exercise of the small muscles of the hand and fingers, and continuous visual effort. The affections met with are in general the result of the sedentary life, the confinement, and work prolonged into the evening.

The diseases cited by various authors (skin diseases and lead and arsenic poisoning) are certainly of less frequent occurrence to-day than in the past. Besides cases of anaemia, chlorosis, dyspepsia, and tuberculosis, a fairly high incidence of cases of lead poisoning, due to the use of lead chromates, white lead (handling lead patterns and flowers dusted with lead colours), cases of arsenical poisoning (from use of arsenical colours, particularly green) characterised by cutaneous eruptions,
and general symptoms of poisoning have been reported. It is well known that fuschin was formerly prepared by the arsenical method, with the result that the colour was always contaminated by arsenic, whence the frequent cases of arsenical poisoning. Cases of mercurial poisoning were found to be of rarer occurrence.

Amongst other products which may injure the workers' health may be cited picric acid, which imparts a yellowish colour to the nails, methyl alcohol used to dissolve aniline colours (risk either in course of dipping or of drying; in an American factory an analysis of the air showed two parts in weight of methyl alcohol in 10,000 parts of air), celluloid (burning accidents), poisonous gases, glues (risk from their solvents), etc.

The authors who have dealt with this question report likewise cases of spasm of the fingers, of paralysis (due to lead poisoning from lead chromate). conjunctivitis, dermatitis, due to methyl alcohol, irritation of the mucous membrane (eyes, throat, etc.) due to silicon dust. Vernois met with thinness of the epidermis of the palm of the hand amongst women engaged in making up bouquets, and he found that they also suffered from redness and hyperaesthesia of the inner surface of the top joint of the thumb and index finger which was often the seat of a psoriasis-like eruption.

According to Hirsch, flowermakers present a fairly high rate of myopia (14 out of 146 examined); this class of work does not, however, figure amongst those noted as constituting an important cause of shortsightedness.

In a case studied by Vollert the use of grass plants with seeds was the cause of serious mydriasis and paresia of accommodation: it was, in fact, the effect of datura stramonium.

The authors who have dealt with this subject are Follin (1857), Vernois (1859), Van Den Broeck (1861), Charcot (1886), Pichard (Paris Thesis, 1900-1901), etc.

The legislative measures passed as regards the use of toxic colouring matters in industry (especially lead and arsenic) have effected an increasing reduction of the risk of poisoning amongst this class of worker. Never- that would have been impossible to provide special regulations relative to dipping, brushing, and drying of the colouring agents, especially when these are dissolved in liquids (methyl alcohol, carbon tetrachloride, benzol, etc.), which may liberate harmful fumes (with modern exhaust apparatus, use of tools, etc.); general hygienic precautions for the workrooms (requisite floor space, good ventilation, lighting, etc.).

Arsenical poisoning occurring amongst women workers in artificial flower factories is subject to compulsory notification in Holland. ***

Artificial Silk

Artificial silk, the chemical composition of which differs from that of natural silk (see article on that subject), is derived from cellulose and contains only a trace of nitrogen. Natural silk is distinguished from cotton and artificial silk by the solubility of its fibre.

RAW MATERIALS

The raw materials usually consist of waste cotton, and pulp of wood or paper. The last are used particularly in the viscose process.

Method. — Cellulose or its derivatives are dissolved in a suitable liquid; after this liquid has been passed through capillary tubes it is coagulated either by neutralising or diluting the solvent, or by breaking up the dissolved product; when necessary the cellulose is also regenerated.

Artificial silk is made by four methods at the present time:

(a) by dissolving nitrocellulose in a mixture of alcohol and ether, or in colloid (Chardonnet, Lehner, Tubize);

(b) by the copper ammonia process (Despeysis, Pauly — "Glanzstoff ");

(c) by the viscose process (method of Cross and Bevan);

(d) by the acetate of cellulose process.

INDUSTRIAL METHODS

Artificial Silk from Nitrocellulose

The idea of manufacturing an artificial silk is due to Réamur (1734), but the first patent only dates from 1853; that was followed by the patent of Hugues (1857) and the method of the Englishman, S. W. Swan, who passed nitrocellulose into alcohol and denitrited it by ammonium sulphide.

The first method to be used commercially, however, was that of Chardonnet (1884) based on the following processes: nitration of cotton (bleached, carded and dried); preparation of colloid by dissolving nitrocellulose
in a mixture of alcohol and ether; drawing the cellulose so dissolved into threads and evaporating the solvent during the winding and throwing processes; and, lastly, denitrating the thread so obtained.

Lehner, the factory of Tubize, and others have added several modifications to the method of Chardonnet.

Preparation of the cotton. — The cotton is bleached, carded and then dried in a drying-stove with warm air. Steps must be taken to suppress as far as possible any fine cotton dust which escapes during the carding and when the carded cotton is moved. Nevertheless fine dust is always present in these workshops, but it may be considered as relatively of little danger. In some factories nickel respirators are provided for the workers.

Nitration. — Perfectly dry cellulose (from cotton or wood) is added by degrees to a mixture of sulphuric and nitric acids. The strength of this mixture will vary according to different factors, such as the quality of the cotton and the external temperature; but, generally speaking, the mixture consists of 5 parts of sulphuric acid (at 60° Baumé) and of 2 parts of nitric acid (at 41° Baumé).

It is heated at 40° C. without pushing the nitration too far; it is dried and passed into sulphuric acid (specific gravity = 1.35); then dried again and washed with water, but not thoroughly. For the nitrated product should contain a very small quantity of free acid. The nitrocellulose so obtained is a mixture of hexanitrocellulose \((C\textsubscript{6}H\textsubscript{2}NO\textsubscript{24}O\textsubscript{5})\) and octonitrocellulose \((C\textsubscript{6}H\textsubscript{2}NO\textsubscript{32}O\textsubscript{5})\).

Dangers. — Acid fumes (especially nitrous fumes) may be set free in considerable quantities either during the mixing of the sulphuric acid with nitric acid, or during the process of nitration. Nitrous fumes (see article “Gas and Fumes”) act either in a caustic manner upon the skin and mucous membranes, or, by a general action on the system, especially on the red blood corpuscles.

Hygiene. — The health of workers employed in the preparation of the acid solution and in the nitration and drying departments bears a direct relation to the adoption of well-known hygienic measures. Some enquiries have shown that the labour turnover is decidedly high, but medical examination has not brought to light any serious troubles. It is nevertheless wise to provide the most effective means of protection, such as localised ventilation specially arranged to remove the greater part of the nitrous fumes which escape from the earthenware pots during the steeping and stirring, and especially while decanting the mixture into vats and into the hydroextractors. But it sometimes happens that in this last operation considerable quantities of nitrous fumes escape owing to the exhaust draught being insufficient.

It is often found that the material of the ventilating plant is rapidly corroded and put out of action by the acid fumes when suitable material is not employed nor appropriate technical methods applied. The hoods and ducts must be constructed of material which will not become rapidly corroded, like exposed metal, nor must they be covered with such material. The passage of dust into a chimney provided with an efficient draught has given good results.

Dissolving nitrocellulose. Drawing the threads. — Dried nitrocellulose is mixed with an oil, the drying properties of which are rendered more effective by the addition of half its weight of ordinary either. Twelve to 20 per cent. of chloride of sulphur is added while constantly stirring; it is allowed to stand and then decanted; the whole quantity is thereafter dissolved in five times the amount of methyl alcohol or alcohol and ether.

The collodion so obtained is drawn through very strong pipes, with capillary glass tubes fitted through their sides; these tubes are controlled by taps. The fluid escapes from each small opening (size from 25 to 50/100 mm.) in the form of a liquid thread which solidifies almost instantaneously, and is passed into a bath which removes the free acid as well as the solvent, and hastens the oxidation of the oil. The threads are collected by revolving drums (glass spools) upon the surface of which they are wound, or by a hollow drum on which they are deposited in hanks by centrifugal force. For dissolving nitrocellulose, acetone, acetic acid, ethyl-acetate, etc., are also used.

Dangers. — The ether-alcohol solvent (of which up to 10 or 12 litres are used for 1 kg. of commercial silk), having been used for the dilution of the nitrocellulose, evaporates during the processes of thread-drawing and silk-throwing. Danger arises in equal measure from the saturated hydrocarbons which may be found mixed with this product.
The workshops in which the thread-drawing and silk-throwing are done are, on account of the evaporation of the ether and alcohol, the parts of the factories most condemned by hygienists, despite the fact that some investigators have not found any characteristic troubles nor any particular disturbance, such as others seem to have found, even at the end of a day's work. Nevertheless, exception must be made in regard to the work of pregnant women; it would be preferable to employ them, when the pregnancy has become clear, in a workshop other than that used for thread-drawing. Similarly, in the somewhat rare case of a mother feeding her child at the breast, the same precautions should be taken.

During the throwing and waving the amount of alcohol which evaporates is very slight. Brisk ventilation is sufficient to dispel any troubles which may arise (giddiness, faintness) when beginners, who are specially liable to suffer, first enter the workshops.

Although experimental research has shown that the poisonous action of an alcohol-ether mixture is very serious and that the fumes of the mixture are more poisonous than the fumes of either alone, there is no mention in literature of any characteristic trouble among the women employed in the manipulation of threads of artificial silk.

It is especially at the commencement of their career in the workshop that beginners experience all the phases of ether intoxication: excitement, feeling of discomfort amounting almost to stupor, etc. The expired breath smells of ether or alcohol (according to the exposure). But the doctor has only on rare occasions the opportunity of seeing workers at this stage. Acclimatisation is rapidly acquired, when work can be continued without the workers showing any apparent ill-effect. Nevertheless, individual susceptibility varies considerably and it may be necessary for some workers to cease work.

The early symptoms are local troubles of the conjunctivae (smarting, watering; earliest symptoms of the effect of the fumes); and blepharitis (principally caused by contact with dirty hands). Respiratory troubles follow (cough, hoarseness, abundant nasal discharge, constriction of the larynx, dysphagia, and a desire to expectorate). If the worker does not become habituated the following symptoms are observed in the serious cases: loss of appetite, vomiting, insomnia, and periods of restlessness and somnolence.

**Hygiene (vide infra).** — For fuller details see articles “Alcohol”, “Ether”, and “Explosives”.

**Denitrating.** — The denitrating of the threads is done by means of sulphide of ammonia (with the addition of a neutral salt of magnesium) or a solution of ferrous chloride. In the latter case the threads are passed through an acid bath to remove the iron. The process then consists of rewashimg and cleansing with additions of hypochlorite of lime, washing again and drying.

If the threads are to be dyed they are softened once more with suitable reagents (soap, dilute alkalis, acids), or by solvents of the substance of the thread, such as acetone and alcohol.

**Dangers.** — These arise from the employment of sulphide of ammonia, of acetone, of alcohol, of acid fumes, of ammoniacal fumes and on certain occasions of sulphuretted hydrogen which may be given off.

During denitrating ammoniacal fumes may cause sharp irritation of the mucous membranes, especially of the conjunctivae. In order to avoid, at least in part, this inconvenience, the sulph-hydrate of soda is used instead of that of lime. The smoothing by a practised hand of the hanks (to prevent the deposit of sulphur resulting from the breaking up of the sulph-hydrate of lime) calls for the provision of indiarubber gloves for the workers, as this operation causes ulceration, or particularly painful dermatitis.

**Hygiene.** — The fumes of hydrogen sulphide and the small quantity of ammonia should be eliminated by means of localised ventilation, which must of course be installed with suitable technical adaptation and without inconveniencing the workmen employed at the vats. In the same way the very serious discomfort which is caused by fumes which are given off in the several branches of the industry — and which, according to circumstances, are strongly acid or alkaline (during the bleaching of cotton, drying, cleansing, washing, etc.) — can be kept down by modern methods, although some difficulties are occasionally encountered. Elimination of fumes is closely bound up with the removal of injurious gases.

**Silk from the Copper-Ammonia Process**

This process is based upon the solubility of cellulose in Schweitzer's fluid (an ammoniacal solution of copper oxide). The solvent is obtained by the
The precipitation of copper hydrate from a solution of copper sulphate by means of soda. The precipitate is washed and dissolved in ammonia. Another method of preparing the solvent is to make air bubble through ammonia containing metallic copper, an electric current being then passed through (Pauly).

The solution of cellulose used for threads contains 7 to 8 per cent of ammonia and a little cane sugar. The precipitation formerly obtained by 50 per cent. sulphuric acid (followed by washing the threads with acetate of ammonia diluted with a tepid solution of soap) is now obtained by an alkaline medium (with or without glycerine). The threads, having been soaked in a bath of soda lye at 48° to 50° C. (which at the same time produces a mercerisation of the silk), are then washed, passed into a bath of sulphate of magnesium or aluminium (in order to displace the base) and again washed and dried. The thread after twisting is wound on bobbins. The copper remaining in the thread is removed by passing it through dilute acid. This is followed by washing, cleansing with soap, and drying.

Dangers. — In the copper-ammonia process risks arise from the employment of alkalis and acids.

Some workmen in Germany in 1919, who were employed in washing artificial silk with lye, suffered from very painful dermatitis, confined to the hands and forearms. In another German factory irritation of the eyes and of the skin due to the ammonia were noted, but such cases were completely abolished by introducing a good system of localised ventilation. The fumes absorbed were washed with dilute sulphuric acid in order to eliminate the ammonia.

The Viscose Process

This process, dating from 1892, is the one which is most widely applied. In it use is made of waste cotton and especially of paper pulp. A remarkable product is obtained, namely the thio-carbonate of cellulose, or "viscoïd". Viscose is a viscous solution of xanthate of cellulose and of sodium, obtained by the action of sulphide of carbon upon alkali-cellulose. Paper pulp in leaves bleached by bisulphite is placed in a special chamber at a temperature of about 20° C. in order to maintain for the paper a constant percentage of humidity (from 10 to 12 per cent.).

The steeping and pressing of the paper takes place in vats (steeping presses) into which is directed soda, or the steeping lye (at 20 per cent.), which is a solution of the soda used in commerce (or of caustic soda), in water, mixed with the soda used in the pressing. A male screw movable in a female screw and holding a large metal plate ensures slow compression of the leaves of paper in the mixing vat itself. The excess of alkali is removed at the lower part of the vat.

The leaves are then spread out on canvas sheets and dried for 15 minutes.

The alkali-cellulose so obtained is an oily pulp of a white or yellowish colour, slightly transparent or silky in appearance. This pulp is then ground between granite millstones (or better in crushers or mills) and allowed to stand for from 48 to 72 hours at a fixed temperature. The ground or crushed alkali-cellulose, which, after it has lost a light flaky product is then treated with bisulphide of carbon in a hermetically-sealed mixer with temperature regulated by water circulating through a water jacket. The process is stopped when the mass assumes an orange colour and is slightly sticky to the touch. The excess of bisulphide of carbon is evaporated at the end of the reaction by a system of vacuum tubes.

The pulpy mass is then dissolved in a solution of soda by means of "mixers" and a homogeneous solution obtained, which is the brown or black, and very viscous, colloidal salt of viscose; it is filtered and then allowed to stand for some days (the maturing process). The soda contained in the mass is then neutralised by the addition of ammonium sulphate; it is next filtered and the filtered solution is thereafter subjected to the action of a vacuum.

Hydrocellulose, made according to the method of Girard, may be substituted for pure cellulose; in that case the consumption of soda and sulphide of carbon is much reduced.

Thread-drawing is done as for the other silks. The thread coming from the capillary tubes is coagulated by means of a cold bath of ammoniacal salt followed by boiling. It is then washed and treated with lye-wash, hypochlorite of soda and dilute acid; after which follows desiccation and drying. Other makers produce coagulation by means of other agents such as bisulphite of soda, ferrous sulphate, etc.

The product obtained can be bleached or rendered impermeable by means of formaldehyde in the presence of acid, etc.
Dangers. — These arise mostly from the sulphocarbonic fumes. Lehmann mentions serious troubles which occurred among women workers at a Hungarian factory in 1909: headache, gastric trouble, diminution of sight, psychic condition, delirium, and even loss of consciousness. Some similar cases have also been reported recently (1924). The poisonous action of the vapour of carbon bisulphide is favoured by the temperature, so that during the warm season cases of sickness and poisoning are more frequent. Dermatitis, caused by the irritating materials, has also been reported. Inflammable products utilised may give rise to fire and explosion.

The thread-drawing operations are usually carried out at a temperature of 18° C. with a humidity percentage of about 60. This percentage is sometimes exceeded, especially in the processes of washing, winding on reels, and retwisting (up to 70 per cent. relative humidity). In Italy also it has been remarked that workers who come from the country only become acclimatised with difficulty and that managers have to hold a reserve personnel (6 per cent. for men and 12 per cent. for women in 1924).

According to a recent report of the French inspectorate (Chevalier, 1922) no serious accidents or cases of poisoning, even of a slight degree, have occurred in a factory using the viscose process.

The sulphide causes very little harm when a tightly closed apparatus is used with exhaust ventilation for fume removal. In the same way sulphuretted fumes (sulphuretted hydrogen, etc.) should be removed by good localised ventilation. After bubbling through a vat containing caustic soda, the fumes should be discharged into the atmosphere from a very high chimney.

The fairly serious troubles, reported since 1910 by the German factory inspectors as caused by bisulphide of carbon, have in the course of time been largely reduced by the introduction of more effective apparatus.

In the Dutch viscose factories dermatitis (confined to the fingers) has been noticed among the workers in the bleaching section, and cough caused by the action of the fumes of chlorine and hydrochloric acid. The attention of medical practitioners and of the medical inspectors of labour has been drawn to quite a large number of cases of an affection of the conjunctival epithelium, a superficial keratitis (Nederl. Tijdschr. v. Geneesk., 11 August 1923, page 576). Dr. Bakker, who has studied these cases, says that the keratitis has a close resemblance to electric keratitis. He has excluded sulphuretted hydrogen as a cause and attributes the condition to some organic compounds of arsenic or other similar compounds. He has drawn attention to the facts that good ventilation has sufficed to prevent the troubles which were formerly of such frequent occurrence among the workers, that such workers show no other symptoms of poisoning by sulphuretted hydrogen, and that this gas was detected at the level of the head of the workers in a strength not exceeding 0.09 mmgr. per litre. He is of the opinion that the organic compounds of arsenic are able to exert their poisonous action in a strength of a hundred millionth of a milligram per litre of air, and that in the viscose factories in which solutions containing chlorine are employed arsenic is always present as an impurity. These solutions acting upon organic compounds (cellulose) may, then, set free in the course of complicated reactions products similar to those in question.

Lehmann, having directed his attention to this subject, has put forward the opinion that sulphuretted hydrogen is likely to be the cause of the troubles rather than organic compounds of arsenic. Similar cases reported in Germany, France and Italy have as a matter of fact been attributed to the action of sulphuretted hydrogen. In Italy it has been shown that small drops of alkaline solutions of sulphate and bisulphate of soda or of xanthogenate carried to the eyes by dirty hands have also caused conjunctival troubles. Clearly, if certain operations are done in a manner which is a little primitive (especially the filling of the baths, the taking of samples) more acid fumes will be emitted in consequence and the particular troubles will be both more serious and more frequent.

In addition, Parmenter described in 1921 some cases of poisoning by tetra-chloroethylene which had been previously reported in an American factory among workers employed in winding the thread on bobbins and drying it. The number of cases among 95 persons during five months was 21, of which 9 were fairly severe.

The Acetate of Cellulose Process

This process, which is quite recent, makes use of the triacetic acid compound, or triacetate of cellulose, with various acetic ethers of cellulose. Bleached and dried waste cotton is treated with a mixture of acid and
acetic anhydride for several hours at a low temperature in the presence of a catalyser (sulphuric acid or the sulphate or chloride of zinc, etc.). It is then diluted with 50 per cent. acetic acid with sulphuric acid added to it; it hydrolys for three hours and is allowed to mature. The acetate of cellulose is precipitated by cold alkaline water if the solvent mixes with water, if not by alcohol, or benzene; it is then filtered, washed and dried. The white flaky mass so obtained is scarcely inflammable at all; it is insoluble in water, in methyl alcohol, ethyl alcohol, benzene and carbon tetrachlorid. In order to draw the thread use is made of its property of dissolving in acetone, glacial acetic acid, formic acid, chloroform, methyl acetate, acetalddehyde, tetrachloroethane, etc.

The thread produced coagulates very rapidly and, after washing and drying, is ready for use. The silk obtained can be considered as a pure ether of cellulose.

Dangers. — These arise in the course of the preparation of nitrocellulose and thread-drawing, from the employment of alcohol, ether, glacial acetic acid, benzene, tetrachloride, carbon, tetrachloroethane, acetone, etc., containing up to 30 per cent. of sulphurous anhydride, etc., used in the various processes of the manufacture of artificial silk.

Uses

The uses of collodion, of viscose, and of acetate of cellulose are very numerous. In addition to the making of different artificial silks, they are used in the preparation of varnishes and lacquers (see also article "Tetrachloroethane"); for waterproofing fabrics; for gumming paper used for packing; for embedding paper or materials when receiving art impressions; for preparing materials (in dyeing); as a mordant in treating cotton with iron, aluminium or chromium; for the manufacture of films (cinema and photographic), and of insulating material (used in electrical work); for capsules for bottles; for sponges; for bristles; as a substitute for gelatine (mixtures of viscose with viscose, and collodion, mixed with india-rubber and celluloid); for billiard balls; and generally as a substitute for wood in the manufacture of small articles. The solution of cellulose nitrate in alcohol ether (collodion) is well known and is used in photography; in surgery, in the manufacture of artificial silks, in that of celluloid and of cellulose ether see those articles.

Hygiene

The special precautions recommended for the construction of factories classed as dangerous or unhealthy on account of danger from fire or explosion must be taken.

Operations should be carried on in closed apparatus or provided with ventilating hoods connected with an efficient system of ventilation. Removal of poisonous fumes (nitrous, alcoholic, ether, bisulphide of carbon, etc.) should be carried out in connection with a recovery process by ventilation as far as possible localised or in closed apparatus. Wherever it is possible manual labour should be replaced by machines. Greasing of the hands or wearing india-rubber gloves may be recommended in order to avoid contact with irritating substances, but the workpeople consider these measures of no value and generally do not adopt them. In one German factory women, found too susceptible to dermatitis, were replaced by men.

It is not possible to state in detail here the best measures for preventing the escape of fumes. It is a difficult problem which requires a particular solution for each factory. It is in fact the problem occupying the attention of all industries in which fumes escape (see articles "Air: Hot and Humid", "Textile Industries", etc.).

The condensation of poisonous vapours, and especially those containing alcohol ether, is an operation important from the viewpoints both of economy and health. The recovery of these products represents considerable progress in hygiene, although very serious technical difficulties are encountered. The collection of the fumes should be effected at their point of origin without allowing them first to diffuse in the air of the workshop.

Residuary fluids should be subjected to chemical treatment by lime, salts of iron, etc., precipitation of solid materials, aeration, etc., before they leave the factory. Acid fluid from the nitration and alkaline fluid from the washings to remove the sulphides, neutralise each other; but the denitrification of the waste water is never complete, and it always contains nitrates, sulphides, or at least sulphur.

If escape of sulphuretted hydrogen is feared it is desirable that the air should be analysed at regular intervals (this method was adopted in a German factory).

It is equally desirable that the workers should be examined every three months and that those who are not in
good health, or who show a predisposition to the kinds of sickness described above, should be removed. If possible a rotation of workers should be organised. Persons exposed to risks at their work should be instructed as to these, and facilities for personal hygiene should be placed at their disposal.

The risk of fire from solvents is much more serious than that from nitrocellulose. In fact it has been found that nitrocellulose with above 30 per cent. of water is not inflammable and that the solution in alcohol ether can be quite well used, even with a hydrate of cellulose at 40 per cent. As precaution against outbreaks of fire, there should be a good system of hydrants lodged in the most convenient places, and of hose-pipes arranged near the roof of the workroom and capable of being easily manipulated by the workers themselves. An automatic system for flooding those parts of the workshops when the temperature for any reason reaches 50° C. should be required. With regard to thread drawing, the product burns slowly and a woman worker always has time to extinguish any fire at its commencement with a pail of water placed at the end of each machine.

LEGISLATION

No special regulations exist for the manufacture of artificial silk. As regards the protection of women and children, and the compensation of industrial diseases, see articles " Alcohol", " Ether", " Carbon Disulphide ", " Explosives ", " Celluloid ", " Nitrocellulose ".

Notification of cases of conjunctivity is compulsory in Holland.

Artists

Under this title are included data on occupational pathology relating to artists, understanding by this term all persons carrying on an artistic profession connected with the theatre — dramatic and lyrical, dancing, music, painting, sculpture, etc. Cinema artists, lecturers, acrobats, etc., are also included.

Stress, however, must be laid on the fact that the data are few and scattered throughout medical literature. Only of late years (1925-1926) have new studies commenced to appear. These relate to special categories, for instance musicians, and it is to be hoped that the specialists will direct their attention to the different branches of this art in order to make a more intensive study of its pathology.

It is impossible to analyse even briefly the very detailed enquiry of Peri (1913) on the professional pathology of dramatic artists and the hygiene of the theatre.

This enquiry confirmed the findings of Brown, carried on mainly among French artists, showing that damage to health is bound up with their profession and the surroundings in which they pursue their calling. If attempts were made to summarise the different ill-effects revealed by Peri, they would be found to be:

(a) Causes exclusively personal to the "child of art": weakly constitution; nervous temperament; predisposition to tuberculosis, syphilitic heredity, etc.

(b) Causes connected with the profession: excessive exertion of the respiratory system and especially of the voice in recitation; the strain on attention; nervous tension while on the stage; hard work.

(c) Causes connected with life in the profession: irregular meals and rest, etc.; frequent changes of climate and food; moral effects; poor pay; preoccupation for the future and for the family; feeling of discouragement following on excessive criticism by art directors, etc.

(d) Causes resulting from the vices easily contracted by artists: abuse of alcoholic drink and tobacco; sexual excess; addiction to drugs, cocaine, morphia, etc.
Professional diseases are very frequent among dramatic artists; anaemia, chlorosis, chills, illness due to dusts, tuberculosis, alcoholism, digestive and circulatory troubles (varicose veins), etc. Fatigue of the voice troubles, etc., also are frequent.

Among forms of chronic poisoning, that from lead should be mentioned, arising from paints (make-up) with a white lead basis. The same thing is reported at present among the artists of eastern counties.

Brown recalls also the fact that artists, often compelled to live in dirty lodgings, run the risk of contracting infectious or parasitic diseases (itch, pediculosis and syphilis, etc.). He mentions, too, the danger to be anticipated from the loan of clothes, wigs, etc.

A peculiar timbre, and a peculiar timbre of the voice is known (that of a famous actress).

Recently (1925) Schlafranova, again emphasising the scantiness of contributions to medical literature relative to artists, has drawn attention to the profound influence on the emotional side of any form of professional fatigue of long standing. Among the professional neuroses of actors that results from the fatigue of the preparatory work of interpreting a role, the symptoms and the physical fatigue sometimes involved in the part; hence the physical and mental exhaustion acting generally of inherited neurotic temperament.

Pulmonary emphysema is the most frequent lesion among persons whose work necessitates continual deep inspiratory and energetic expiratory efforts.

Myocardial hypertrophy as the results of the preparatory work of interpreting a part (study of the rôle, examining documents to understand it properly, etc.), and the physical fatigue sometimes involved in the part; hence the physical and mental exhaustion acting generally of inherited neurotic temperament.

Among dancers, besides the physical fatigue and consequences of the considerable effort demanded of the circulator and respiratory system, there are the ocular effects produced, mainly by the action of the luminous rays (white and coloured) thrown on the stage and often on the artist himself. Several cases of eyestrain, retinitis, etc., have been described. The tiring effects of the serpentine dance on the eyes of the dancer who evolved and carried it out in very brilliant coloured light are known.

According to a report in the Deutsche Musiker Zeitung (1925), professional diseases of musicians have not received the attention they deserve. It is, however, notorious how artists who play on stringed instruments (violonists, harpists, etc.) raise callosities on the fingers, which may become inflamed and suppurate. They suffer also very often from pain localised in the fingers of the left hand which may cause incapacity of long duration. The part of the hand attacked swells and exhibits circulatory changes. Diagnosis is difficult, a fact of importance if compensation is in question. The pain is localised, mainly in the thumb and index finger. The latter shows a small red patch of small size, which from which the coagulum can be easily removed. The skin around the nail is affected more or less widely; the pain is situated in the palm, on the right thumb, and even in the wrist and forearm. This pain is very common as a result of overstrain among pianists, in whom the pain extends to the shoulder, especially after playing pianissimo for a long time. A fairly frequent cause of the trouble is to be...
found in a faulty manner of holding the instrument or in the faulty position adopted in playing.

The maladies most commonly found are functional nervous affections, especially among pupils obliged to gain their livelihood, and who should be induced to avoid abuse of excitants such as coffee and tea.

Myopia is peculiarly prevalent among artists and particularly amongst a certain class. Thus, for example, a person playing a stringed instrument must have his music stand at a distance of over half a metre. This distance, however, should have little effect on refraction. Other players bring the stand nearer, especially if the music is written in small characters or in a cramped style. Myopia often is found among composers and conductors engaged in theoretical study, but it affects principally the music copiers.

Stillings is of opinion that the number of musicians affected by myopia is very large, and believes it to be caused by their having to look downwards so much. Cohn does not share this opinion, as he classified the ocular defects in musicians and, of 60 per cent. of those examined, found only 32 per cent. troubled with myopia. His opinion was that the myopia had existed before the persons in question took to music; nevertheless, it should be noted these people had been copying music for a long time and principally at night time; 9.7 per cent. only had become myopic during the time they had been engaged in the work.

A study of the stigmata of a violinist's hands and fingers necessary, the character of the movements and the condition under which they are made (exercises for studying the piece, for concerts, etc.). The absorption of oxygen is also increased, as well as elimination of carbon dioxide and the heart's activity. In healthy and well-trained persons the heart resumes its normal rhythm soon after the close of the piece.

Finally, Chlopine states that the work of the pianist must be ranked among those requiring the highest qualifications as it demands the expenditure of so much physical and psychical force. A neurosis characterised by pain and cramp and a sensation of fatigue and constriction localised in the right knee has been reported in players on the triangle and drums which are set in motion by a pedal (Aldrich). Each blow, it was calculated, required an effort of 5 to 12 kg. and the artist had to give 180 blows a minute. Von Strumpell assembled 62 cases of paralysis among drummers affecting the extension of the distal phalanx of the left thumb. Chronic tenosynovitis is said to be a fairly frequent consequence of the way in which the drum sticks are held, setting up mechanical irritation of the tendon of the long extensor of the thumb and, more rarely, even rupture of the tendon at the moment of the paroxysm of rolling, and, still more rarely, even spontaneous rupture.

Among the professional neuroses, first and foremost is the cramp of the pianists, especially common among young women, but which has been reported in men over forty.

Violinists' cramp of the right hand rather than the left is interesting. Cramp may often affect such musicians as players of the organ, the harp, the flute, and even conductors; in the last named it takes the form of a neuralgia localised in the muscles of the right shoulder (Curschmann).

Cramp of the legs is less frequent, but can occur in dancers who rest too long on the point of the toes. Cases of neurosis affecting co-ordination of the head are fairly rare, but some have been described, e.g. as affecting a flute player (Von Strumpell) who developed a cramp of the tongue, and a trombone player and trumpeter (cramp of the muscles of the mouth).

A study of the stigmata of a violinist's profession by Calobresi raises them to the number of five: stigmata localised in the neck showing the cutaneous reaction, either circular or irregularly elliptical and generally occupying the parotid or subhyoidean region on the left side and due to the injury caused by the violin: callosities on the fingers of the right hand set up by holding the bow. Chronic tenosynovitis is said to be a fairly frequent consequence of the way in which the drum sticks are held, setting up mechanical irritation of the tendon of the long extensor of the thumb and, more rarely, even rupture of the tendon at the moment of the paroxysm of rolling, and, still more rarely, even spontaneous rupture.

In players on wind instruments lesions of the teeth are frequently observed (especially of the incisors), as well as spasm of the tongue and muscles of the larynx. Emphysema, formerly so frequent in military musicians, has not been found either by Fischer (who examined 300 players) nor by...
physicians. However, an enquiry by Kahn, Herzheiner, and Brose (1925) among 50 athletes over 40 years of age did not show that they suffered from circulatory diseases or arteriosclerosis. On the other hand, some of these athletes were found to suffer from a slight degree of aortic dilatation, for which the authors were unable to furnish a satisfactory explanation.

Some writers maintain that cases of nervous diseases are common in artists generally and most frequent in painters. The nyctagmus believed to have been contracted by Michael Angelo from painting the frescoes in the Sistine Chapel is a classic instance, and has been attributed to forced retraction of the head. The instances of lead poisoning, so common in the Middle Ages among painters, seeing that they ground the paint colours themselves, have disappeared nowadays, although cases are occasionally reported among artists on retouching work who prepare sketches for posters. Fifteen cases were reported to the Illinois Committee of Enquiry among members of the Painters’ Society who had contracted the poisoning by permanently poisoning the paint colours with lead. They thought they were dealing with zinc paints, but they were really white lead.

Sculptors are sometimes attacked by paresis or paralysis of the hands. The action of some kinds of dusts might also play a part in the etiology of certain respiratory troubles and irritation of mucous membrane of the nose and eyes.

The first case of paralysis among sculptors was perhaps that described by Sand, of Brussels, in 1910 as affecting one of the greatest Belgian artists. Naturally, an attack of weakness and enfeebled by years of hardship and dis-appointments, originally a painter, for the last twenty years he had been engaged in sculpture for ten hours a day. Atrophy involved all the muscles of the right hand supplied by three different nerves. The condition had come on in subacute form following severe influenza, which had fatigued the muscles of the hand. He recovered completely, although slowly.

Sand remarks that the sculptor uses not only the thumb and index finger, but that the preliminary work, the "massage", consisting in kneading and compressing masses of clay and in particular the other hand, some of these athletes were found to suffer from a slight degree of aortic dilatation, for which the authors were unable to furnish a satisfactory explanation.

The extraordinary development of the cinematographic industry has brought with it a whole series of injurious effects on the persons engaged in it. This has occurred naturally to the great army of artists and players working out the scenarios, among whom numerous prejudicial effects have been noted not only on the general health but also on certain organs in particular. In addition to fatigue and a peculiar neurosis known as "cinematographic fatigue or neurosis" attention has been called to very serious lesions of the eyes. Already quite a literature on the subject exists, as well as on the problem of the lighting of studios.

These lesions, which are set up by the electric lighting, comprise generally cases of kerato-conjunctivitis, the majority of moderate severity, but healing readily. The cornea also has been involved, especially when the patient has been myopic. According to Sedan (1925) while lateral illumination plays a very important part in producing the lesion, the factor duration of exposure, on the other hand, to the rays is practically negligible. An individual tolerance may be produced, but is not present among those taking up the work for the first time. Electricians, managers, and mechanics are less affected by these eye injuries, either because they adopt the necessary precautions, or because they have become acclimatised to the luminous rays.

Mercury vapour lamps seem to be innocuous. But measures of prevention to which reference is made later meet with practical difficulties raised by the necessity for "make-up" of the artists.

The lesions arising from the powerful sources of electric light affect the skin and the eyes. The skin lesions are characterised by swelling of the skin, especially of the eyelids, and very severe pricking sensations. They terminate in desquamation, leaving a brownish pigmentation more or less persistent.
The conjunctiva is injected; the patient feels as if sand were in the eyes and the lachrymal secretion is increased; the eyelids, on waking, stick together; the patient complains of photophobia, fatigue, weeping and weak sight. The question of lighting of studios was also discussed in 1920 by the Illuminating Engineering Society. The opinion was expressed that, from an artistic point of view, use of diffused light approaching more nearly that of daylight was most desirable. Seeing that lighting is one of the least costly items in the production of a film, obviously a little more money should be applied in this direction so as to obtain more healthy lighting and at the same time more satisfactory conditions from the point of view of technique.

Directors of studios ought to pay attention to the quantity of rays emitted by the different sources ordinarily used, because the colour and the richness in ultra-violet rays vary considerably for certain types of lamps.

In England a committee composed of representatives of the cinematographic industry, ophthalmic surgeons, photographers, and others was formed in 1921 to study the whole subject of the illumination of studios in all its aspects.

While the ultra-violet rays are the most injurious, they are not the only ones; because violet and even blue rays can produce the detrimental effects.

Since the very refractive rays cannot be kept back by yellow glasses in front of the eyes of the artists, then yellow screens ought to be placed in front of the arc lamps. Unfortunately, the ordinary film is not sensitive to light transmitted through the yellow screens, and as this cannot be overcome either by longer exposure or increasing the light, some other type of panchromatic emulsion for the film must be sought which, like the retina, is sensitive to colours of low refraction.

If some such result could be achieved notable progress would be possible for the industry (Comandon).

The heat given off by the sources of light must not be forgotten, as they cause the atmosphere of the studio to be heavy, especially in the summer. The artists complain of physical depression analogous to that experienced in summer before a thunderstorm. Fresh air alone can remedy that.

Technicians who have to keep an eye on and regulate the lamps may also be affected by the injurious action of the sources of light used in the studios. The glass of these lamps, therefore, should be fairly opaque so as to keep back any dangerous quantity of ultra-violet rays.

**Legislation**

A Bill in Czechoslovakia (1925) proposes provisions of old-age pensions for artists, writers, and composers so far as they are not already insured elsewhere and are without means.

In France there is no special regulation as the labour laws are applicable to such work. A Bill was, however, presented to the French Senate in January 1926 proposing a modification of the Industrial Code so that children under 15 years of age (instead of 13) should not be employed on the stage as actors or in theatres, café concerts and other establishments, including cinemas.

In Germany the Act of 1903 on the employment of children in industrial undertakings has been amended so as to apply equally to their employment in studios (31 July 1925); their employment, subject to certain exceptions, is prohibited in the production of films. Except in the interests of art or science, no authorisation is allowed to children under three years of age; for those above this age the authorities must satisfy themselves that the work is not such as to affect physique or morals. An Order on the employment of children in the taking of films has been issued by the City of Berlin (30 June 1924). According to the Deutsche Musikzeitung German musicians are demanding a regular contract with the right of a pension for old age and compensation for dependants in case of death (1925).

The same is the case in Great Britain which has no law expressly dealing with employment of children in cinematographic studios. The Home Office understands that such employment is very rare. Even if the Factory and Workshop Act, 1901, and the Employment of Women and Young Persons in Theatres, etc., Act are inapplicable, the Education Act, with its clauses regulating generally the employment of children, still applies and can be enforced. Practically all local authorities have now made by-laws for employment of children in studios, but no intervention of any local authority has so far occurred.

A pension scheme is provided in Greece by an Act of 20 October 1925 for artists employed in theatres.

In Italy the recent Act of 10 December 1925 on the protection of children prohibits the employment of children under 15 years of age on the stage, where they are engaged as actors, walkers on, etc., in cinema performances or in open-air entertainments, and those under 16 years of age in dangerous acrobatic feats.

In the Netherlands musicians' cramp is compulsorily notifiable.

In the United States, the State of New York has laid it down that children under 16 years of age may not take part in film production without the authorisation of
extensive. Including lessons lasting four hours given in part in film production must not be made every three months. Carried out by a medical man in the Child can be employed in a studio unless duly no child under at least 16 years of age week.

Asbestos is most commonly used; the first of these is the hornblende asbestos which are the most serpentine known by the name of talcator and is not attacked by most acids.

When cut up it presents a silkycotton-like form which lends itself easily to weaving. It is incombustible, prevents heat loss, is a thermic and electric insulator and is not attacked by most acids.

The uses to which asbestos is put are very varied. The long fibres are used in the textile industry for the manufacture of cloth, braid, rope, theatre curtains, decoration, upholstery, hangings, and for finishing pistons for steam engines. The shorter fibres together with an agglomerating agent are used in the manufacture of felt, paper, cardboard, varnishes, covering agents (especially for strong

---

**Asbestos**

**Chemical Properties**

Asbestos is a brilliant filamentous mineral, oily to the touch, white, silvery grey, greenish or bluish. Its density is 2.3-2.9. Its chemical composition consists, according to its origin, of calcium silicate and magnesia or of a magnesia silicate accompanied by quantities of iron, more or less extensive. Analysis of different varieties of asbestos reveals a silica content of 40-50 per cent. — 41.2 in Canadian asbestos, 41.8 in Siberian asbestos, and 51.1 in the African variety — while oxide of magnesia varies between 2.3 (African) and 41.7 (Canadian), oxides of iron between 2.52 (Canadian) and 35.8 (African). In Siberian asbestos there is besides 16.39 per cent. of alumina. When cut up it presents a silky cotton-like form which lends itself easily to weaving. It is incombustible, prevents heat loss, is a thermic and electric insulator and is not attacked by most acids.

Of the three different mineral varieties known by the name of asbestos, it is serpentine asbestos or chrysotile and hornblende asbestos which are the most commonly used; the first of these is the most sought after variety. Industrial asbestos is chiefly derived from Canada, Russia, Italy, and the Transvaal.

**Technology**

Extraction involves two distinct operations: (1) quarrying of the asbestos-bearing rock, generally mined in open quarries or, in countries having a severe winter climate, in galleries; (2) separation of the asbestos from the surrounding rock. The rock is cut in terraces, sometimes reaching a depth of some 150-200 ft. Quarrying is more economical and effective than underground work even despite exposure to weather. Drilling and blasting are engaged in as in ordinary stone quarrying. The mineral got from the quarry is rough sorted, different grades being chosen for length of fibre and sent to "cobbing sheds" where dressing is carried out. This consists of separating the asbestos fibres from the surrounding rock and may be done (a) by hand — the stone being broken by a small sledge hammer and the fibre thrown thereafter into one box and the waste into another — or (b) by machine ("mills").

Hand separation ("picking and sorting") is not difficult since the fibres lie in layers more or less loosely attached to the rock and can frequently be picked off with the fingers; hand dressing is not thorough and the waste material from the cobbing tables contains much fibre, the further utilisation of which represents large profits to the mine, and these fine pickings have to be dressed mechanically. They are passed after drying to crushers where they are broken by successively finer-set rollers and further reduced by cylindrical fibreisers and the cyclone machine, which reduces them to fine powder. The cotton-like fibres come to the surface and are mechanically withdrawn by suction. The pulverised rock and ground asbestos are then separated by passing them through a shaking screen. In some mills the particles of iron present are taken up by strong electric magnets. The crude fibre on separation from the waste rock resembles mineralised wool. The asbestos is graded according to the length of fibre on a series of cylindrical screens. It is then carded and packed in sacks and placed on the market in bulk.

**Industrial Uses**

The uses to which asbestos is put are very varied. The long fibres are used in the textile industry for the manufacture of cloth, braid, rope, theatre curtains, decoration, upholstery, hangings, and for finishing pistons for steam engines. The shorter fibres together with an agglomerating agent are used in the manufacture of felt, paper, cardboard, varnishes, covering agents (especially for strong...
rooms), cements, rubber tyres for automobiles and bicycles. Asbestos is also used as an electrical insulator for covering electric wiring for high and low pressure currents, in the manufacture of tiles, planks, panelling and exterior coverings for buildings, mattresses, heat insulating gloves, firemen's clothes, laboratory equipment, porcelain, balls for gas fires (made of fireclay and asbestos), etc.

**Dangers and hygiene**

The worker engaged on the extraction and manufacture of asbestos is constantly exposed to danger from dust, more especially, however, in the operations of spinning and weaving.

The baneful influence of the dust in relation to the production of tuberculosis is brought out in the Annual Report of the Chief Inspector of Factories for England and Wales for 1910, which records 5 deaths from tuberculosis amongst 40 workers engaged in an asbestos weaving factory, where the most dangerous process was revealed to be the weaving of asbestos mattresses composed of bags of woven asbestos filled with short asbestos fibre. They were placed on a table and beaten out flat by a man with a wooden flail, which process occasioned the production of much dust. Women sewed the mattresses into sections using asbestos threads and as they worked beside the beaters they also of necessity inhaled much dust.

Towards the beginning of 1924 a fatal case of poisoning by asbestos dust was reported at Rochdale (England). The victim was a woman who had been employed in an asbestos factory. A post-mortem examination revealed death as due chiefly to a fibrosis of the lungs due to the inhalation of mineral particles and in part to tuberculosis. A microscopic examination of the lungs and of dust samples taken from three different workshops of the factory revealed the same black particles present in each, alike in form and dimensions.

Another fatal case was studied in 1927 by Cooke and Hill (Great Britain). A striking example of the noxious property of asbestos dust is instanced by the following case: in an asbestos spinning and weaving factory (Calvados) there were 40 deaths in the five years 1890-1895. The mortality rate decreased considerably with the installation of a good system of local ventilation over the carding machines.

(See also article "Tuberculosis.") In an asbestos weaving factory in Saxony the workers complained of headaches and loss of appetite. These affections were caused by fumes given off by a rubber solution with which the asbestos cloth had been coated to eliminate dust.

An investigation carried out in Canada in 1911 revealed that hygienic conditions were greatly improved as a result of the adoption of an effective system of ventilation. Nevertheless, a local doctor with long experience stated that respiratory troubles, and in particular tuberculosis, were of very frequent occurrence amongst asbestos workers.

Rambousek drew attention to the risk of lead poisoning during the weaving of asbestos when a thread of lead is added to the weft, as is sometimes the case.

Marked frequency of chronic conjunctivitis, with hypertrophy of the rims of the pupils has also been noted amongst the asbestos workers of the Island of Cyprus. The workers in question were chiefly engaged in grinding, screening, and packing the asbestos in sacks.

The weaving of asbestos has only developed importance during the last twenty years. Now that it is widely practised the application of local exhaust systems during such processes as that above described is called for. All processes from extraction onwards unquestionably involve a considerable hazard, and American and Canadian life insurance companies generally refuse asbestos workers on account of the assumed deleterious conditions in the industry.

The lack of more accurate and detailed data in medical literature regarding this industry in its various branches, including the utilisation of by-products, is to be deplored in view of the self-evident importance of asbestos dust as a predisposing cause of pulmonary tuberculosis, more especially since the rapidly-increasing development of industries utilising asbestos adds greatly to the urgency of studying the conditions with a view to their amelioration.

All provisions already described for withdrawal of dust should be enforced in this industry.

**Legislation**

In Italy boys under 15 and girls under 21 years of age are excluded from workshops where dyeing and weaving of asbestos are engaged in, unless effective
means are taken to prevent the diffusion of dust throughout the atmosphere.

**Ashes, Cinders**

Ashes present problems from the point of view of industrial hygiene, not only when cinders from hearths are in question (dangers from hot dust, presence of certain products, etc.), but especially when they are employed for special purposes. Thus, for instance, treatment of goldsmiths’ ash by lead may cause injury by reason of the metallic dust which it liberates.

Hygienic measures assure covering of any openings giving on to the public streets, thorough ventilation of the workshop, the installation of hoods for the furnaces and cupels connected to the chimney by a strong exhaust. If the treatment is effected by means of mineral acids, application of measures of protection against toxic fumes is required, viz., condensation of lead fumes. Noisy machinery should be isolated, and measures applied for evacuation of residues and the protection of workers from the heat and glare of the furnaces.

Pearl ash from combustion of organic material, such as shoots of vine, wine lees, vinasse from beetroot, etc., is composed of impure potassium carbonate and its treatment liberates sharp, piquant, thick, and disagreeable fumes and injures vegetation in the neighbourhood. Factories should be erected at a long distance from dwelling houses and calculation should be effected in closed ovens. Gases and fumes should be led to special hearths or requisite measures taken for their destruction. The chimney must be a very high one. It would be advisable to collect the incandescent mass of carbonate of potassium in a special apparatus so that the gases of combustion may be burnt. Hoods should be installed above the evaporation boilers. The water should be fed to a sewer; the residues require fairly frequently to be removed and can be utilised as manure.

By the expression “dust shot with a lead content” is meant the impure oxides which form in the vats where each bath containing lead or lead alloys. This scum or black dross is removed as it forms and is often put aside on the floor, where it becomes mixed with other substances. In appearance it resembles ashes, hence the French expression “cendres de plomb.” Kelp ash is lixiviated for the extraction of the salts of potassium. The ash is got by burning different kinds of sea-weed known as kelp or wrack and thrown up on the seashore. Dried in the sun, they are thereafter reduced to ashes in furnaces lined with refractory bricks. The product of this process of reduction, or “kelp ash” is in the form of a solid compact block, from which the salts of potassium are extracted. The blocks are then ground and put into special apparatus for gradual dilution with water. The solution is concentrated in iron boilers and poured into vats where, after cooling, the potassium chloride is deposited in crystals, which are then subjected to purification.

Hygienic precautions to be recommended are impermeable flooring, cement walls to the height of one metre, hoods provided above the boilers to draw off the fumes to the chimney, all openings to the public highways to be kept closed, and neutralisation of the water used before it enters the sewers.

The Recommendation adopted at the International Labour Conference at Washington (1919) regarding the protection of women and children against lead poisoning demands the exclusion of women and young persons under eighteen years of age from work involving manipulation, treatment, and reduction of ashes containing lead.

***

**Asphalt**

(Mineral Pitch, Hard Bitumen)

Earth and rocks impregnated with bitumen are called asphalt. In mineralogy, however, the name asphalt is also given to bitumen in a free state. It is highly important to distinguish between these two products. Asphalt is generally in the form of fine grained rock, black or dark brown in colour according as it is more or less
rich in bitumen. The earth or rocks impregnated are in general calcareous rocks, dolomites or sandstone.

Bitumen is the solid product deriving from slow decomposition of organic matter. It is composed of a mixture of heavy hydrocarbons containing, besides oxygen, nitrogen and sulphur compounds. In commerce it is frequently met with under the name of asphalt.

Whilst the best known deposits of asphalt are found in Switzerland, France, Italy, and Dalmatia, the deposits richest in bitumen are those of the Dead Sea, Trinidad, Cuba, Bermudas, Venezuela, the United States, Mexico, Russia, etc. The extremely large deposit in the Lake of Trinidad fills the crater of an extinct volcano, and it is estimated that it contains 158,400 tons of asphalt per foot of depth and in the substratum of this deposit large quantities of petroleum are found. It is supposed to be produced as the result of evaporation and oxidation of liquid petroleum which has escaped from the outcropping strata.

Asphalt is a solid or semi-solid mass black or blackish brown combustible burning with a fuliginous flame. Its specific gravity varies between 1 and 1.6. It is insoluble in water, soluble in ether, petrol, carbon disulphide, etc. It is often replaced in commerce by pitch, the residue of coal tar distillation.

Refined bitumen coming from the Isle of Trinity is purified by fusion at about 160-170° C. It becomes soft at 85-95° C, and contains 55-65 per cent. of pure bitumen. Its specific gravity is about 1.40. It is soluble in carbon disulphide, partly so in petrol ether, carbon disulphide, etc. It is often replaced in commerce by pitch, the residue of coal tar distillation.

Asphalt is detached in large blocks by the use of nicks and thrown into special recipients which convey it to the unloading base. The cavities made are soon filled by the influx of plastic material from below. Part of the asphalt undergoes refining at the place of extraction; the remainder is transported thence in the form of blocks.

This material still in a soft condition coagulates during transport and requires to be again hocked out on arrival. Refining is simply effected and comprises such operations as crushing, grinding, and riddling or pulverising with a hammer. Melting or even boiling is necessary for use in a compressed state. The asphalt is mostly heated in open tanks by means of steam coils, the water being driven off by steam.

The richer quality of rock is used for the making of asphalt mastic which is got from powder of the first or second order mixed with Trinidad bitumen 15-17 per cent.

Besides the system of extraction applied in the case of the vast deposits of Trinidad and Bermudas, Venezuela, etc., other deposits of lesser importance are worked either in mines or in the open.

Distilled dry asphalt yields oils which like those of schist serve as lubricants or combustibles (heating, lighting).

Artificial asphalt is only tar pitch mingled with powdered coke, limestone or sand.

**INDUSTRIAL USES**

The industrial uses to which asphalt may be put are many and varied. It is used as a paving material (macadam), employed in building as a "damp course", as a water-excluding coating for concrete floors and in the manufacture of roofing felt. In the making of asphalt roadways the material used is chiefly an asphaltic or bituminous limestone. Asphalt mastic is used for footpaths, floors, roots, etc., while machine bases for steam hammers, dynamos, and high-speed engines are made of asphalt concrete. Asphalt is also used as a constituent of artificial fuel (briquettes), of metal paints and varnishes—chiefly as a constituent of anti-rust coating materials. It is used for ships in this way and is a constituent of a number of extensively used commercial products of this kind (see article "Painting Industry"). For this purpose it is employed in a solvent (usually benzene) and after dilution is applied as in painting in a thin layer. Asphalt is further used as an insulator in the electro-technical industry, in photography, and for fixing bristles in the brush-making industry.

**TOXIC ACTION**

The action of asphalt and bitumen can be related to their geological origin. The presence in these products of certain mineral oils offers a ready explanation of the serious troubles they give rise to amongst the workers who handle them. Skin eruptions seem to vary roughly in relation to the specific gravity and the boiling point of the asphalt or bitumen. Cases of dermatitis in the form of acne affecting the whole body were noted, the victims being fourteen workers engaged in boiling asphalt. The skin had a yellowish tinge, the cause of which appeared to be the yellowish green fumes evolved during boiling.

In the large lake deposits the softer parts of the surface continually evolve gases consisting largely of carbon dioxide and sulphuretted hydrogen.

The fumes from boiling asphalt are noxious and unpleasant with a very strong odour, so that in factories and places where the product is boiled the asphalt kettle may be regarded as a source of discomfort. Open pans for heating asphalt should therefore be avoided and all fumes generated should be absorbed by a condenser.
Asphalt used in the brush-making industry can be very satisfactorily replaced by shellac (gum-lac), resin, linseed oil or any similar product. It must be admitted that cases of poisoning reported amongst workers using asphalt coating preparations (ships, metal reservoirs, etc.) are due rather to the solvents (benzene derivatives, phenol, etc.) than to the asphalt itself.

Hygiene

All measures enforced for the prevention of fire should be applied not only in the production of asphalt and bitumen but also in all branches of industry where it is used. Grinding and pulverisation should be effected in closed apparatus with an efficient exhaust system. Depots should be well isolated from other buildings. Exhaust hoods should be installed over the boiling kettles and steam and fumes should be condensed as the product liberates volatile empyreumatic substances such as ammonia and hydrosulphuric acid.

Legislation

In Canada (Quebec) boys under sixteen and girls under eighteen are excluded from preparation of asphalt.

In the Netherlands skin diseases such as eczema, dermatitis, cancer of the skin, cancerous ulceration, peripheral paralysis, ulceration of the cornea, and conjunctivitis caused by asphalt and products containing it are listed for compulsory notification.

Epitheliomatous cancer, ulceration of the skin and of the corneal surface of the eye due to bitumen are subject to compulsory notification in France and Great Britain, and compensated as accidents in Germany, Great Britain, and Minnesota and New York (U.S.A.).

Atropine (Daturine)

The alkaloid (formula: \( C_{35}H_{23}NO_3 \)) is extracted from the roots of belladonna and ripe seeds of stramonium. It should, however, be noted that it is not previously present in these, but is formed during the process of extraction (as the effect of the dilute alkalis), in consequence of a molecular transformation of another alkaloid isomer, hyoscyamine. Its characteristic action of dilating the pupils is well known. Herxheimer found in 1912 cases of eczema amongst workers handling atropine for the preparation of apo-atropine. In one case of atropine poisoning, tetanus was also reported.

Kruger, of Dresden, in 1925 met with eczemas localised on the hands, arms, neck, and face of workers in a factory for production of chemical products. The workers complained also of headaches, insomnia, and sensation of heat (fever?); these phenomena persisted for a long time after the workers had ceased work. The enquiry led to the conclusion that the symptoms were caused by the alkaloid preparations and in particular by atropine emetine and veratrine, while emetine was the principal cause of the dermatitis affecting the workers. Kruger found, on the other hand, that the workers who prepared the atropine suffered from dilatation of the pupils. Further, they were almost unable to read after quitting their work. They complained in addition of dryness of the mouth and of vertigo.

Auramine

This synthetic organic colouring substance [formula: \( (\text{C}_8\text{H}_8\text{N}_2\text{H}_2)\text{CNO}_3 \text{HCl + H}_2\text{O} \)] is got from hydrochloride of imido-tetra-methyl-diamino-diphenyl-methane.

Not easily soluble in cold water, auramine is soluble in hot water or acidulated water or in alcohol.

It is used for dying wool, silk, paper, leather, cotton (mordanting with tannin), etc.

It should be remembered that in course of its preparation the workers are exposed to the action of fumes of ammonia and sulphuretted hydrogen, and that it is not improbable that cases of poisoning by nitro and amino derivatives are connected with this colour group rather than with any other.

When the auramine is prepared using as the starting point Michler’s ketone, carbon oxychloride is used.

See also article “Tumours”.

***
Aurantia (Emperor Yellow)

This synthetic colour (formula: $(\text{C}_6\text{H}_4(\text{NO}_2)_3)_2\text{N.NH}_3$) is a sodium or ammonium salt of hexa-nitrodiphenylamine in the form of reddish brown crystals soluble in water. Heated on a sheet of platinum, aurantia burns brilliantly; it only explodes when present in large quantities.

It is used for dying orange-yellow wool, silk, leather (in an acid bath), shoes, and other yellow products dyed yellow and sold cheap.

During preparation of aurantia the workers are exposed to ammonia fumes. Hamilton noted two severe cases of pulmonary oedema amongst workers engaged in the manufacture of aurantia and indigo.

Aurantia gives rise to great quantity of small vesicles in close formation and appearing symmetrically on the palm of the hands (cases cited by Radcliffe, Crocker, Moser, Segueira, etc., and by P. White), attributed at least in part to the bad habit of cleaning the hands with chloride of lime.

Crocker reports that the dermatitis found amongst dyers is due to the use without precautions of a sponge soaked in the colouring solution and then applied to the article to be dyed.

Aurine (Rosolic Acid)

Aurine is a colouring substance derived from tar of the triphenylmethane group, erroneously called rosolic acid, for it is chiefly composed of para rosolic acid $(\text{C}_6\text{H}_4\text{OH})_2\text{C.C.H}_3\text{O}$. It is got by heating concentrated sulphuric acid with oxalic acid and phenol. In the crude state aurine is very impure and has a brownish green colour, being insoluble in water, soluble in alcohol, to which it imparts a yellow colour. It is used for lakes employed in dying carpets, paper, etc., for varnishes with an alcoholic basis (for metals), and as an indicator in chemical analysis, etc.

It should be recalled that its sodium salt — yellow corallin — may contain arsenic, according to the process followed in its manufacture. Another derivative, chrome violet or chrome ruby, is used for dying violet, cotton, mordanted with chrome for printing material, etc.

This substance only causes dermatitis which, in general, follow a benign course.

Aviation or Aviators' Sickness

The human body cannot with impunity ascend to great altitudes, often rapidly attained, and from which the descent especially is too rapidly effected. While definite symptoms are experienced by those who climb high mountains (mountain sickness), still more marked when ascending in a balloon, these become even more important in flying.

Quite a train of rather complex symptoms are comprised under the name of "aviation sickness". When repeated and under certain conditions they may induce a state of physical and mental overstrain.

Running parallel with physiological researches on the effects of flying, there has developed study of the pathology of flying, that is, of the nervous phenomena noted among aviators, during or after flying. These are of a transitory nature or more lasting when excessive fatigue due to piloting has also been endured.

Certain authorities, among others Galeotti and certain English experts, take the view that the clinical picture, in future to be referred to as "aviators' sickness", is not really a new malady added by the invention of the aeroplane to the "ills which flesh is heir to". In other words, no specific malady results from flying such as can be differentiated in any essential way from maladies provoked by causes analogous to those which occur in flying.

PATHOLOGY

The symptoms as described by those who allege there is an entity — aviators' sickness — are very different: "descent sickness" (Herlitzka), which befalls pilots and passengers; symptoms of neurasthenia following long flights, high altitude sickness analogous to mountain sickness, although no absolute identity exists between the two (it attacks aviators generally at or above a height of 5,000 metres).

In rising, at a height varying according to season and conditions of ascent, a feeling of cold is felt. First there is dryness of the mouth and nasal cavities, accompanied sometimes by slight headache, and sore throat necessitating efforts of swallowing.
Apparent hardness of hearing occurs, and this is more marked in foggy or cloudy weather and gives rise to a sensation of buzzing due to the noise of the motor.

Later, buzzing in the ears is felt, which may come on fairly soon according to the type of motor employed, rapidity of ascent, action of the wind, and internal injury.

Respiratory distress ensues, characterised by air hunger, short, weak and difficult inspiration, and easier expiration which readily disappears in coming down but a very little in height; the respiratory rate is increased as a result of the altitude, etc. Only when the height is great (about 5,000 metres) does respiration become difficult with breathlessness exaggerated by the muscular movements, and the cold. Occasionally Cheyne-Stokes breathing is observed (constant during sleep at high mountain elevation — Mosso).

As soon as the earth is left behind, the heart begins to beat more rapidly but without palpitation. The pulse is rapid and small Blood pressure (systolic) increases regularly especially in the first 500 metres; when planing is done it tends to become stabilised and return to the point at which it stood on leaving. The diastolic pressure on the other hand tends to get less, but also to revert to the point at which it was on departure, when horizontal flying is engaged in.

Sometimes peripheral congestion, especially of the face, occurs (peripheral vaso-dilatation following on original vaso-constriction), due to the cold — little observed now that aviators dress so much more suitably. It comes on mostly at about 4,000 or even at 1,500-1,500 metres if precautions against cold are not taken.

Slight frontal headaches when wearing a helmet cap with throbbing of the temples may appear at 2,000 metres, sooner if the ascent is rapid, and sooner still in novices than in trained flyers. Generally it is not troublesome before reaching 5,000 metres.

Nausea and vomiting, feeling of distension of the stomach, sea-sickness (in eddies of hot and cold air) are sometimes very intractable, especially when affecting tired persons and those suffering from intestinal atony.

At a high altitude voluntary movements are more clumsy, worried, nervous and jerky. Control is lost over the voluntary muscles, sometimes the fingers tremble nervously, there is tingling of the hands and feet, lowering of sensibility and of the fineness of the sense of touch. Cold, breathlessness, tachycardia, sun-glare, and troubles of hearing, nervous strain and fatigue, suffice to explain these motor troubles.

At about 5,000 metres a feeling of torpor, listlessness and sleepiness may come on. At first the effect on the nervous system, at slight elevations, shows itself in excitement followed by a feeling of well-being which again is followed at greater heights, by diminution in the power of fixing the attention; sense of distraction increases, and visual appreciation of things leaves much to be desired. Ideas come slowly, accompanied sometimes by derangement of intelligence, of memory, of judgment or a feeling of weakness.

In full flight aviators may be seized with sudden malaise. Cases of conjunctivitis and pterygion are fairly frequent, especially when the goggles are poor. Binocular vision may be interfered with at high altitudes. In many otherwise normal subjects diplopia appears, due to fatigue from continued convergence of the pupils, troubles of the nerve supply of the extrinsic muscles of the eye (abduction, adduction, elevation).

The imperious desire to micturate during the flight, which comes on at about 1,800 metres, is due to several factors: lowered atmospheric pressure, cold, urinary toxic action, vibratory action of the aeroplane, psychical emotional tension.

In horizontal flight when a high altitude has been reached, apart from effects related to length of the voyage, the different sensations just referred to seem to diminish; this fact is due to the establishment of physiological equilibrium to the new surrounding conditions followed by acclimatisation rapidly acquired.

During the descent (done by planing or direct descent) the sensations experienced are the stronger the more rapid the descent, and the latter is the more dangerous the greater the height from which it is made. The phenomena observed come from physiological disequilibrium of the organism and emotional nervous causes.

At the moment of the descent the tired novices and pilots may be seized with emotional disturbance from which even the strongest may not be exempt; fear of short duration, a feeling of emptiness, thoughts and visions of death conjured up by the rapidity of the fall (60, 90, 150 km. per hour: as e.g. 3,000 metres in three minutes; 2,585 metres in 1 min. 40 sec.). The flyer always has a disagreeable feeling.
of falling the moment the aeroplane commences to point downwards. The breathing, especially inspiration, seems to stop for a moment; it returns after a brusque inspiration, then according to the rate of the descent, it regains its rhythm; but this progressive return has not become complete on alighting on the ground.

The heart, momentarily slow, beats strongly, then quickens and palpitation increases with the rapidity of the descent. The aviator has a sense of constriction, sometimes slight, but capable of feeling like a burn, accompanied by a sensation as though his temples were bound. The pulse slows down and becomes more regular and fuller. The systolic blood pressure diminishes and may get lower than it was at the start; the diastolic on the other hand increases during the descent. Hearing again becomes difficult; the feeling of fullness and of auricular tension reappear, followed by buzzing, salvoes or hammering, whistlings, neuralgias, tearing pains, acute pricking sensations, intolerable pains unaffected by swallowing, which bring about mistaken sensations as to equilibration (faulty impression of speed), rendered so much the more dangerous as the eye loses momentarily the power of judging distances, which the altimeter may fail to indicate accurately.

These sensations, which last during the whole of the descent, seem even to become more intense in the course of the first few minutes after landing; they do not appear unless the descent has been a forced one (thousand metres per minute). In such cases there is great inclination to fall asleep (imperious at times), sensations of torpor, of confused thought, with a state of faintness (relatively frequent especially in the case of very rapid descents, or in that of aviators who carry out tricks, or of old, tired pilots), sometimes loss of consciousness (a probable cause of a large number of unexplained accidents and deaths of many aviators: Chavez, Hoxsey, Madiot), very marked fatigue (slow, voluntary movements, lazy, clumsy movements, nonbalance, of which some aviators are aware); impossible to resist on the part of certain aviators when run down is the imperious desire to return as quickly as possible to the earth (earth's attraction).

If the descent is slow (3 to 4 minutes per 1,000 metres), only slight buzzing in the ears, a feeling of auricular fullness, and slight oppression are experienced.

At greater speeds the recompression is very badly borne, especially in the last few thousand meters.

On landing may be noted slight incoordination, with, occasionally, markedly uncertain movements, a whim to jump out of the machine, a heavy although firm step, sometimes shaky, drunken gait, of the cerebellar type, especially after a long flight, febrifugal trembling of the limbs, transient nervous excitement, manifesting itself in joy and satisfaction experienced from the journey.

The effects on the cardio-vascular system are much more important. The cardiac movements do not regain their normal rhythm rapidly and sometimes cardiac insufficiency is prominent. Excessive systolic pressure with diminution of the amplitude of the oscillations is a habitual manifestation in aviators descending from high altitudes, especially when the descent is rapid. The systolic tension, which lasts for a few hours, is notable in trained pilots; it is less so in tired subjects or in those suffering from palpitation or very rapid pulse; it does not occur amongst aviators flying at moderate heights. The systolic pressure shows an almost need to increase. Some times it falls after a flight at low altitude.

Frequently headache lasts for some hours; an imperious desire to micturate comes on after landing (diminished secretion follows after a rest); a feeling of great fatigue with need for deep sleep is felt. Beginners suffer from backache due to the greater strain placed on the muscles of the abdomen.

These signs diminish in the following twelve to twenty-four hours, especially after deep sleep, though they may increase and persist longer after a rapid descent.

Occasionally excitability of the generative organs is diminished (the more so the longer the flight) and sometimes even a transient impotence occurs (one case lasted three months); in other cases muscular weakness, loss of cutaneous sensibility, exaggeration of tendon reflexes, a slight hyperglycaemia are found. Lesions of the middle ear, which may in time overtake aviators, are set up partly by the disagreeable noise of the propeller, partly by the variations in atmospheric pressure (see later).

The clinical forms vary from one person to another. Thus, the signs would seem to differ according as pilots or army observers are in question. Pilots are not emotionally affected, while the observers are; it need not be insisted on that aviators flying at night are more affected by
symptoms explained by extreme fatigue, ennui, excessive nervous tension from piloting and locating the position.

An enquiry among American flyers at the front brought out that 33 per cent. had not been at all inconvenienced, 18 per cent. had suffered from respiratory distress, 10 per cent. from cold and respiratory distress, 20 per cent. from headache, 12 per cent. from physical and mental depression.

Headache in aviators generally appears at altitudes higher than those reached in climbing, but lower than those reached in balloons. Malaise among them can be distinguished from that of mountaineers by the presence of vaso-motor reactions with hypertension, vertigo, headache, somnolence following ascents, cough, especially when landing and sometime afterwards. Further, no immunity such as occurs with mountaineers is found among flying men.

The symptoms referred to among aviators are very liable to recur if they do not take sufficient rest. Gradually a state of overstrain develops, which may appear in two forms — one physical, the other mental — or both may develop simultaneously.

**Physical overstrain** among aviators has nothing specially distinctive about it. At the same time because of the cardio-vascular overstrain, fatigue is apt to come on early, last longer, and attack the heart muscle more rapidly. It shows itself in cardiac asthenia which subjectively appears as intense lassitude and extreme fatigue, objectively by lowered systolic and especially lowered diastolic pressure, not only on landing, but particularly after the flight when resting.

Sometimes tachycardia is noted, and even increase of the heart's volume has been described as being pronounced in those who had been engaged actively in the capacity of pilots over a more or less lengthy period.

These symptoms which are accompanied by instability in the arterial pressure disappear after some weeks' rest except in severe cases which may last for several months.

Among general symptoms are seen a tendency to become thin, loss of fat about the face (cheeks, nose, drawn features), a roughened dry skin (hyperpigmentation, resembling shagreen, rough to the touch), dermographism, change in temperament, irritability, restlessness, indecisiveness, etc. Intellectual or physical work may become irksome, scintillating scotomas may be present, lack of appetite, difficult or slow digestion, constipation alternating with diarrhoea; insomnia or, on the other hand, sleep heavy and deep, constantly disturbed by dreams and nightmares; waking up often with a feeling of great tiredness; muscular pains and intense but relatively transient headache, exacerbation of physical pain.

Some part of the *psychical fatigue present in aviators* is due to physical exhaustion; the rest to brain fog incurred in flying—emotional strain, strain on the attention and will which may weaken at any given moment. The part played by the nervous factor comes into prominence in persons who experience exacerbations of these sensations or other abnormal sensations when they change aeroplanes or in those who have had to make a descent by parachute. Suddenly restlessness, loss of confidence, the feeling of distress supervenes, leading to aviators' nervousness.

One of the first signs is difficulty in appreciating distance and the bad landings which are a consequence. Diplopia comes on with diminution of retinal sensibility and of the muscles of accommodation.

The neurosis of aviators, peculiar to pilots, although its picture is not characteristic and some authorities express doubt about it, presents the same symptoms as those met with in the victims of neurasthenia, and psychasthenia. In forms recalling the former at the end of a period during which he has been expending the maximum energy, the pilot notices his working capacity, resistance to altitude, down in altitude during the flight by emotional disturbance, modifications in metabolism under the influence of anoxaemia, and by the changes brought about in the functions of the kidneys and suprarenal capsules. Jegerow, of Moscow, has described (1920) the results of his inquiry into the heart's action in 142 aviators on active service. His conclusion is that his examination brings out for a fairly large number of pilots, an insufficiency in the cardio-vascular functions.
and duration of flight diminish, the considerable nervous tension brings on depression, which, at first slight and transient, may become persistent and profound. The effect or distressing influence of altitude or impressive incidents or accidents during flying flourishes in such a soil without possibility of reaction. The resulting emotivity may be rendered dangerous on account of the illogical reactions so determined.

In psychasthenics the same symptoms are noted as in neurasthenics except that, in addition, impulses and phobias may be present. Constitutional neurasthenics, therefore, ought, at all costs, to be eliminated as in their case flying so often brings out latent abnormal psychical reactions. Nevertheless, nervous exhaustion is not a morbid condition to which the majority of aviators are subject.

English and American authorities are accustomed to refer to the existence of a flying temperament impossible to define medically, but enabling some persons, with recognised clinical symptoms, to execute more or less well certain functions of flying.

While the pathogenesis of psychical and physical overstrain and of aviators' neurosis is easily explained by the recurrence of accidents, it is not so with flying sickness, for which numerous theories have been put forward. Thus there is the theory of anoxaemia (Jourdainet, Bert; see article "Air: Diminished Pressure"), according to which lowered atmospheric pressure exerts its influence because it diminishes the partial pressure of the oxygen, which becomes lowered in proportion as the ascent is made (it is the failure to absorb oxygen which is at the root of the sickness trouble among flyers); the theory again of fall in atmospheric pressure; that of acapnia (Mosso) and the theories invoking distension from intestinal gases (pushing up the diaphragm interfering with thoracic respiration), or a diminution in pleural pressure (occasioning stasis in the pulmonary venous system), or further inability to aspirate the blood into the lungs; finally there is the view that fatigue is the cause, which finds some confirmation in the slower appearance of altitude sickness among balloonists than in alpine climbers and of its occurrence among flying instructors who have been out several times in the same day even at altitudes less than 1,500 metres in two-seater machines which involve hard work.

Analysis of the troubles arising in descending (aviators' sickness, as described by Cruchet and Moulinier) brings out the effects on the ear and general state of health. Herlitzka explains them as due partly to tubal insufficiency, that is, insufficient opening of the eustachian canal and failure, therefore, to equalise the pressure on both sides of the drum, which fails then to vibrate properly, and partly to abnormal excitation of the vestibular apparatus of the semilunar canals. Two very important functions depend on the ear: one tubal, peculiar to the middle ear (rapid modification in pressure); the other vestibular, adaptation of the three dimensions of space, the sense of acceleration and the regulation of muscular tone.

The unequal pressure on the two sides of the membrana tympani explains very well the ear troubles, the giddiness, and the vomiting which occur in rapid descents. But the general and circulatory phenomena do not conform to such an explanation. The hypothesis put forward by Cruchet and Moulinier, namely, transitory increase in blood pressure to explain a clinical picture which other authorities have not been able to find, even in pilots descending at the rate of 1,000 metres in 2 seconds, would appear to be insufficient in view of the smallness in variation of such a pressure. Herlitzka thinks that the cause of the trouble in question is to be sought in the inner ear. A rapid descent will provoke and increase excitation due to the inertia of the small bones of the middle ear, and when this is great, in addition to the subjective symptoms, sympathetic and para-sympathetic reflexes are also set up, with alteration in the circulation resulting in some cases in fainting, tonic spasms, in the characteristic positions of the limbs.

The sickness from descending is explained by Herlitzka as due to two superimposed factors: auricular disturbance from unequal pressure on the drum and altered position of the latter with hyperaemia, defective hearing, pain, etc., and to the changes affecting the vestibular apparatus brought about by the movement of the body in rapid descent. Sleepiness is said to be due to several factors, such as nervous fatigue, wind, diminution of atmospheric pressure, etc.

It is unnecessary to insist on the influence which various individual lesions may play (renal insufficiency, indigestion, heart weakness, etc.). Cold can only serve to increase such unfavourable influences because while
it provokes torpor and fatigue it also weakens the physical forces and moral energy by inducing an imperious demand to sleep. Cold, which is extreme at high altitudes and is influenced by the rapidity of flight, the position of the engine, etc., not only sets up congestions fatal of themselves, or from the falls they bring about, but is further a cause of fatigue of the heart and consequently of high blood pressure. The wind, against the action of which civilian aeroplanes are to-day well protected, plays an important role in badly protected military machines. Aviators and observers complain of headache, respiratory trouble, nausea, vomiting, etc. Probably wind has a reflex action on the respiratory rhythm, the centre for starting such reflexes being situated in the mouth. In the opinion of some authorities early cardiac fatigue due to necessary adaptation to fluctuations of atmospheric pressure and the physiological consequences of this, the transient anaemia of different organs offer sufficient explanation of the bulk of the troubles and symptoms met with in the nervous system, the lungs and the kidneys. So far as the kidneys in particular are concerned, auto-intoxication would add to the malaise known as aviation sickness (Cruchet), which is said to be only the first stage in the aviation sickness of Ferry, and characterised by a transient central ischaemia and slight renal auto-intoxication. If the auto-intoxication continues, then a syndrome of renal insufficiency shows itself, more or less severe and lasting. If the aviator does not take rest, this passes into the second stage, corresponding to the asthenia of aviators.

Some authorities seem finally to attribute much importance to the emotivity of the subject, to his physical and psychical constitution, while others attribute to auricular damage most of the malaise felt by aviators. As to the breakdown of some pilots who fall short of what they have expected to be able to do, they believe this must be ascribed to general weakness, cardiovascular and renal, first physiological, then pathological, with low tension, or as the result of general nervous deficiency, especially associated with slow and irregularly timed psychomotor reactions or, eventually, defect of the sympathetic nervous system.

Employment of aviators in scattering insecticides on trees, etc. (compounds of lead and arsenic, toxic gases, etc.), exposes the pilots to risk of poisoning.

### Statistics

**Aviators’ Sickness**

Distinction in flying accidents must be drawn between civil and military aviation. In the latter accidents are much more frequent, due to the machines used (in which speed is often sacrificed to safety) and to the conditions under which flying is done. In civil aviation, too, distinction must be drawn between apprenticeship, piloting, and ordinary flying. The following figures are particularly interesting from this point of view:

**France.** — For all the routes:

<table>
<thead>
<tr>
<th>Number of</th>
<th>Number</th>
<th>of km.</th>
<th>passengers</th>
<th>flown</th>
<th>included</th>
</tr>
</thead>
<tbody>

<td></td>
</tr>
</tbody>
</table>

The same aerial routes at the end of the first eight months of the year 1924 give:

1 accident per 2,426,086 km.
1 fatal accident per 808,895 km.
1 accident per 3,873 passengers

The following figures for the year 1923 of the airways companies are also interesting:

<table>
<thead>
<tr>
<th>Coeff.</th>
<th>Flights</th>
<th>Pil-</th>
<th>Passengers</th>
<th>gers of safety (per cent.)</th>
</tr>
</thead>
<tbody>
<tr>
<td>Franco-Romanian Company</td>

<td>86.5</td>
<td></td>
</tr>
</tbody>
</table>

In 1924 (to 31 September) the figures for the Franco-Romanian Company were as follows: kilometres covered, 189,279; passengers, 414; no accidents.

**Great Britain.** — From 1 May 1919 to 31 March 1920, 37,821 aeroplanes had flown about 681,859 miles and carried 67,940 passengers. The flights with passengers totalled 18,096 hours. Fatal accidents numbered 4, non-fatal 11, which gives nearly 1 accident per 2,872 miles flown and 1 fatal accident per 195,000 miles.

The percentage of accidents to the personnel in charge can thus be shown:

| Pilots killed per 1,000 hours in flight | 0.415 |
| Pilots injured | 0.294 |
| Passengers killed per 1,000 passengers carried | 0.014 |
| Passengers injured per 1,000 passengers carried | 0.176 |
| Passengers killed per 1,000 hours of flight | 0.065 |
| Passengers injured | 0.063 |
**AVIATORS’ SICKNESS**

**United States.**—From 17 September 1908 to 1 April 1914 462 aviators had met with accidents. In 1920, 1,000 aviators spending 74,900 hours in flight met with only 312 accidents distributed as follows:

<table>
<thead>
<tr>

</table>

The Manufacturers’ Aircraft Association from 1 January to 30 June 1921 had a total of 3,250,000 miles of flight with 58 accidents, of which 10 involved 14 deaths, 20 with injuries and 18 without accident to the occupants—a proportion of 1 fatal accident per 325,000 miles flown.

The Aero-Marine Airways Company, in the fourth year of its existence, after having carried 30,000 persons over 1,610,000 kilometres with only 1 serious accident, could provide, in 1922, a 100 per cent. service and in 1923, 99 per cent.

In Italy, the flying accidents in the army in 1924 numbered: 0.46 per 100 hours of flight in January 0.03 per 100 hours of flight in February 0.056 per 100 hours of flight in August

With a total of 108,000 km.

In Switzerland the statistics of aviation were as follows:

- Number of flights: 19,952
- Total duration: 5,900 h. 11 min.
- Kilometres flown: 660,500
- Number of falls: 16 | (with destruction of aeroplane)
- " of deaths: 1
- " of severely injured: 1
- Bad landing due to accident to the aeroplane or bad weather: 42

The statistics of commercial flying in the same year showed that for 3,500,000 km. flown there were 30 accidents, and that in 1923, for 3,900,000 km., only 12, with a single fatality.

At a recent conference (1926) in Paris, Volmerange discussed the question of safety.

Of 10 accidents, 8 affect military aeroplanes, one only transport, the tenth being traceable to a civil aeroplane of another kind.

To appreciate the degree of confidence which aerial transport deserves, this expert proposes to establish a safety coefficient proportional to the number of kilometres flown to one fatality or seriously injured person. As the value of this coefficient he proposes to take the number of hundreds of thousands of kilometres traversed per victim. Safety would be designated by the figure 2.

In 1912 it was only 0.9, whilst for the period 1923-1924 it reached the figure of 3.3. Safety, therefore, had been more than tripled in the last three years and the figure for 1926 ought to be about 5.5.

To translate these figures in concrete fashion, it would be safe to say that today the world would have to be encircled eight or nine times in an oceanic aeroplane before one chance in two of being seriously injured arose.

The passenger service is not submitted to the same exigencies of punctuality as the postal service. If flights were stopped during foggy weather accidents would be considerably reduced in number, as the percentage due to poor visibility is 20 per cent. Most progress, however, is to be sought in improvement of the aeroplane itself as more than 5 per cent. of the accidents result from the machine itself flimsy and nearly 30 per cent. of the victims of civil aviation perish by fire.

Motor troubles have been reduced very rapidly since 1923. Thus the reduction in 1924 was from 45 per cent. to 22 per cent. and to 7 per cent. in 1925. Skill of the pilots is the principal cause of this happy result because the percentage of accidents to the aeroplanes themselves has only diminished in the same period from 30 to 27. Half the stoppages are due to accessory parts of the engine (escape from joints, radiators, etc.). Fifty per cent. of the stoppages of the engine proper are due to breakages of mechanical parts.

The following statistics show that selection of candidates for aviation, made by the most complete methods which science knows to-day, has a fundamental bearing on the prevention of flying accidents.

**In Great Britain in 1916, 90 per cent. of the accidents were due to faulty piloting. After utilising rational methods of selection the percentage fell in 1917 to 65, in 1918 to 20, and in 1919 to 12.**

Further proof is furnished by the number of rejections following the physiological examination.

Thus, in France, for example, of 4,645 candidates examined between 1 May 1921 and 1 December 1923, 1,726 were found unsuitable for flying. Among the candidates rejected (38.2 per cent.) 11.7 were due to ocular defects, 6.4 to chest affections, 5.6 to diseases of the circulatory system, 4.9 to troubles of hearing and equilibration, 3.2 to general constitutional defects, 2.8 to urinary affections, 0.9 to nervous affections, 0.5 to digestive derangements and 2.5 to various causes.

In the United States 29.3 per cent. of the candidates were found unsuitable for flying, and of these 5.9 were due to ocular defects, 2 per cent. to hearing and equilibration, 1.5 to circulatory, 1.2 respiratory diseases, 0.8 to diseases of the nose and throat, and 0.4 to diseases of the urinary passages, etc.

C. F. Shook (1925) states that during three years, of 300 candidates in Great Britain, 23 per cent. were rejected for permanent defects which could be thus
classified in order of frequency: defective sight (110), physical defects of the nervous system, diseases of the ear and nasopharynx.

Defects in equilibration were less frequent (8). Among other causes of rejection were: increased blood pressure, poor chest expansion, hernia, haemorrhoids, asthma, rheumatism, etc.

Examination of the candidates for the Italian army and navy-air service carried out in the psycho-physiological services in Turin, Rome and Naples in 1917 and 1918, gave the following results:

<table>
<thead>
<tr>
<th>Number of candidates</th>
<th>Number of rejections</th>
<th>Percentage of rejections</th>
</tr>
</thead>
<tbody>
<tr>
<td>14,580</td>
<td>4,733</td>
<td>33.14</td>
</tr>
<tr>

<td>33.14</td>
<td></td>
</tr>
<tr>
<td>9,547</td>
<td>4,733</td>
<td>66.86</td>
</tr>
</tbody>
</table>

The causes of rejection were:

1. Excessive nervousness: 292 cases (4.00%);
2. Affections of the muscular sense: 44 cases (0.92%);
3. Defective reaction time: 297 cases (4.79%);
4. Heart affections: 885 cases (13.70%);
5. Albinism: 118 cases (2.49%);
6. Defective sight: 1,668 cases (26.05%);
7. Daltonism: 144 cases (2.35%);
8. Defect in vestibular apparatus: 302 cases (4.88%);
9. Defective nutrition: 354 cases (5.86%);
10. Thyroidism: 99 cases (0.74%);
11. Defects in ear, throat, nose: 406 cases (6.75%);
12. Nervous exhaustion: 179 cases (2.95%);
13. Various: 292 cases (4.67%);

Total: 4,733 cases or 100.00%.

In Russia a committee attached to the principal sanitary and war administration carried out a series of enquiries, in 1921, into the question of the safety and selection of aviators, of which the principal are due to Professor Schpilrein.

**DIAGNOSIS**

The diagnosis of aviation sickness is based especially on the vasomotor reactions with lowered tension, vertigo, headache, somnolence following on flights and showing itself most frequently on the ground and some time after descending.

**HYGIENE**

Aviation sickness, and especially the asthenia from strain, can be avoided by progressive education carefully controlled and by adopting carefully considered hygienic measures.

Protection is required against cold, and after reaching a height of 2,000 metres recourse should be had to oxygen inhalation, or, better, a mixture of carbon dioxide and oxygen (Mosso's method; Garsaux's apparatus). 1

While practical necessities require that flying be done at heights above 6,000 metres, care must be taken to protect the pilots against the ill-effects from high altitudes. Automatic administration of oxygen, or still better of a mixture of oxygen and carbon dioxide, so arranged that a greater amount is supplied in proportion as the height increases, is important as a protection. The Germans recommend liquid oxygen, and many types of apparatus have been devised by Garsaux.

Cotton wool should be placed in the ears. Swallowing should be practised to reduce pain and the buzzing in the head.

The ascent and descent should be made slowly. If the descent is made in sections the painful sensations on coming down are lessened, especially in the last 1,000 metres. The desire to come straight down should be resisted (earth's attraction). A sportsmanlike attitude and behaviour should be observed and excess of whatever kind avoided.

Regular periods of rest should be taken three weeks every four months or still better a certain number of hours after every flight.

Periodic medical examination should be enforced with a view to determining the aviator's state and suspending those showing signs of over-fatigue.

Pilots should be selected from those who are between 18 and 25 years of age; persons over 35 should be discouraged from entering.

Physiological examination of aviators yields only negative criteria for purposes of selection, that is, it is not enough to say that a certain individual will make a good flyer merely because he has sound organs which function properly. Nor will it eliminate the unfit. On the other hand, the psychological examination gives positive data to determine whether the candidate has the necessary psychical qualities demanded of rapid flying, can stand high altitudes, etc.

An examining station to-day would comprise:

A service for carrying out general medical examination with special reference to personal and hereditary antecedents, habits, success in sports, accidents, subjective symp-

1 These inhalations diminish the acceleration of the pulse produced by depression of the respiratory rhythm, as well as subjective pheno-

mena (headache, buzzing in the ears, etc.), but their usefulness depends on how they are taken. The partial tension of oxygen should be habitually equal to 21 per cent. The apparatus must be carefully regulated and frequently verified by competent persons.
toms, height, weight, other biometrical data, clinical data, morphological and endocrine state, etc.

A neurological service to determine especially the demeanour of the candidate, to test the coarse and fine muscular force, sense of space and position, estimation of weight, epicritic and protopathic sensation.

A physiological service to determine the psycho-motor reactions, emotivity (which varies with the psychical state from moment to moment), the external factors in candidates for piloting duties, well-trained and super-trained pilots, the psycho-sensitive-motor instability, etc.

An ear and throat service to analyse especially the functions of the vestibular apparatus and tracts, the permeability of the Eustachian tube, exact sense of position, etc.

An eye department to examine visual acuity to normal light, night vision, quickness of perception, effects of dazzle, the visual field, binocular vision, perception of depth, etc.

Other enquiries should also be made by the medical examiners as to circulatory, renal and motor functions, etc. In Great Britain, on returning after sick leave a determination of the haemoglobin, enumeration of the red and white blood cells, of the parasites; a culture of the blood is made for the typhoid and paratyphoid A and B, dysentery, Malta fever, etc.; a Wassermann test is made; the urine is examined for blood, pus, sugar, casts, bilharzia, tubercle bacillus, etc.

The following findings are generally considered to be contra-indications for the grant of an aviator's licence:

(a) Digestive troubles, especially gastro-intestinal atony, flabby abdominal musculature (brusque displacements of the aeroplane being capable of injury to the abdominal organs and so giving rise to syncope, or, at any rate, lipothymias the consequences of which may be fatal).

(b) Constitutional circulatory insufficiency, high blood pressure (which rapidly predisposes to cardiac insufficiency).

(c) Chronic lesions of the respiratory system; asthma, emphysema, old pleurisy with adhesions, chronic bronchitis, pulmonary tubercu

losis (flying may further reveal latent tuberculosis and cause it to develop rapidly).

(d) Nervous diseases such as tabes, epilepsy, affections of sensibility in general, and specially tremor, incoordination of movement, etc. The psycho-motor reactions of sight to visual, auditory and tactile stimuli must be exactly determined. Attention is paid to the consistency of response rather than the actual time value. It should be said that some authorities consider the psycho-motor tests as pre-eminently important, while others attach more weight to aptitude for flying, to variations in blood pressure, and respiratory rhythm.

(e) Affections and diseases of the ear; chronic otorrhoea, vertigo, buzzing in the ears, middle ear catarrh, undiagnosed otosclerosis; nose and throat lesions (enlarged tonsils, adenoid vegetations). Hearing should be carefully noted and sense of equilibration also determined by suitable turning tests.

(f) All affections of sight. The intrinsic muscles, the fundus oculi, the retina, refraction, visual acuity, even that of the effect of dazzle, night vision, quickness of perception colour vision, visual field, binocular vision, and, according to some, perception of depth, etc., should be submitted to minute examination.

Finally some authorities think that the Eustachian tube should be examined as to permeability, fine sense of position, dissociation of sensibility, degree of emotivity, and, in addition to all these tests, supplementary examination as to resistance to lowered pressure in a rarefaction chamber (resistance and at the same time functional state of the Eustachian tube).

Every method of physio-psychological and clinical examination as well as examination by X-rays should, therefore, be employed in the selection of pilots.

Most countries have organised special centres for psychological examination of candidates and for their periodical examination. Germany, Belgium, Denmark, the Netherlands, etc., possess such centres; France has nine, where periodical examination is made every six months, or after an accident or illness, and before resuming employment; in the United States there are 67 offices, and a special school for the medical officers of aerial navigation.
(at Mitchell Field, New York) forms a part of the medical flying unit; in Italy three centres and a fourth in preparation are charged with the medical control and with scientific research into matters connected with aviation.

In January 1925 the British Air Ministry published a pamphlet entitled The Medical Examination of Civilian Aviators, and in March 1928 another one entitled The Medical Examination of Civilian Aviators.

Further, it should be stated that in most countries aeronautical insurance companies have combined in a federation with the object of insuring against a greater number of risks and giving a more generous rate of pay in case of accident.

Generally military pilots insure themselves against accidents; in Czecho-slovakia, Italy, etc., the State intervenes to insure all of its pilots en bloc in the usual way with the grant of an indemnity in case of death or permanent incapacity (Act of 8 July 1925). An Order of 10 June 1926 of the Serbo-Croat-Slovene Kingdom insures the flying personnel.

Legislation

In general each country has laid down rules for guidance in the choice of pilots and drawn up a list of the disabilities and maladies which constitute incapacity and inaptitude for flying.

The Aeronautical Inter-Allied Health Union laid down in February 1919 certain views, and expressed the hope that an effort should be made to codify the different criteria to which expression was given to apply the medical conditions as to aptitude for aerial navigation are fixed internationally in the Convention of 13 October 1919, stipulating that the medical certificate necessary for obtaining a licence as pilot, navigator, or aircraft mechanic should be given in the different States by medical men specially appointed for the purpose.

The conditions of physical and mental fitness both for initial selection of the personnel as well as for the periodic medical examination (to be held every six months or before resumption of employment after an accident or illness) should be as follows: absence of all moral or physical damage which could possibly affect safety in aerial navigation; minimum age for pilots, 19 years; absence of wounds of surgical operation or deformities, congenital or acquired, making management of aircraft difficult; perfect vision and perception of colours; quickness of vision, not more than two diopters of latent hypermetropia; good accommodation; normal hearing, and normal vestibular apparatus without excessive or diminished excitability; absence of obstruc-

Azines

Azines are organic bases called also by some “chinoxalines”. They occur generally in the form of yellow crystals and are only intermediate bodies in the manufacture of several important organic colours (safranines, indulines, etc.). The bodies of this series have the property of causing damage to the cells of higher organisms when they
are exposed to the action of light while remaining inactive in the dark. (See article "Anthraquinone").

---

Azobenzene

Azobenzene (formula: C₆H₅N₂C₆H₅) is obtained by reducing nitrobenzene by means of a sodium amalgam, zinc and solution of caustic soda. It can also be prepared electrolytically, or by heating under pressure a mixture of coal and solution of caustic soda.

Other nitro-compounds may here be mentioned which are of some practical importance. They are obtained generally by reducing nitro-derivatives of the aromatic hydrocarbons or by oxidation of aniline and its homologues. These compounds are yellow or red substances and are insoluble in water. The most interesting are: azo-azobenzene (C₆H₅N₂O₂C₆H₅), hydro-azobenzene (C₆H₅NH.N₂C₆H₅), obtained electrolytically by the reduction of nitro-benzene; on boiling it with acids benzidine is formed (see that article); amino-azobenzene (C₆H₅(NH₂)N₂C₆H₅) with three isomers and their derivatives, used in the manufacture of synthetic organic colours.

The homologues of benzene, especially toluene, also yield a series of nitro-compounds, among which may be cited azotoluene (C₆H₅CH₃N₂C₆H₅), of which the para-isomer especially is used. It is obtained by reducing paranitrotoluene, or by treating paratoluidine with chloroform and chloride of lime.

---

The diazo compounds are also analogous compounds, generally prepared by the action of nitrous acid on aromatic salts of the amines, amino-acids, etc. Thus, e.g. diazobenzene is obtained by treating a solution of aniline in hydrochloric acid with nitrate of soda at 0°C. (see article "Dyes"). These compounds are not very stable as they decompose readily, sometimes exploding and giving off free nitrogen. They are very important in the manufacture of artificial colours.

According to Stoeber, amino azotoluene has a chemiotactic action on epithelium which it converts very readily into Keratin. The ortho isomer is said to have an action even more powerful than scarlet red. These products are usefully employed in hastening a cure in cases of severe burns. Two cases of industrial poisoning have been reported, the symptoms being cyanosis, vertigo, effect on sensibility, delirium, coma, etc. (See articles "Benzene", "Toluene", "Xylene", etc.)

---

Azo-Triphenylmethane

This acid colour — green — of which the formula is (H C₆H₅)₃C₆H₅ — is reported by O. Sachs (1911) to have caused warts (papilloma) on the face and arms of a painter who had manipulated it for a period of nine months. An English writer also (1912) has described an eruption on the fingers and hands in the case of a woman who had handled cloth dyed with azo-colours.
Bakelite

Under the name of bakelite, called after the inventor Bakélard, are comprised generally the synthetic resins obtained by condensation of a phenol and an aldehyde by heating the phenols (phenols, cresols, xylenols) with formaldehyde in presence of small quantities of bases or acids acting as catalysts.

The reaction takes place in two successive stages: by the first is obtained a product soluble even in a cold state in the different organic and plastic solvents, but which may, however, become hard and fragile by cooling, and which resembles in appearance colophane (A bakelite); the second stage transforms the A bakelite into a product insoluble in ordinary solvents, plastic when hot (B bakelite) or hard whether cold or hot (C bakelite).

The soluble resins are used in the preparation of varnishes resisting the influence of the weather and having a marked insulating quality in regard to electricity. The mixture of A bakelite with inert substances permits of the manufacture of many different objects employed for the most part in electric construction and in motor-car manufacture. Mixed with asbestos it is at present used in chemical apparatus (recipient, basins). Mixed with different colouring agents the resins are used in the manufacture of objects in imitation amber, ivory, etc., which can be manufactured in the same way as wood.

In one case studied by the Dutch medical inspectorate (1926) manipulation of bakelite was said to have caused very marked nervous troubles, amongst which the most noted was strong somnolence. During turning and polishing dust is generated which smells distinctly of phenic acid and it is to this product that the medical inspector felt justified in attributing the symptoms met with. Cases of dermatitis are of more frequent occurrence amongst workers handling bakelite. Sachs (1921) reported serious cases in Austria. He also calls attention to the fumes of phenol, formic aldehyde, and hydrochloric acid given off during the process which give rise to irritation of the mucous membrane (eye, respiratory passages) as well as of the skin (face, forearm).

The doctors at the formaldehyde and derivatives factory of Perth, Amboy, in the State of New Jersey (U.S.A.), have reported that bakelite acts as an irritant of the skin and that an affection known as bakelite itch is frequently met with amongst the workers. It would not, however, appear that manipulation of the finished product is the cause of injury (Hamilton).

Bakery Trade

The term "bakery", used in the widest sense, includes the making of bread, pastries and sometimes even biscuits.

It is true that in certain countries and in certain districts the introduction of machinery and of continuous ovens, the development of wholesale and semi-wholesale trade, and the application of legislative provisions, by greatly modifying technique in the bakery trade, have considerably improved working conditions from a health aspect. The baker's occupation, however, is nevertheless, in other countries and other districts, carried on in accordance with very antiquated methods and health conditions in such cases leave much to be desired. The statistics quoted later, certain of which are not quite recent (Epstein, 1908; Zadek, 1913), refer at times to countries which, in the interval subsequent to the publication of these statistics, have happily modified working conditions in the baking trade. They are nevertheless of value as presenting an estimate of the evils which threaten working bakers in certain countries which are still without improved methods of working.
BAKERY TRADE

TECHNICAL OPERATIONS

The conditions of bakery work are peculiar to the trade; as bread has to be consumed comparatively new, and as the customers require a different kind of bread in different localities, there are practical difficulties in organising production on a large scale. Thus there are three types of bakery, the small family bakery, the small bakery that employs outside labour, and the big bakery that uses machinery.

The first type is typical of country districts and of small towns and may even be found in big centres of industrial districts; it is represented by a bakery where the owner makes and sells his bread himself without the help of outside labour, and where either no machinery is used, or only a very limited amount.

A type of small bakery employing paid workmen is also very commonly found where some use is made of machinery, such as kneading troughs. Only big modern bakeries employ a large staff and up-to-date machinery.

The making of bread includes the following operations:

Preparation of the dough.— Different localities vary in their methods of bread making. Without entering into details which have no direct bearing on the hygienic conditions of labour, it is enough to note that fermentation of the dough is the essential operation in preparing some kinds of wheat bread; this fermentation generates carbonic acid, which gives a porous and elastic consistence to the crumb when baked. The method most often employed consists in mixing into the dough yeast or barric, just a piece of raw dough kept over from the day before, or else sometimes in aerating the actual water which is used to mix the dough.

The ingredients having been mixed, kneading follows either by hand or by machinery in kneading troughs. When kneaded the dough is left alone to "rise", which requires special conditions of temperature, etc. When ready it is divided by hand or by machinery, and thus every kind of shape is made according to the requirements of customers. Then it is weighed, moulded and passed on to be baked.

Oven work begins with stoking; when the oven has reached the required temperature, the workers begin to introduce the bread which is baked at a temperature of between 200° and 300° C. With old-fashioned ovens stoking has to be done in the same room where the baking takes place. The ovens are heated with wood or peat, with coal or coke; and before baking, the oven, which often has only one door, has to be cleaned out and stoked. For putting the bread into the oven and taking it out again a long wooden shovel is used, and the bread is laid right on the bottom plate of the oven. This is a very tiring process and not over quickly effected.

With modern ovens, heated by oil, gas, or even electricity, the heating chamber is separated from the chamber where the baking takes place. These types of oven make it possible to obtain a high temperature and to keep it regulated. An oven with a movable bottom plate, mounted on wheels and moving on rails, constitutes an important improvement, which makes it possible to put in, or take out, a batch of bread in three minutes.

The question of delivering bread is connected with its making. Bread is often sold in the shop, but is very often delivered at the home. The question of transport is of special importance for large bakeries, as many of them have branch establishments or depots, which must be regularly supplied first thing every morning.

SOURCES OF DANGER

It must be noted that any danger in the industry arises not from the actual raw materials handled, but from conditions of work; with regard to these conditions, it is impossible to compare small bakeries with large up-to-date establishments. As a matter of fact, all the sources of danger which exist in small bakeries have been almost eliminated from large ones.

The fact remains that under present-day conditions, while small and medium sized bakeries still predominate, in a certain number of countries, the chief sources of danger for the workers are represented by fatigue due to work, by the action of injurious or toxic products, and of high temperatures and close atmosphere; and, finally, by the conditions of life inevitably associated with the trade. The life of a working baker is certainly a laborious one, due to the nature of the work, the long hours, and particularly to night work.

When not effected mechanically, the operations of preparing the bread, kneading it and dividing it, call into play all the muscles of the body for a lengthened period. Putting the bread into the ovens and taking it out is very trying owing to the need for rapid action and to the exposure to radiant heat from the ovens, and also to the
posture which the workman is obliged to assume.

Particularly when done by hand, operations ancillary to baking, for instance, carrying sacks of flour, are also trying for they then call for strenuous effort. The transport of bread itself is tiring, even if a bicycle or a tricycle carrier is used.

This overstrain has a particularly bad effect on young workmen, who soon exhibit signs of chronic fatigue and exhaustion, and, in a short time, more serious organic troubles, such as heart disease and vascular troubles, deformities of the legs and body, hernias.

Another source of fatigue is the long hours of work, which formerly amounted to as much as fourteen to eighteen hours without regular intervals for rest. The time-table of a bakery naturally depends on the importance of the batches and the materials used, on which times of the day bread is in greatest demand, and on the organisation for sale and delivery. It has to be reckoned that the preparation of a batch from the moment of putting it into the baking tins until it is fit to be handed over for consumption takes from two to four hours, varying with the process and the apparatus employed. This explains why there is no uniform arrangement. In some cases work begins at 11 p.m., in others not before 4 a.m. Some machine-bakeries have started working in shifts, and the work goes on continuously; in certain others the work begins in the middle of the night, and goes on without interruption till quite late in the morning. Some delay must be reckoned for such preparatory and supplementary operations as the rising of the dough and the stoking of the oven.

In these circumstances the baking of the bread and taking it out of the oven are not completed before the early morning. But the work is not finished then; for cakes are often baked during the morning, just when the oven is cooling; then cleaning must be done; so that work may easily last till midday.

A German enquiry of 1892 (the report of which appeared in 1893) emphasised the disadvantages of organising the work in this way, which seemed to be the average method in medium-sized bakeries of a large town. It should be added that extra hours were worked: (i) at the week-end in bakeries which did not work on Sundays, and (ii) on the day before public holidays. This same enquiry made it very clear that 46 per cent. of the bakers and pastrycooks have not in the whole year a single day of twenty-four hours free for complete rest. In numerous cases the only rest obtainable was due to the workman being out of work and the days of stoppage were so frequent that one might reckon, taking it altogether, upon a quarter or a fifth of the workers being permanently out of work (Bureau of Imperial Statistics).

According to the same enquiry the hours are even longer for apprentices. In 29.6 per cent. of the bakeries (25.9 per cent. in the big towns) the working day exceeded twelve and even eighteen hours a day. As a matter of fact the bakeries of this group had:

<table>
<thead>
<tr>
<th>Hours</th>
<th>Percentage</th>
</tr>
</thead>
<tbody>
<tr>
<td>12 to 14 hours</td>
<td>15.3</td>
</tr>
<tr>
<td>14 to 16 hours</td>
<td>51</td>
</tr>
<tr>
<td>16 to 18 hours</td>
<td>15</td>
</tr>
<tr>
<td>more than 18 hours</td>
<td>1.5</td>
</tr>
</tbody>
</table>

At the present time in most countries the maximum hours are fixed by law, but it sometimes happens that the regulations are not strictly observed.

The ill-effects of too long hours only begin to be apparent at the end of a few years, and are added to other causes of ill-health. It is an historical fact that a fatal case once occurred (London, 1894), viz. an English baker died after twenty-one hours of continuous work.

The third important cause of fatigue is night work, which favours the action of all adverse physiological influences.

Bakery work, except in a big business, is very often carried on at night without any shift system, and generally under unhealthy conditions. On principle there is no objection to night work with shifts that allow for alternating spells of work, if carried out under hygienic conditions, and with all possible improvements in the processes of making bread — such are found in some big concerns — but it must be realised that this improved state of affairs has not always existed, for the hours of work are decided on the one hand by technical considerations and economical reasons, and on the other hand by the demands of the public, upon which it is not necessary to insist.

The system adopted for "raising", i.e. the rising of the dough, is a very important matter from the point of view of night work; thus, for instance, there is one method, used in Scotland, which makes it impossible to bake the dough until fifteen hours after starting the preparation; but, then again, there are other processes by which the time
required for raising is reduced to ten, eight and even two hours. Direct aeration easily converts two sacks of flour into a batch of 400 loaves weighing one kilogram each ready for the oven in forty minutes.

Night work makes it possible to deliver hot bread in the morning, to have new bread in the shop all through the day and to have ready, an hour later, cakes and pastries baked after the bread. But when it is realised that the introduction, or rather the re-introduction, of night work dates in France from the reign of Louis XVI, in England from 1824, and that it has only become general in Belgium since about 1881-1882, the thought occurs that it is not quite accurate to state that it is absolutely essential to bake bread at night.

During the war for reasons of economy, and also to facilitate the distribution of food, Governments saw fit to forbid the sale of new bread, and night work was almost everywhere given up. It was started again when the restrictions were removed. Speaking generally, it might be said that in countries where night work is not prohibited, about half the bakeries have recourse to it. An enquiry by the British Board of Trade revealed the fact in 1911 that 39.9 per cent. of the bakeries began work before 4 a.m.

The German enquiry of 1892 reported the various hours at which the bakeries started as follows:

<table>
<thead>
<tr>
<th>Hours</th>
<th>Per cent</th>
</tr>
</thead>
<tbody>
<tr>
<td>Before 8 p.m.</td>
<td>1.6</td>
</tr>
<tr>
<td>Between 8-10 p.m.</td>
<td>15.8</td>
</tr>
<tr>
<td>10 p.m.-12 midnight</td>
<td>29.1</td>
</tr>
<tr>
<td>12 midnight-2 a.m.</td>
<td>36.1</td>
</tr>
<tr>
<td>After 2 a.m.</td>
<td>21.2</td>
</tr>
</tbody>
</table>

Besides variation in the number of hours of work at separate bakeries, there is also often variation for the different workmen in the same bakery, so that it is very difficult to control the maximum duration of work done.

It must, however, be pointed out that in some countries the custom of working by day is kept up, notwithstanding the absence of any legislation forbidding night work (Argentina and Scotland).

The adverse physiological, ethical and social influences of night work are well known.

Night work is such that it must always be carried on under abnormal conditions, abnormal from the point of view of social as well as organic life. It favours and aggravates the condition of strain, as well as the other injurious agents. This harmful effect can be explained by the fact that the bodily system does not get sufficient rest, and that the sleep or rest taken during the day is not enough to repair the weariness due to work.

Even when it has happened that the time for rest is sufficient in duration, it is not sufficiently reparative, on account, among other reasons, of variations in neuro-humoral irritability (Blondi).

This inversion of normal life, food taken at irregular times and not wisely chosen, and also the want of the stimulating influence of daylight and lack of or insufficient sleep, rob the system of all power of escaping the condition of chronic fatigue, which slowly, but surely, takes a firm hold.

Without going into details, there is no doubt that continuous night work affects people in different ways. There are some persons who easily become accustomed to night work, perhaps because they know how to get the most out of their rest times, and these show no negative signs of ill-effects. But these are by no means the majority, and night work undoubtedly has deplorable results from ethical and social points of view; it disorganises family life, especially if the worker's wife goes out to work; it makes it very difficult for a single man to start a home; and it is an obstacle to all social activity.

Bakery work, besides, exposes workers to the action of harmful or poisonous products: dust of flour and dried yeast, which are apt to cause lesions on the skin, the teeth, the mucous membranes, the respiratory system (although, of course, this is not so serious as in the case of millers); poisonous or disagreeable gases, such as carbon monoxide from the ovens, braziers and stoves, or carbonic acid, especially in the place where the dough is left to ferment (Emmerich observed as high a percentage as 2.4 in one of these places). Cases of lead poisoning have been caused by burning in the ovens pieces of wood taken from old building materials painted with lead colours.

There is also the risk of pulmonary mycosis developing owing to mycelia, which often grow in damp and dark surroundings. These cases are often diagnosed as bronchial catarrh (Blondi).

The effect of high temperatures and stagnant air also presents an important occupational risk. The high temperatures, 38°-40° C. and even higher, compel the men to work comparatively lightly clad, and sometimes even naked. The cramped space, its unhealthy situation, often, for example, underground, and lack of ventilation add to the ill-effects of stagnant air. In summer, the factory is often heavy, damp and hot; it is difficult to avoid these conditions if the nec-
Bakery Industry and Health

Essary technical appliances have not been provided, for there is a risk of causing draughts which are unpleasant for the worker and dangerous for baking operations, e.g. for the rising of the dough.

In some countries these conditions are even worse: the workplace serves also as a dormitory for the men who sleep on the premises. It has even been reported that workers are often not provided with beds, but actually have to sleep on the shelves where the bread is placed and make their toilet in the room where they work. Even if beds are provided, the material conditions are not much better; several workers often have to share one bed.

Official and private enquiries have brought into prominence the fact that many of these premises are unsatisfactory, often dirty, and filled with all sorts of refuse; walls and partitions are seldom washed down; the sanitary conveniences are filthy, and sometimes one even finds them in a corner of the room where the work is carried on; too often lavatories are lacking altogether, and cleaning arrangements are absolutely primitive.

The bad food and irregular meals bring on diseases of the alimentary canal. These diseases of the digestion, combined with the other adverse influences referred to above, lower the general physiological state, so that there is very little resistance when the worker becomes exposed to infectious diseases.

The bad hygienic and social conditions fully explain the heavy labour turnover prevalent in this industry.

**STATISTICS**

(a) The statistics available for general sickness do not accurately represent the injury to the health of bakers caused by their occupation, for the following reasons: a considerable number of slight illnesses are not notified; serious physiological disorders generally escape the observation of those who are making enquiries, especially when the worker lives with the owner of the business; many of the harmful effects become apparent, and bring on incapacity for work, only when the worker has already adopted another trade, for the baker often leaves his trade when he feels his health is endangered.

The statistics show that the days of sickness while there is still capacity for work are more numerous than the days of sickness accompanied by incapacity. It is just the opposite of what takes place in other trades, and this explains why the rate of sickness, and also the duration of the cases of sickness, are below the average for occupations in general. This also makes it possible for experts to say that there is no question of considering that an excessive degree of sickness among bakers is definitely established as a statistical fact.

According to the Sickness Bureau at Frankfort (1900), respiratory troubles come first on the list of sicknesses which involve incapacity for work, and digestive illnesses come first amongst those not involving incapacity.

Undoubtedly the youth of the workers explains the sickness figures, for 75 per cent. of these workers are from 15 to 19 years old. In many cases children were employed (Zadek) and even women (Epstein).

(b) Enquiries and researches on the particular sickness rate of bakers show that some diseases are found much more frequently among these workers than among others.

Out of 98 bakers examined, Epstein found 52 cases of respiratory diseases, 32 of which affected the apices, 18 cases of cardiac affections, 19 cases of phlebitis, 10 cases of jaundice. After another enquiry embracing 183 sick bakers who had been treated in the Munich hospitals during 1889, the same author reported 60 cases of respiratory diseases, 54 of infectious diseases, 23 of gastro-intestinal troubles, 20 of rheumatism, etc.

Experts especially emphasise the frequency of respiratory diseases among bakers. Hirt gives 58 per cent. for all internal diseases, of which 7 are phthisical, 1.9 emphysema, 10.9 bronchial catarrh, 8.4 pneumonia.

The Berlin Local Sickness Bureau gives for the years 1889 to 1892 a relative value of 6.4 per cent. for respiratory diseases among bakers, compared with 3.8 per cent. for the total of its members, and 3.5 per cent. for acute and chronic bronchitis against 2.9 for all its members.

The Bakers' Sickness Society in Vienna points out that for 1890-1893 the average annual incapacity for work of 1,190 members was 102 caused by respiratory diseases which were classified as follows: 58 acute and chronic bronchitis, 5 emphysema, 6 pneumonia, 5 pleurisy.

According to Schuler and Zadek, pulmonary tuberculosis takes a heavy toll of bakers, and this is confirmed by numerous statistics (Epstein, Fox; statistics from Switzerland and Vienna, etc.). The older men (26-35 years) seem to show a higher percentage (57) than the younger men (24 years). This is accounted for by the fact that the frequency of tuberculosis increases with the length of employment.

Bodily deformities were also of frequent occurrence. According to the Vienna Sickness Society they figure as 22.7 per 10,000 in the case of bakers, whereas they only reach 7.1 for other trades.

For some time past the frequency of hernia among bakers has been pointed out. According to Oldenberg, it would appear that 70 per cent. of working bakers over 40 years of age suffer from this trouble, and according to the Vienna Sickness Society (1900-1907) there were 45.9 cases among 10,000 members who are...
bakers, whereas the number is only 19.9 for other associated trades.

As regards diseases of the cardio-vascular system, originally mentioned by Ramazzini, according to the numerous data collected by Layet, Spatz, Ogles, Epstein, Hoessel, Maligne, etc. according to the figures supplied by the Austrian Sickness Societies, it appears that the percentage for bakers is 3.9 and for confectioners 3.1. Of these only 1.5 represent heart disease among the former, and 1.9 among the latter group.

The reports relating to skin diseases are more important. The Munich Sickness Society in 1889 reported 49 cases of dermatitis among 175 bakers who were treated; the Frankfort Society in 1900 gave, among 905 bakers, 32 cases of dermatitis accompanied by incapacity for work and 86 cases without incapacity.

Amongst 168 bakers, of whom 18 were confectioners, Epstein reported 172 cases of dermatitis for the period 1903-1905 classified as follows: eczema 37, puritic eczema 7, various cutaneous lesions 14, itch 12, and venereal diseases 102.

Statistics on bakers' eczema (itch) deal chiefly with cases in Great Britain, where this dermatitis has been studied. At the Liverpool Charity Skin and Cancer Hospital, 197 cases were treated from 1910 to 1921; 18 cases from 1910 to 1913, 81 from 1914 to 1918, and 98 from 1919 to 1921. Parsons reported a total of 126 cases observed in different parts of England, dating from 1913, out of which 7 of the 48 cases reported at Liverpool affected master bakers.

As regards acne Galewski treated, at Dresden from 1898 to 1908, 181 bakery workers who were suffering from skin trouble, and about a third of these had acne.

The frequency of venereal diseases amongst bakery workers is explained by the conditions described above. From 1903 to 1905 Epstein observed 102 cases of venereal diseases out of 172 cases of sickness among bakers; these figures were sub-divided as follows: gonorrhoea 74, syphilis 28.

Dental lesions and diseases of the alimentary canal are also very common and take the third place in the statistics of the Munich Sickness Societies, and the first place in the Frankfort Societies. The health conditions of bakers, the direct result of the hygienic conditions under which they work, explain, according to some experts, why these workers are so seriously subject to infectious diseases.

(c) However, according to statistics, this trade has not a heavy death rate. As a matter of fact, German, Austrian, English, and Swiss statistics uniformly affirm that the death-rate is under the average in the case of young workers, and only increases in the case of those over 40. This statement has been confirmed by the work of a Commission of the British Ministry of Labour in 1919. Nelson gives the following figures for the death-rate: bakers, from 20 to 40 years old, 2.12, as against 2.31 for workers of all other occupations; bakers from 50 to 70 years old, 13.18, in contrast to 9.46 for workers of all other trades. An enquiry made by the Federation of Viennese Bakers in 1910 disclosed that the death-rate among the members of the Sickness Society for bakers was for the period 1892 to 1902, 9.7 per 1,000 and 6.4 per 1,000 among bakers and confectioners; these rates being lower than those prevailing among the members of the other federated societies.

On the other hand, Rosenfeld reported a higher death-rate among bakers under 20 years of age than among members of the same age in other federated societies. As a matter of fact, according to this expert, the Vienna Sickness Society is said to have reported in 1905 that on the one hand the death-rate per 100 members was 3.33 under 15 years, and 0.58 between 16 and 20 years, and on the other hand, per 100 bakers under 20 the death-rate was 6.28.

In the United States, according to statistics furnished by Hoffmann, and referring to 1,307 deaths among bakers, the death-rate due to respiratory diseases is 34 per cent., including 20.4 due to tuberculosis. The statistics for deaths in 1909 show a total of 952 for bakers and these are divided up as follows: out of every 100 deaths for the group aged from 25 to 34 years, pulmonary tuberculosis 29.1, pneumonia* 12.1, chronic nephritis 2.8, suicide 5.7, accidents 12.8; for the group aged from 35 to 44 years, deaths due to the same causes were respectively *99.9, 7.4, *3.9, *4.5, 5.7; for the group aged from 45 to 54 years, **15.7, 8.9, *9.8, *4.3, 5.6. In this last group the figures for cancer are 9.6, and diseases of the heart 9.6. [The figures which are marked with an asterisk (*) show a higher percentage than those referring to all occupations. It must, however, be noted that this latter group includes 210,507 deaths, whereas the group of bakers only contains 952 deaths, including 141 at ages 25 to 34 years, 176 at ages 35 to 44 years, and 198 at ages 45 to 54 years.]

According to the statistics, the highest death-rate is due to respiratory diseases and the next highest to diseases of the heart. According to Bertillon's early statistics, the death-rate used to be higher for all ages in the big towns. Most experts draw attention to the existence of a high death-rate from respiratory diseases in the bakery trade, which is considered a definitely established statistical fact.

A recent enquiry carried out at Nancy (1925) shows a death-rate of 10 per 1,000 due to tuberculosis among working bakers, whereas for the whole population of the city it was only 2.5. A comparison with the number of confectioners shows that confectioners have a lower death from tuberculosis than bakers. The morbidity in the bakery trade is nil and the morbidity below 1 per cent. This difference is due to the fact that bakers work longer hours and to the fact that working bakers do not benefit by the eight-hour law, nor do they get a weekly rest.
In Italy an enquiry was effected in 1925 in regard to hygiene in bakeries. It was carried out by public health authorities under the control of provisional health officers. It was also intended to effect an investigation into health conditions, but the data on the incidence of dermatitis, eye disease, respiratory troubles, etc., were not considered to be sufficiently exact to warrant being made the subject of a statistical enquiry.

This enquiry revealed the fact that through the baking industry has, especially in certain districts, made great progress, it has not as a whole attained a satisfactory level of technical perfection. The industry comprises even at the present time too many family businesses, with the result that, especially in Southern Italy, the hygienic conditions are below the average.

The 29,067 bakeries inspected employed about 60,196 workers (12,684 women, 21.1 per cent., and 2,614 children, 4.4 per cent.): approximately 21,000 of these workers were about 80,196 workers (12,684 women, 21.1 per cent., and 2,614 children, 4.4 per cent.).

It was also intended to effect an investigation into health conditions, but the data on the incidence of dermatitis, eye disease, respiratory troubles, etc., were not considered to be sufficiently exact to warrant being made the subject of a statistical enquiry.

This enquiry revealed the fact that through the baking industry has, especially in certain districts, made great progress, it has not as a whole attained a satisfactory level of technical perfection. The industry comprises even at the present time too many family businesses, with the result that, especially in Southern Italy, the hygienic conditions are below the average.

The 29,067 bakeries inspected employed about 60,196 workers (12,684 women, 21.1 per cent., and 2,614 children, 4.4 per cent.): approximately 21,000 of these workers were.

Some 3.7 per cent. of these bakeries were found to have unsatisfactory lighting and 3.5 per cent.

On the other hand, cleanliness left much to be desired in the case of 34.7 per cent., 32.8 per cent. were without sanitary conveniences (17,351 workers, 28.8 per cent.), 67.2 per cent. were without washing accommodation (51,825 workers, 85.1 per cent.), 88.5 per cent. without cloakroom accommodation (50,105 workers, 83.2 per cent.); in 25.8 per cent. no working clothes were provided; if 2.1 per cent. of the bakeries the workers slept in the bakery itself.

PATHOLOGY

Diseases of the locomotor system are represented by muscular and articular rheumatism due chiefly to chills supervening on a state of exhaustion; by troubles connected with the growth of bones, which is an indication of strain in the case of young workmen, but which are often found in the case of adult workers also; by flatfoot, also due to fatigue of the posterior tibial muscles and to relaxed ligaments of the plantar arch caused by standing for long hours.

The most characteristic lesions were deformities of the legs, and the most frequent was certainly *Genu valgum* — the knock-knee of the baker. In the case of this lesion, which is all the more easily developed because bony growth is not completed in the case of young workers, the leg forms with the thigh an angle opening outwards; there is contraction of the adductors of the thigh with hyperextension and external rotation. The lesion is sometimes uni- and sometimes bi-lateral; it is chiefly observed among workers who formerly suffered from rickets, or who suffer from a delayed form of the disease.

The lesion is due to the fact that the worker chooses a position which, while it tires the muscles less, involves pathological modifications of the bones. When only one leg is affected by *Genu valgum*, or if the condition is uneven and especially noticeable on one side, shortness of the affected leg develops with lowering of the pelvis and a pathological curvature of the vertebral column.

*Genu varum* — that is to say, bow legs, concave inwards, with contraction of the adductors — used to be, and still is, much rarer.

These two lesions reappeared during the war among young bakers who had been rejected by the military doctors. These young men provided extremely favourable ground for the development of these lesions, for apart from their physical weakness and their disposition to rickets, they were the victims of bad environment and insufficient feeding. The long hours of standing and the loss of elasticity of the vascular walls bring on, in the case of old bakers, trouble in the venous circulation of the legs, with varicose veins, swollen feet, thrombosis, phlebitis, and abscess in the leg.

Physical degeneration, the result of the work, explains why the apprentice bakers appear lowest on the list, from the military point of view, as regards size and weight.

Cardio-vascular lesions affect the kneaders chiefly (Shann, Hallfort) and the men who carry the bread (Zadek) — these latter are especially susceptible owing to their youth. The lesions consist essentially of hypertrophy of the heart, acute or chronic dilatation, and valvular lesions.

As regards vaso-motor disturbances, congestion of the head, epistaxis and erythema are reported.

Strain and overwork are not alone responsible in the etiology of the cardio-vascular lesions, for an important part is also played by anaemia, brought on by bad ventilation, etc. Nervous troubles take the form of neurasthenia, which often shows itself in a sexual form and this is encouraged by the promiscuity referred to above; 4 cases were observed by Kopp in 1903-1905 among 168 bakers suffering from various affections.

Suicides occur frequently. The regular statistics published in Great Britain for 100 trades prove that the bakery and pastrycooks rank third among the trades where suicides are most frequent.
The most important injuries caused by the various forms of dust are itch or baker's eczema, described for the first time (in 1817) by Willan under the name of "diffuse psoriasis".

This disease starts with a sensation of burning on the anterior and cubital surfaces of the forearms, as well as on the back of the hand, associated with some degree of pruritus. When the disease takes an acute form, a little papular vesicular eruption appears, becomes vesicular, opens and begins to weep. Itching is pronounced and becomes exasperating when the arms are exposed to heat.

The chronic form the skin is infiltrated and hard, with tags and dry scaly patches more or less circular in shape; sometimes the patches weep (the moist kind).

Baker's eczema is protein and the various states of its evolution — papular, vesicular, and pustules — are often associated with each other. The lesion is generally bilateral, but often spreads, through scratching and auto-inoculation, on to the face, the genitals, and even, in bad cases, all over the body. This eczema is often infected in a secondary way, forming pustules at some depth.

According to recent reports there does not seem to be any seasonal distribution; in some cases it is very hard to cure this dermatitis, especially in the case of elderly persons.

The etiology of baker's eczema has been discussed a good deal. According to Prosser White, a very important point is to distinguish and to exclude occupational diseases from the two following pathological conditions: seborrhoeic, eczematous, lichenoid, psoriasis-like, and the erosive, papuloid or pustulous. Blame attaches to the flour, the dust of which mechanically obstructs and irritates the skin. Different qualities of flour vary in their irritant capacity: a good quality of flour does not cause dermatitis, which, for example, is not found in biscuit factories where a superior quality of flour is used. Chemical products mixed with the flour are also blamed, such as persulphates or nitrates of calcium, or acid phosphate of lime; or again those chemicals used for whitening flour, e.g. chloride of lime and peroxide of hydrogen. Yeast, sugar and salt have also been blamed. De Jong has attributed the dermatitis to some peculiar property belonging to salt, and supported his hypothesis by the fact that the same lesions are found among salters and packers of herrings and packers of rock salt. The salt which is contained in the dough, and which impregnates the arms of the worker, crystallises when he approaches the oven.

Other agents appear to be responsible for baker's itch: exposure of bare parts of the body to heat; maceration of the skin by sweat, and by kneading the dough (as a matter of fact dermatitis is most often found among the staff of bakeries where the dough is prepared or kneaded by hand); water used for washing the hands; individual negligence and lack of cleanliness. Then again the blame is put on the action of ordinary parasites — encouraged by sleeping together in bed, and by lack of cleanliness — and on the specific parasites of flour (acari) or on the inferior qualities of the sugar sometimes used for adulterating the flour. McCormick, of Liverpool, considers that 55 to 65 per cent. of the 180 cases of itch he observed between 1914 and 1921 were due to an acarus.

Undoubtedly individual predisposition must be taken into account, whether local or general, and particularly the condition of anaphylaxis (sensitivity to proteins) of each individual.

On the other hand, lack of cleanliness, and numerous little cracks in the skin encourage the formation of boils, whillos, etc., and are liable to bring on inflammation of the subcutaneous cellular tissues (phlegmons, abscesses, etc.) and even of the lymphatic system.

It must be realised that cases of itch may be met with among bakers, and that, by the act of scratching, this may pass on to eczema, and it is really very difficult to distinguish whether it is eczema or a recurrence of the itch. Besides there may actually be seen, in the same person, baker's eczema, itch, and eczema secondary to the itch.

Dental lesions are very important and are characterised by a soft progressive form of decay, which starts in the neck of the tooth, and spreads over the surface towards the crown (superficial caries). The front teeth are affected first; they are naturally the most exposed to whatever causes the lesion, and turn brownish or blackish. In the case of young men, other lesions are observed, due to the flour dust forming a kind of mastic which impedes the growth of the teeth.

The pathology of these lesions is rather complicated. The dust which comes from flour, and especially that which comes from sugar deposited on the free surface of the teeth, becomes transformed into saccharic, acetic and oxalic acids, etc., encouraged by the constant presence of bacteria in the
temperatures, causes, typical and can be explained by other points out, but these changes are not diminished in haemoglobin has been living and feeding, and to dental caries. A diminution in haemoglobin has been chiefly due to the irregular condition of the carrier finds conditions favourable to persistent effect, but the hygienic condition of flour dust does not seem to.

Cases of gastroalgia and gastritis are mostly reported, generally than the acute form, which is common than the chronic forms are reported, generally as a matter of fact, this form of caries is most often found among pastrycook confectioners, who handle sugar most of the time, rather than among the bakers who work mostly with flour.

The action of acids is to decalcify the tooth; the phosphates and carbonates of lime in the enamel and the bone become dissolved; then, when the decalcification has taken place, the bacillus of putrefaction enters the stage and plays its part. Of course this process of destruction is favoured by predisposing conditions, such as bad feeding and lack of attention to the teeth.

Lesions of the mucous membranes are due to dust caused by flour and sugar, etc., which combine with the secretions to form a sticky, irritating mass. But there are quite a number of experts who deny this irritating action of flour and attribute more importance to the high temperatures, which parch the mucous membranes, and to chills. Whatever may be their cause, these lesions are specific by their etiology, but not by their symptomatology.

Amongst forms of sickness may be quoted blepharitis, conjunctivitis, and external otitis. Among the more important forms must be noted lesions of the respiratory passages. As regards the nose and pharynx, chronic forms are reported, generally accompanied by swelling and redness of the interarytenoid region, and lesions of the vocal chords. Chronic bronchitis, which may extend to the furthest branches of the respiratory tree, is more common than the acute form, which is peculiar to beginners. Of all lesions, chronic bronchitis is the worst. It is due to the inhalation of large quantities of flour dust.

Narrowing of the small bronchial tubes brings on capillary bronchitis accompanied by cough, glairy expectoration, atelectasis of the corresponding pulmonary alveoli and emphysema with dyspnoea (asthma). These lesions, in their turn, bring on circulatory troubles sometimes ending in complete cardiac insufficiency. The inhalation of flour dust does not seem to have a persistent effect, but the hygienic conditions are such that any bacillary carrier finds conditions favourable to the diffusion of disease by spitting. Cases of gastralgia and gastritis are chiefly due to the irregular condition of living and feeding, and to dental caries. A diminution in haemoglobin has been pointed out, but these changes are not typical and can be explained by other causes, such as the effect of high temperatures, of poisonous gases, carbon monoxide, lack of sunlight, bad hygienic conditions, long hours spent in badly ventilated, and badly lighted premises, and fatigue.

The high temperatures also cause congestions, epistaxis, and erythema of the exposed part of the body.

Rheumatic troubles arise from sudden changes of temperature, and from draughts. It must also be noted that bakers are exposed to many accidents arising from defective lighting of underground premises and stairs; from active work carried on at night and, sometimes, when the man is half asleep; and from machinery, such as doughmixers, dialers, kneaders, and cutters. These accidents take the form of burns, fractures, and cuts.

HYGIENE

Prophylactic measures consist essentially in general hygienic measures, either in relation to the premises where the work is carried on, or to the baker himself, or even to the organisation of the trade.

Among the chief hygienic improvements of the premises, the first to be urged should be abolition, if possible, of underground bakehouses, better conditions of natural or artificial lighting, of ventilation and of cleanliness.

The question of ventilation is no doubt difficult, for it involves problems of heat, of smoke production, and the constant condensation of moisture; but the difficulties are not beyond the capacity of modern technique. Arrangements should also be provided for freshening the air, which ought not to be too dry.

The working premises should be kept scrupulously clean. Regular cleaning down with water of the floors of rooms where kneading is done, and of ovens is recommended, and also scrupulous cleanliness of all receptacles used for preparing and making dough and bread, including machines, tins, and baskets. No one should be allowed to sleep in the rooms where the kneading is done.

As regards personal hygiene the worker should be admonished to safeguard his health by paying scrupulous attention to cleanliness; this will, however, only be possible where adequate material facilities are available for his use. Lavatories must therefore be provided and kept in working order in a part of the building quite separate from the rooms where the breadmaking goes on. These lavatories
must be up to hygienic standard (see article “Personal Hygiene”) and must be provided with the necessary means for cleansing the mouth and nails, for this is essential if eczema and dental caries are to be successfully avoided.

Arrangements must also be made for the provision of douche baths, drinking water, dressing rooms, and canteens. Where the workers are housed by the owner of the bakery, the sleeping accommodation must conform to hygienic requirements (see article “Social Welfare”).

Among the measures of personal hygiene must be included the practice of medical examination on commencing work and also periodically.

An adequate working organisation should make use of all practical means for improving the hygienic and sanitary conditions of the trade. First and foremost hand work should be superseded by mechanical means, by mixers, kneaders, and machines for cutting up and shaping; this step is not only a means of prophylaxis against fatigue, but it also prevents the diffusion of flour dust. Most machines are closed in, and can be adapted in such a way that no dust is liberated either from the flour or from dried particles of dough.

Then the hours of work must be limited, and night work must be stopped in the baking trade as at present generally carried on. Yet as regards big establishments where work goes on continuously, and is executed in three shifts, and which, as a matter of fact, are very well equipped from both technical and health points of view, the drawbacks of long hours and night work completely vanish; the workers are not overstrained and night work can be taken in alternate spells.

**LEGISLATION**

The work of women and children is regulated either by general laws or by special laws to be dealt with further on.

In addition to general regulations on the hygienic conditions of the workplaces, special regulations on bakeries have been laid down in the following countries:

**Austria**: Ordinance of 1893 of the Magistrate of Vienna and the Austrian Act of 3 August 1919 on children in bakeries.  
**Belgium**: Royal Decree of 22 July 1925 laying down proper measures to ensure the hygiene, health and safety of bakers and bakery workers.  
**Finland**: The Regulation of bakeries of 16 July 1908.  
**France**: The Decree of 26 August 1923 laying down the ban on night work.  
**Germany**: The Prussian Ordinance of 1911 relating to children and adolescents. Act No. 71 of 31 March 1926, modifying the Act of 9 June 1920 on sleeping accommodation of the personnel.  
**Great Britain**: Section 27 of the Factory Act of 1901 and the Order of 30 December 1902 on the minimum cubic space. The Act of 1920 regarding women and children. Welfare Order of 26 February 1927 for factories and shops where bread, pastries and biscuits are prepared.  
**Norway**: The Royal Decree of 26 August 1916, etc.  
**United States**: Indiana Act, 1919; Massachusetts Act, 1921; etc.

These laws or regulations lay down measures which are more or less detailed, as to the depth, height and cubic capacity of the workshops, the cleaning or white-washing of walls, lighting, ventilation, removal of waste water, the provision of drinking water, sanitary conveniences and lavatories; prohibition of the use of underground work places which do not meet the minimum of hygienic requirements; the prohibition of the use as sleeping quarters of places annexed to bakeries and not completely separated from them.

Medical examination on commencing work, and periodically, is quite frequently laid down.

The question of the hours of work is intimately bound up with that of the prohibition of night work.

Acts restricting the duration of work have been passed by Austria (1912, 1919, 1920), Belgium (1921), Czechoslovakia (1919), Denmark (1921), Italy (1898), Germany (1896-1923), Netherlands (1919, 1920, 1922, see section 4, Article 33 and following, 1923), Poland (1921), Sweden (1920-1923), etc.

For a long time the problem of prohibiting night work has been the subject of discussions at hygienic and sociological congresses, as well as of demands from the workers.

Night work is actually (1926) prohibited by law in a large number of countries (about 23). Various enactments differ in their details as to the compulsory period for rest (generally from six to nine hours), as well as with regard to exemptions. Various exemptions deal with certain kinds of work or certain kinds of bakeries, and temporary ones deal with unforeseen circumstances, such as accidents, and matters beyond control or with foreseen overtime at holiday seasons. The text of these exemptions is sometimes loose, sometimes rigid. Amongst others may be mentioned the Austrian Act of 3 April 1919; the Belgian Act of 14 June 1921 on the eight-hour day, and the Royal Decree of 10 August 1924 relat-
ing to the length of the working day in the baking trade; the 
Chilean law of 31 December 1924, and of 24 February 1925; the 
Czechoslovakian Act of 19 December 1918; the Danish law of 
9 June 1920; the law of Finland of 4 June 1908; the 
French Act of 23 March 1919; the German Ordinance of 23 November 1918; the Greek 
Ordinance of 14-27 September 1912, modified by the Royal Ordinances of 24 December 1921; the Italian 
Ordinance of 22 March 1908; the Latvian Act of 
11 March 1923; the Norwegian Act of 
14 April 1906 and the provisional Act of 
4 June 1918 (length of rest to be twelve hours); the Act of New South Wales of 
23 December 1919; the Dutch Act of 1 Nov-
ember 1919, modified by the Acts of 1921, 
1922, and 1923 (length of rest to be ten 
hours); the Polish Act of 18 December 1919 
and the Ministerial Decree of 10 Decem-
ber 1923; the Decree of the Central All-
Russian Council of Soviets of 29 November 
1921, and the Decrees of the Commis-
sariat of Labour of 24 August 1922 and of 
10 March 1923; the Spanish Decree of 
3 April 1919, and the Ministerial Decree of 
10 June 1919; the Swedish Act of 
22 June 1923 (length of rest: 10 hours); the 
Cantonal Acts of the Swiss Confederation; the Act of Uruguay of 
19 March 1908 and of 15 October 1920; etc.

From the international point of view it should be mentioned that at the Session of the 
International Labour Conference in 1925 a Draft Convention concerning the 
prohibition of night work in bakeries was adopted. The Draft Convention prohibits 
the making, during the night, of bread, 
pastries, or similar products with a flour 
basis, but does not apply to the wholesale 
manufacture of biscuits. The prohibition ap-
plies to the work of all persons, masters 
and workmen alike, with the exception of 
domestic manufacture on the same family.

The period of rest laid down is at least seven hours and includes the interval be-
tween 11 p.m. and 5 a.m. (10 p.m. to 4 a.m. 
under certain conditions).

Permanent exemptions deal with the 
carrying on of preparatory and supple-
mentary work which may not be done by 
young men below 18 years, with bakeries 
in tropical countries, and the weekly rest.

Temporary restrictions relate to over-
time, to emergencies of an ordinary kind, 
to accidents and circumstances beyond 
control.

Compensation for occupational diseases 
of bakers is provided by Great Britain, 
where baker's itch is included under the 
heading of dermatitis produced by dust 
or liquids, and by Queensland for phthisis 
among bakers.

Barium (Compounds of)

French: Barium (Compôsés du). — Ger-
man: Bariumverbindungen. — Italian: 
Composti di bario. — Spanish: Com-
puestos de bario.

CHEMICAL PROPERTIES

Metallic barium (symbol Ba; atomic 
weight, 137) is a metal which alters very 
easily on exposure to air and which is 
not applied industrially. Amongst its 
compounds the following should be noted:

(1) Sulphate of baryta (barite, heavy 
spar, or fluo spar) (French: Sulfate de 
barium, baryline, spath pesant, or spalt: 
German: Bariumsulfat oder Schwefelhydrat 
Barium; Italian and Spanish: Solfato di 
bario) (formula, Ba SO₄), a white solid 
insoluble substance very dense (4.5) and 
widely distributed in nature in the form 
of elongated strata. All other compounds 
of barium are usually prepared from 
barytes passing through the sulphide. 
There is found on the market the natural 
sulphate and the sulphate prepared arti-
ficially. The bits of barytes extracted 
from the mine are washed, dried, crushed, 
and very finely powdered. The paste is 
sometimes made with water. Artificial 
sulphate is obtained as a by-product in 
the manufacture of hydrogen peroxide.

Large quantities of sulphate of barium 
are also manufactured as the chief pro-
duct by precipitating solutions of barium 
chloride by means of sulphuric acid or 
magnesium or sodium sulphate. Like the 
chloride (see later) it is prepared by 
starting with barytes; this method of 
manufacture is in fact a process of purifi-
cation of the natural sulphate. 

The barium sulphate is found on the 
market under the name of "fixed white " 
(blanc fixe), a paste with 15-20 per cent. of 
water. Its fine white colour, quite unalter-
able, causes it to be used in painting, but since its covering power is poor it is mostly used mixed with other pigments or colours: white lead, Venetian white, Hamburg white, Dutch white (see article "White Lead"), chrome green, Prussian blue, etc. It is very largely used for imparting a satin sheen to papers (wall paper, decorative paper, photographic printing papers), in the manufacture of lakes made from tar colours, of artificial ivory, of rubber goods, etc. Gorgonzola cheeses are sometimes covered with a crust of barium sulphate.

(2) Lithopone, a mixture of zinc sulphide and barium sulphate (see article "Lithopone").

(3) Barium carbonate (French: Carbonate de baryum; German: Bariumkarbonat, Kohlensaures Barium; Italian and Spanish: Carbonato di bario) (formula, BaCO₃), a solid white salt, very slightly soluble in water, and which only decomposes at a very high temperature. It is found in the ground (witherite) in Great Britain, Silesia, Hungary, Syria, Russia, South America, etc.

The industrial preparation consists in heating a mixture of heavy spar, coal, and carbonate of potassium or "pearl ashes". Potassium sulphide and carbonate of barium are formed and separated by washing in water. This process also facilitates the preparation of other barium derivatives.

(4) Barium sulphide (formula, BaS), obtained by reducing the natural barytes by coal and draffing it with water. Substances facilitating reduction are often added to the mixture of barytes and coal — such as resins, oils, bitumen, sawdust, sea salt, etc. Barium sulphide is very alkaline and serves as the starting point in the manufacture of most of the barytic compounds: Caustic baryta (Ba(OH)₂), which presents the same properties as the caustic alkalis (see also article "Lithopone").

(5) Barium chloride (BaCl₂), a crystallised substance, soluble in water, used in laboratories as a reagent of sulphuric acid and of sulphates and for preparing and fixing white. Barium chloride is obtained by heating in a reverberatory furnace heavy spar mixed with limestone and calcium chloride.

(6) Barium nitrate (Ba(NO₃)₂), a colourless crystalline substance, prepared from barium sulphate, is used in pyrotechnics for preparing green fireworks.

**Toxic Action**

The metal presents no danger. The compounds equally would not seem to be of great importance from the point of view of industrial hygiene, yet when absorbed in strong doses by way of the mouth they may give rise to serious poisoning (Lehmann). In theory the occurrence of acute and chronic poison-
He found amongst these workers caustication of the conjunctivae and of the cornea differing from ordinary caustication by certain characteristics typical of the evolution of the lesion.

Sequira states that workers using salts of barium in the manufacture of fireworks have their hair whitened, and fairly often lose their hair and their eyebrows.

Whilst the neutral salts only exert a local action, the soluble salts are said to be absorbed and to give rise to a general action on the circulatory system (heart and blood vessels), digestive system, central nervous system, as well as the muscles. Elimination is by way of the salivary glands, the intestines, and in small quantities by the urine. Certain substances likely to liberate oxygen when mixed with inflammable or oxidisable substances, whilst free from danger when isolated, demand many precautions in course of transport. Thus, for instance, the presence of bioxide of barium in a cargo caused a fire on board ship. It is for this reason that adequate measures are required if accidents of this kind are to be avoided (B. Müller).

STATISTICS

Besides the cases reported above, it is known that four cases of poisoning by sulphuretted hydrogen were notified in Austria in a chemical undertaking, where barium carbonate was prepared by causing natural carbonic anhydride to pass through a solution of barium sulphide contained in large saturation vats. Two cases of serious poisoning by the same gas were reported (1908) in an establishment where barium chloride was prepared. One of the workers remained unconscious for two days.

The 1905 report of the German Trade Association for the Chemical Industry similarly cites a case of poisoning by barium chloride. Kipper noted (1926) a case of poisoning affecting a worker who had been employed for a few days on grinding barium peroxide. He suffered from paralysis of the right arm and leg, acceleration of cardiac activity, cyanosis of the skin, he complained of gastric pain and vomiting. Death supervened at the end of three days. The dust raised in course of the occupation was very abundant and contained 14 per cent. of barium oxide and 30 per cent. of carbonate (both highly soluble in the system).

HYGIENE

In salts of barium factories, where the product is got by reducing barium sulphate, adequate measures should be taken to render the flooring impermeable and for ensuring thorough ventilation of the workrooms.

Construction and maintenance of the furnaces should be so organised as to prevent all danger from radiant heat and all risk of fire for the workers as well as for the neighbourhood (exclusion of combustible material from proximity to the furnaces).

Measures of protection should be taken against liberation of sulphuric gas and other injuries, and against disagreeable fumes, in workrooms and in the surrounding atmosphere. Catching and evacuation of dust is also called for.

Condensation of nitrous fumes must be effected when nitrate is decomposed for the preparation of caustic baryta. Vats and baths in which treatment is effected (decolorising of sulphate of baryta by means of hydrochloric acid in open vessels) should be provided with covers and the gas directed in to a very high evacuation chimney with a very strong draught. When stoves are used for drying the sulphate they should be constructed of incom bustible material; washing water should be neutralised with lime or carbonate of lime before being cast into sewers.

Preventive measures should be taken to avoid risk of contamination of the subsoil and of water, either by raw materials or by the products and their residues especially on account of the toxic properties of salts of barium.

Workers should receive protection during manipulation of acids and also against risk of poisoning.

Measures of personal cleanliness should also be enforced.

LEGISLATION

In Italy, boys under fifteen and women under twenty-one are excluded from salts of barium factories; they are also excluded from baryta factories when dust is liberated freely in the workrooms. Barium and its salts are not included in any schedule for purposes of compensation.

***

Bark

Bark is the external covering of the trunk and branches of trees. The bark of trees generally varies greatly as to thickness, being sometimes 4 cm. thick, but
often much thicker. Types of bark used in industry are:

1. Bark for tanning. This kind of bark is obtained from numerous common native and also exotic and tropical trees. The kinds used are very numerous and contain, according to the type, from 4 to 30 per cent. of tannin. Without giving a complete list, the following kinds of bark may be mentioned: alder, birch, chestnut, oak, beech, pine, willow, aspen, etc. There are, however, a very great number of trees in addition to these which contain to a greater or lesser extent astringent matter. The kind of tannin contained in the different plants varies.

2. Bark for dyeing. This kind of bark is becoming less frequently employed, being increasingly replaced by artificial dyeing substances. Amongst others are used prickly-ash (bright yellow), chestnut (grey and black), pomegranate (grey), buckthorn (green), quercitrin oak (yellow), brown and red.

3. Pharmaceutical bark used for tonics and febrifuges; carcarilla, cinchona, willow, imitation angustura, monesia, antihelminthics, rhatany; bark applied for other purposes: spurge flax bark, etc.

4. Bark for domestic use, such as Panama bark, which contains saponin, enabling it to replace soap when boiled, in making whisky, brewing, soaps, and other purposes. spurge flax bark, etc.

5. Cork bark (see article "Cork").

6. Bark used in the manufacture of fancy goods and wooden goods (frames, mouldings, etc.). Wild cherry bark and birch bark (the bark of the black birch), for instance, are notably used for the manufacture of light watertight craft.

**INDUSTRIAL PROCESSES**

Stripping, the object of which is to separate the bark from the wood in more or less extensive sheets, is generally effected in spring while the sap is rising. It is done by hand by tracing in the lower or upper or both extremities of the trunk a circular incision penetrating to the sap wood, then vertical incisions all round the trunk. With a curved tool in wood or iron the bark is detached in strips following the incisions. Barking may be carried out by a more effective method by injecting steam between the bark and the wood (Maitre, Nomaison, Vacheron processes, etc.), the latter possessing the further advantage of permitting stripping of bark at all seasons.

For the manufacture of tan, the bark is reduced to powder in a drum provided with knives and thereafter put into a ball mill or ground under pestles. Often tanners prepare the bark themselves.

For the manufacture of objects in moulded wood made from bark, the bark is stamped by pressure in moulds.

**SOURCES OF INJURY**

(See article “Plants”.)

**HYGIENE**

Reference should be made to the abovementioned article. It must, however, be stated that bark mills situated in towns come within the category of scheduled establishments and are thus obliged to enforce certain hygienic provisions. In this manner, workshops must always be well ventilated and provided with exhaust installation for removal of the dust liberated. Apertures giving on to public highways or neighbouring properties must be closed or protected with sheet metal. Pestles and mills must not be situated near common walls and must be so installed that neighbours are not disturbed by the noise made. The emplacement of the power machine must be separated from the workshops and stores, etc.

In France young persons under 18 are excluded from bark mills in towns when dust is freely liberated in the workshop. In Spain boys under 16 and women under 21 are excluded from grinding rooms in bark factories.

---

**Basic Slag**

**TECHNICAL DATA**

Progress in industrial technique led to the discovery that the manufacture of cast steel and iron ("homogeneous iron") by the Bessemer process gave cast metal rich in phosphorus which did not lend itself well to decarbonisation, and produced a defective and useless iron because the phosphorus did not burn and remained in the iron instead of passing into the slag.

Thomas and Gilchrist demonstrated in 1878 that this disadvantage was due to the presence of a considerable quantity of silicic acid in the interior linings of the converters, which had the effect of rendering the metallic bath and preventing the transformation or separation of the phosphorus in the slag to the state of calcium phosphate. The acid phosphates or phosphoric acid resulting therefrom
became reduced by the iron, and the latter always contained phosphorus.

These experts then proposed to replace the acid lining of the converters by a basic coating formed of pulverised magnesia and dolomite mixed in a paste with a little tar and compressed, and to add eventually to each charge some quicklime (10 to 15 per cent.) and a covering flux.

The slag thus contains all the phosphorus, which separates out in the form of calcium phosphate. Dephosphorisation takes place in four or five minutes, and the slag is discharged by inclining the converter at a suitable angle. It may be staved roughly that for each ton of steel there is obtained two to three hundred kilograms of slag, which float on the top of the molten steel in the furnace and which may easily be removed from the surface by means of an iron tool. The slag thereafter takes the form of a hard spongy mass, which is pulversised in half an hour.

At present phosphorated slag is also obtained in the Martin steel process. It can be rendered more friable by making it flow, still in a molten state, into water.

The slag extracted from the converters and cooled is generally stored for a more or less lengthy period. It is then sorted by hand to remove the pieces of iron which it may contain, and thereafter passed to extractors (electro-magnetic) which retain the iron or steel contained therein.

The slag is then submitted to crushing, with a view to reducing it to pieces of the size of a nut, and thereafter to a series of grinding and sieving operations, rendering it more and more fine with a view to obtaining finally a powder of the requisite quality.

The slag is transported mechanically to storing silos, to an automatic bagging apparatus, or to a wagon-loading centre.

The modern Mathesius process does away with the operations of crushing and grinding by submitting the crude slag for two or three hours to a pressure of ten to twelve atmospheres in a steam boiler, which has the effect of reducing it to dust.

For the preparation of "silicate of cotton" or "mineral cotton", a jet of molten slag is violently pulversised by being brought into contact with a jet of steam. The sudden cooling gives rise to the formation of small particles of slag in the form of filaments similar to cotton threads, which fall on the floor of the pulversisation room like threads of wool or spun glass.

The Thomas slag has a colour which varies from reddish brown to nut yellow. It contains phosphoric acid (14 to 20 per cent.), probably in the state of tri-calcic basic phosphate combined with a molecule of calcium. It also contains free lime (10 to 20 per cent.), silica, oxide of iron, manganese and magnesium, etc.

Thomas slag is put on the market in the form of a very fine powder, since its efficiency as a manure is proportionate to the fineness of the powder.

**USES**

Having remained for long without being utilised industrially, Thomas slag is to-day becoming more and more generally employed as an artificial manure, after reduction to a fine powder. It is also used in the manufacture of "silicate of cotton", which serves as a heat-insulating material or for deadening sound (for walls and floors, etc.).

**SOURCES OF DANGER**

It is sufficient to note the risk of burns in the course of manipulating Thomas slag while still hot.

Granulation of the slag in a jet of water prevents, it is true, the liberation of dust, but gives rise to the production of sulphuretted hydrogen. The principal risk, however, is that caused by dust liberated in a state of very fine subdivision. The discharging of slag is particularly harmful, since this operation is excessively dusty, especially when it is a question of slag which has been stored for a long time and which has started to disintegrate as a result of the influence of carbon dioxide and atmospheric humidity. Crushing, grinding, and passing through sieves also gives off a considerable quantity of dust due to lack of airtightness in the apparatus in which these operations are effected or in the localised exhaust devices with which they are furnished.

Bagging is a very dusty operation despite the precautions taken (automatic apparatus with localised exhaust), since the dust has a tendency to pass through the material of which the sacks are made and to fall on the ground when the sacks are moved, with a result that the floor of the workroom becomes covered with a layer of dust which is continually raised by the feet of the workers or by the wheels of vehicles.

The storing of sacks may itself be a source of danger. Some sacks burst under the pressure of those placed on top of them, but chiefly because the powdered slag attacks the material of which they are made. As a protection against this, resort has been made to a system of storing the powdered Thomas slag in wooden silos, only filling the sacks as required.

Beating emptied sacks which have contained Thomas slag is a dangerous operation on account of the dust liberated. This is also carried out in closed receptacles, which is all the more necessary since it is essential to avoid exposing the workers occupied in repairing
the sacks to the harmful action of the dust.

The transport of Thomas slag is also a source of danger for workers in the transport industry (dockers, railwaymen), who have complained of the harmful effects of this product. Dust, in fact, may pass through the sacking even when it is of very close texture.

In the course of manufacture of silicate of cotton, risk is connected with the action of small particles of this product, especially at the moment of packing.

Finally, agricultural labourers engaged in spreading the slag over the fields are exposed to the same dangers as the workers. The danger in question is specially serious when gusts of wind raise the fine slag dust in the atmosphere, thus facilitating its entry into the eyes and respiratory passages, etc.

**Harmful Effects**

According to certain authorities, Thomas slag is said to possess mechanical action, the reason for which is to be found in the very sharp cutting points of the small, hard grains of which the dust is composed. Other authorities hold that it is chiefly a question of chemical action due to the presence in the dust of particles of free quicklime, phosphorous compounds, sulphuric acid, etc. This hypothesis would seem to be confirmed by the fact that different varieties of slag are more or less harmful without microscopic examination being able to explain such variations for physical reasons. As regards lime, Roth draws attention to the fact that it cannot be an exclusive cause of injury, since slag, after long storing involving the transformation of all the free lime into carbonate of lime, still remains harmful. Further, no lesions analogous to those found among workers on Thomas slag are noted amongst limeburners.

As regards phosphoric acid, the opinion is held that this product in combination with quicklime in the form of tetra-phosphate is neither corrosive nor harmful.

It is, moreover, more highly probable that the harmfulness of slag is due at once to a physical and a chemical action (Villaret, Rambousek, Koelsch).

**Statistics**

The available statistics affect chiefly workers engaged in Germany on the grinding of Thomas slag.

A very detailed enquiry dealing with almost all the slag mills was carried out several years ago by the Health Office of the Reich. It reveals the high incidence among the workers of respiratory diseases of serious development.

Statistical returns prepared by Weyl and dealing with three establishments employing 9,994 workers (or an annual average of 998) over a period of ten years (1903-1913) gave the following figures relative to 100 workers:

<table>
<thead>
<tr>
<th>Total number of diseases</th>
<th>Duration of each case of illness</th>
<th>Total number of respiratory diseases</th>
<th>Duration of each case of respiratory disease</th>
<th>Cases of death by pneumonia</th>
</tr>
</thead>
<tbody>
<tr>
<td>Cases</td>
<td>Days</td>
<td>Cases</td>
<td>Days</td>
<td></td>
</tr>
<tr>
<td>Average</td>
<td>100</td>
<td>1,157.9</td>
<td>41.5</td>
<td>505.8</td>
</tr>
</tbody>
</table>

These statistics prove that sickness rates have been very high, as is seen when it is taken into account that for the same number of workers normal morbidity figures (number of cases) are from 40 to 43 cases per annum (statistics taken from the Reich insurance returns) and that the normal gravity of illness (duration of illness) is 850 days per annum. It is therefore seen that in the instance under consideration morbidity is twice as high and twice as serious.

The state of health of the workers in the Thomas slag industry is all the more striking when compared with that of the other categories of workers or social grades contained in the table on page 221.

In 1926, five factories with 633 workers showed per 100 workers: 88.9 cases of sickness, 28.1 cases of respiratory disease, and 1.3 fatal cases of pneumonia.

It must, however, be said that the above statistics refer to too dissimilar periods to be accepted without reserve.

Aufrecht, of Magdeburg, is said to have found among the workers of a slag mill, studied for two years, a very high incidence of pneumonia (48 per cent.) characterised by haemoptysis and a very serious mortality rate (37.7 per cent.). According to Enderlen (1892), quoted by Beintker, one-half of the Thomas slag workers suffered from inflammation of the lungs, with a mortality rate of 50 per cent., with a result that each year one-quarter of the workers belonging to this category die. Fatal cases of pneumonia from slag amongst agricultural workers have been reported by Roth, Borntrager, etc.

In Great Britain, serious epidemics of pneumonia due to or favoured by Thomas slag dust were reported in 1888, 1893, and
1900. In 1924, a fatal case of pneumonia was reported. An enquiry was carried out in 1907 by the Committee on Dangerous and Unhealthy Trades.

The Ballard enquiry, affected on the occasion of the epidemic which broke out amongst the grinders of Thomas slag at Middlesbrough, came to the conclusion that the pneumonia in question was not due to slag but to the fact that during the pneumonia epidemic the persons exposed to slag dust were more susceptible than others to this infection, which more often than not was of fatal issue.

An enquiry conducted by Collins in the mineral cotton factories has revealed the fact that these dusts caused irritation and itching of the skin, leading to dermatitis. When inhaled the particles in question cause bronchitis and cough ("slag-workers' cough"), and pneumo-silicosis. Collins, while examining workers in the packing department, noted that as soon as they began to feel ill they quit the work. Workers who periodically resume work are on the other hand very seriously attacked.

In France, an epidemic of pneumonia due to slag, with a very high mortality rate (44 out of 75 cases), was reported at Nantes, amongst the workers of a manure factory (Ollive, 1888). Other cases of pneumonia have been reported at Nantes by Monnier and Gautret, in 1921 and 1924.

Analogous cases of severe pneumonia due to dust containing lime were reported by Watkins Pitchford among natives occupied in the gold mines.

In 1923, the Dutch Thomas slag workers complained of fits of asthma, coughing, and abundant expectoration. Cases of skin ulceration (face, hands, feet) were reported amongst workers working in the rain.

Opitz reported (1920) that during the war women were employed in Germany in the slag mills. Whilst the monthly medical examination of the staff (1917-1918) revealed that the morbidity rate for respiratory catarrh was 5.7 for women as against 5.9 for men, it was also shown that the susceptibility of the women was more marked for serious respiratory disease (leaving out of account influenza), for they showed a rate of 36.8 against a rate of 27.9 for the men. The difference is still more marked for influenza. There was noted, in fact, for the men a general sickness rate of 31.1 per cent., and amongst the women 66.4 per cent., whilst in the Thomas slag department these figures rose to 73.3 and 93.

According to Wegmann, there existed from 1890-1893 in the district under the Zurich inspectorate a slag mill employing an average of five to eight workers. During the short period of its activity this establishment alone had two, if not three, deaths from pneumonia amongst its workers.

It is not only the workers engaged on grinding who are attacked. Leymann reports 4 fatal cases which occurred in a mill, 2 of which affected a locksmith and a warehouseman. In the same year 2 other fatal cases occurred amongst workers employed in discharging slag. In 1908, in one establishment, for an average of 108 workers engaged in manipulating Thomas slag which had disintegrated into dust, there were noted 67 cases of respiratory disease, 33 of which affected transport workers and 19 unskilled workers in the storing department. In 1912, there were reported 2 deaths of young girls employed in the workrooms for repairing the sacks.

The incidence of injury due to slag amongst peasants engaged in spreading this product over the fields is well known (conjunctivitis, oedema of the glottis, pneumonia, etc.).

Statistics relative to transport workers are unfortunately not available.
of attacks on different foci resembling clinically in such cases the pneumonia known as broncho-pneumonia.

The lesions met with in post-mortem examination reveal the following conditions: multiple lesions of recent bronchitis clear and accentuated, vaso-dilatation, sometimes ulceration and perforation of the bronchial tissue which is, as it were, destroyed by a physico-chemical traumatism from the slag dust, which constitutes a lacerating agent of the first order; multiple pulmonary lesions of different natures in the same patient: simple congestion, grey hepatisation centres, sometimes veritable excavations filled with blood which lead to anatomo-pathological diagnosis of abscess of the lung. Almost always there are found adhesions and exudation of the pleura. It may therefore be said that the lesion in question presents a clinical picture varying from ordinary pneumonia to broncho-pneumonia accompanied by abscess of the lung.

Bacteriological analysis has revealed the presence of the pneumo-bacillus of Friedländer and isolated or associated pneumococci as well as other usual micro-organisms of suppuration.

Chemical analysis has demonstrated the presence of slag dust on the tissue of the bronchial tubes and the alveolar endothelium.

The interpretation given to this condition varies according to the opinion of different authorities. As a result of animal experiment, it might be deduced that lime, phosphoric acid, etc., and slag dust exercise a caustic and wound-ing action on the respiratory apparatus in such a way that the mechanical lesions resulting therefrom become the starting point for acute conditions and penetration of pathogenic germs. This view, which has in its favour arguments of considerable probability and even certitude, is taken by Attimont, Gautret, Agasse-Lafont, Heim de Balzac, Loeb, Briault, and quite recently (1924) Brelet.

Other authorities think that the dusts in question only cause the ordinary effects of normal pneumoconiosis, cutaneous lesions — nasal and bronchial — which follow a chronic course, and that pneumonia is only a condition superimposed on favourable centres. This is the view of Brouardel, etc. Excessive work, fatigue and strain, exposure to variations of temperature and perhaps also a tendency to alcohol-ism, etc., favour the development of the disease.

The so-called epidemics are only in reality the simultaneous appearance of similar symptoms among workers ex-
posed to the same causes. The occurrence of contagious disease never in reality arises.

According to Heim de Balzac and Agasse-Lafont, it was wrong to designate the cases in question as “slag pneumonia”, and it is this error which gave rise to the arguments just summarised.

If cases of slag pneumonia are analysed in detail the following differences are noted between it and ordinary pneumonia: more diffused physical signs, association with signs of bronchitis, inflammation of the lungs, spittle hardly ever rusty, etc. On the other hand, very acute conditions are characteristic of the workers in question. This is proved by the high incidence of cases, their repeated occurrence among the workers, their frequent incidence among new workers, and the clinical anatomo-pathological and experimental data assembled.

PROGNOSIS

Prognosis is very serious. The high mortality among the persons affected has been referred to above. If the patient recovers, convalescence is long and difficult and pulmonary symptoms remain: purulent expectoration, recall-

If cases of slag pneumonia are analysed in detail the following differences are noted between it and ordinary pneumonia: more diffused physical signs, association with signs of bronchitis, inflammation of the lungs, spittle hardly ever rusty, etc. On the other hand, very acute conditions are characteristic of the workers in question. This is proved by the high incidence of cases, their repeated occurrence among the workers, their frequent incidence among new workers, and the clinical anatomo-pathological and experimental data assembled.

The enquiry conducted by Collis in the mineral cotton factories of Great Britain revealed the fact that in general workers become fairly easily acclimatised to the irritant action of the dust, but that before this happens they suffer from conjunctivities, eczema, sometimes haemoptyses, and general discomfort, with the result that many of these workers very soon quit the occupation. It is not, however, a question of serious lesions, and among workers who have worked in these factories for a long time there is noted only a diminution in chest expansion without signs of organic degeneration or tubercular infection.

HYGIENE

The prevention of injury is best attained by the application of measures taken for avoiding risk due to harmful dusts. Thus, for example, it is essential to employ exclusively adult men, and to limit the duration of their daily work. The flooring of the workrooms should be impermeable, cleaned at regular intervals by flushing with water or, better still, by means of mobile vacuum cleaners.

Technically there is also applied as a means of prevention granulation of the slag under a jet of water to prevent liberation of the injurious dusts. This operation, however, gives rise to the production of sulphuretted hydrogen, which must be removed in an adequate fashion by means of good ventilation. All the operations (grinding, crushing, sieving, bagging, transport, etc.) should be effected in closed airtight receptacles provided with efficient localised exhaust devices. Packing especially should be done in sacks of dustproof material. There has been recommended in this connection the use of paper sacks, which, however, was subsequently abandoned (Austria). The use of jute sacks is usually preferred. Transport should be effected mechanically in closed apparatus provided with exhaust devices. The very fine dust given off during the various operations is withdrawn by a ventilator which conducts it to a storing room. Storing of the slag should be effected in wooden silos separate from the workrooms, hermetically sealed under slightly negative pressure in order that the dust may be easily evacuated during the packing operations.

Experience has shown that in well-regulated establishments dust is given off only during loading of the first crushing machines. This disadvantage can be overcome by assuring the airtight closing of the apparatus and the installa-
tion of a well-thought-out exhaust device placed around the loading funnels.

In a German factory a good dust removal device was the means of reducing mortality among the workers from pneumonia from 28 to 1.2 per cent., a figure which is, however, twenty times higher than that for workers in other industries.

Measures of personal hygiene comprise the following: washing accommodation, douche baths, provision of working clothes including caps, where necessary adoption of respiratory masks, intervals during the course of the work spent in fresh air or alternating shifts for workers in the various departments of the factory, prohibition of carrying food into the workrooms, provision of canteens.

Medical examination should be required on starting work with a view to elimination of workers predisposed to respiratory disease (strict examination of the nose and throat), and periodic medical examination required thereafter to supervise the state of health of the staff.

As a protection for the transport workers the only effective measures are the use of airtight sacks (jute, oiled paper) and especially mechanical means of transport (loading and unloading). In Austria the powdered slag is usually acidified with an excess of sulphuric acid which renders the product hygroscopic, slightly sticky, and makes it adhere to the inside of the sack, rendering the latter completely dust-proof.

**Legislation**

Women are excluded in Germany from workrooms into which slag, ground or otherwise, is brought in packing material. In the Netherlands they are excluded from workrooms in which there is exposure to dust during grinding and sieving.

Youths under eighteen years of age, as well as women, are excluded in Germany from the above operations as well as from the work of shaking empty sacks, and in the Netherlands from all workrooms where the atmosphere is contaminated by slag dust.

Youths under sixteen years and women under twenty-one are excluded from manipulation of slag in Spain.

In Germany an Order of 25 April 1889 demands that slag mills should adopt detailed measures of hygiene (protection against dust, personal hygiene). This Order was amended on 15 November 1903 (duration of work), in 1911 (texture of the sacks) and in 1914 (technical improvements). In France there are no special edicts, but that of 29 November 1904 provides for the application of somewhat similar health measures to those usually applied in dusty trades. In Great Britain recommendations were formulated by the Committee on Dangerous and Unhealthy Trades in 1907.

In the Netherlands the law demands compulsory notification of cases of dermatitis and of respiratory disease due to Thomas slag.

**Basket Weaving**

The plaiting of vegetable fibres—branches, tendrils, stalks, weeds, bark, strips of fibre, chips — somewhat in the method of weaving, is engaged in to furnish a vast number of products, and consequently forms the basis of various industrial processes more or less developed amongst civilised nations as well as amongst savage races.

In this way are produced large articles such as baskets for use in mines in the coal trade, transport work, and factories, fine articles such as small household baskets, sieves, basket bread moulds, and other household utensils, luxury articles for florists and confectioners, articles of furniture (seats, tables, armchairs), basket work used in coach building (in cane or wicker firmly woven).

The material to be worked up is of vegetable origin and is derived from a large series of plants, and is mostly long, supple and cylindrical in form, sometimes threadlike, ribbonlike or in lamiae, offering a remarkable degree of resistance and a sufficient degree of flexibility to permit of being bent, twisted, rolled, or plaited. With the material in question fragile objects are covered and protected, as for instance
flasks; or, on the other hand, it may serve in making certain objects such as ropes, matting baskets, hats, etc.

The plants employed vary according to the object to be made and also according to the local vegetation available; in general it is the more flexible part of the plants that is employed, plants which grow in damp valleys and also marsh plants and marine plants such as the alga. The raw material of such industrial processes consists of the actual and veritable matting material such as corn straw (Triticum aestivum), rye straw (Secale cereale), straw from oats (Avena sativa), from buckwheat (Fagopyrum vulgare), from rice (Oryza sativa), from grass (Typha latifolia), from sword grass (Carex riparia), from salt grass (Carex caespitosa), from rushes (Sphagnum holochyronus, Scirpus lacustris), willow branches (Salix viminalis, Salix purpurea, Salix alba, etc.), raffia (Raphia textilis), jute fibre (Corchorus olitorius), the cocculus plant (Coccus nucifera), malacca cane (Calamus Rotang), etc., and fairly often and for certain objects the raw material is also in part composed of pieces of wooden framework to constitute the basis of these objects, as, for example, the sides, edges, bottoms and handles of baskets. These elements used for support are much less soft and pliable than the woven parts and come from various plants both with short and long stalks and even at times from hard wood plants. When this is so, strips, laminae or bands are cut from the trunk of the shrub parallel to its widest axis with a length of 2-3 metres, 2-5 centimetres wide, and some millimetres thick. Besides the framework these rough hard woods are also sometimes used for weaving, for instance, certain coarse types of baskets.

The basket-weaving industry is domestic in character and often gives occupation to a whole family; much of it is done by women, whom the employers provide from time to time with the raw material and who work in their homes, in courtyards or in the open doorway of their houses, with irregular hours; it is fairly rare for the women workers to congregate in some small, poor, and more often than not unhealthy, workplace, provided by the small employer. In either case the gain is in proportion to the amount of work effected, piecework being the system followed. Proper industrial establishments are rare, except sometimes in the case of the production of straw hats, though even this work also is principally domestic, at least the branch of the industry with which this article is concerned, that is to say, plaited straw hats and hand sewing of these plaited strips for making into hats.

As a general rule in this kind of work, the finest and consequently least tiring work involving manipulation of the most flexible and softest materials is consigned to women, and the coarser work (baskets of various types) requiring manipulation of harder and heavier material is entrusted to the men. Thus at times the framework of an object and the warp, so to speak, is made by a man, while the more delicate work of making the woof is done by a woman; such a division of labour is followed for instance in making basket-work coverings for large bottles. As an illustration of this class of work may be taken the covering of wine flasks, domestic work usually effected by women and widely engaged in in the wine-growing districts. The Tuscan flask-coverer winds by hand a strand of straw or salt grass (Carex caespitosa) round the body of the flask, emerging from the foot upwards towards the neck; thereafter, using a metallic needle (25-30 centimetres long) having the form of a flattened lance, with a blunt point and a large eye, the worker draws strands of sword grass (Carex riparia) round the body of the flask, emerging from the foot upwards towards the neck, both obtained from the same vegetable fibre.

Pathology in regard to this occupation is similar for all workers despite the varied forms of production; it is entirely a question of affections of the hands and is always related to the type of raw material used, being directly connected with the degree of softness, smoothness and flexibility of the latter.

Prosser White refers to the enlarged hands of basket makers with transverse lines and thickening of the closed fist. The thumb is covered with horny skin and is likewise flattened and enlarged (pressure against the fibre). Teleky has also described deformation of the hand consisting of curvature of the first and second phalanges of the fingers of the right hand bent towards the cubital edge.

Flask-makers show callosities, flat and not deep seated, chiefly found on the cubital edge of the first phalanx of the little finger extending to the styloid apophysis of the ulna on the two hands, but particularly on the right hand; less thick and extensive callosities are seen

15
on the thenar and hypothenar eminences and on the palm side of the first phalanx of the first fingers, and fairly small callosities on that of the second phalanx. On the contrary, at the base of the palm of the right hand on the carpo-metacarpal joint is found a profound callosity one or two centimetres in height and extending parallel to the width of the hand by the end of the large needle used, as stated, for the outer covering and for fixing the support and the handle of the flask. The needle is pressed against the carpo-metacarpal region with a view to pushing it up from the base to the neck of the flask while it is pressed down from the neck to the base by being grasped by the forefingers. These upward and downward movements are repeated round the flask as if to provide a wide border. The flaskmakers sometimes wound the radial edge of the left hand with the point of the needle (especially corresponding to the thenar surface), since they hold the neck of the flask firm with the left hand while pushing the needle with the right.

The palmar callosity near the pulse already described is typical of flaskmakers since it is due to the use of the needle and wowers who weave vegetable fibres present callosities on the hands varying as to disposition, form and thickness, according to the quality of the raw material used in weaving, according to the particular movement of the hand involved, and in some cases according also to the particular tool employed — for instance amongst straw weavers sewing straw hats, who rub away the edges of the first two fingers of the left hand by repeated piercing with the needle.

It would take too long and be unduly monotonous to enumerate the form and disposition of all the callosities met with on the hands of the different categories of weavers of vegetable fibres (makers of baskets, large and small, matting, straw rope and string, small luxury objects in basket work — fans, cigarette cases, etc.). On the contrary, it is worth mentioning that some of these workers and precisely those who employ natural or artificial materials of a resistant nature such as rushes (Juncus conglomeratus, Juncus inflexus) or bands of chestnutwood (Castionea sativa) for making the framework or bottoms of baskets or fine chips for making ropes (g. Pinus) or again those who use soft flexible materials with fine pointed and cutting edges such as certain rush plants (g. Carex) suffer from cuts. Wounds caused by such materials are almost always slight, but are characteristic of certain categories of workers engaged in making baskets, rope, and petrino cloth and generally the workers cuts are mostly found on the palmar surface of the phalanges of all the fingers and less frequently on the thenar and hypothenar eminences, extending beyond the respective radial and cubital edges. They are almost always inflicted close to the epidermis and rarely to total thickness of the cutaneous tissue; as, however, may be readily understood, the seriousness of the wound depends on the kind of material used and is in direct proportion to its hardness, asperity and particularly the fineness of its cutting edge. Cuts inflicted by any materials used are always numerous, even to the extent that they cannot be counted, on the hands of workers who have for long been engaged on such work; they are darkened with deposits of foreign matter, while the more recently inflicted show side by side with healed cuts and are characteristically disposed perpendicular to the major axis of the hand and parallel to each other, being caused by the drawing across the skin of threads or bands of vegetable fibres held tightly in the closed hand. These linear wounds with clean edges one centimetre or more in length do not cause much trouble to the workers when they are superficial; when more profound they bleed and sometimes require a protective bandage; rarely they set up troublesome and persistent fissures; only in exceptional cases do they suppurate. Workers who meet with such wounds as the latter, and more especially those with suppurating wounds, are obliged to quit their usual work (especially in winter), while women workers are rendered unfit for domestic tasks such as washing dishes and laundry work. Wounds caused by cut edges met with on the back of the hands, and when this is the case they are mostly pricking wounds or stabs due to violent contact of the hand with the raw material in the act of withdrawing it from the bundle or mass in which it is received. Among individuals who definitely quit the occupation in question traces of superficial wounds disappear, but those of more deep-seated ones remain. Almost all the raw material in question is used while still fresh from recent harvesting or else dampened and is therefore incapable of producing dust. Yet some of these materials, such as strands of chestnutwood, branches of hazelwood (Borjuz avelana) — containing tanning substances as well as the fresh and humid wood — may exert a chemical action on the skin of the
Calamus Rotang or Draco. and on the mycetes found on cutaneous Spergillus glaucus, etc. are: Mucor mucedo, Rhizopus nigricans, semination of moulds. stripping, precaution is to damp the reeds before place a newly formed epiderm. A useful weeks the crusts fall, leaving in their stages. These lesions, which never develop into pustules, break easily, and cause pur- erythematous patches which tend the body which it reaches. liable to set up lesions on the parts of wounds, specific infections. Amongst this class of affections may be mentioned the disease of the Pro- vocation causes of the larynx. Certain cutaneous eruptions apart from chemical action may be produced by mechanical causes; such for example is the case with the leaves of a rush plant (Carex maximus), which has fine sawing and cutting edges rendered harder by the abundant silica content of the superficial cells of the wood. Layet has reported chronic gingivitis amongst basket makers, mostly accom- panied by labial herpetic, which he attributes to the bad habit of holding tightly between the lips little strips of wicker or of sucking the end of these. Among workers engaged in the more delicate processes of manipulating vegetable fibres such as weaving, making basket-flask covers, but much more rarely amongst those engaged on the coarser operations, such as making large baskets in all forms, occupational cramp is met with, spastic and painful in character and localised on the hands, sometimes affecting even the forearm. Individuals thus affected re- cover usually after rest, but readily suffer a relapse on resuming work. In this connection Layet remarks that while the sedentary work of basket makers is not tiring, workers of this class are nevertheless afflicted with all the troubles incident to a sedentary life and limited occupational movements effected by the arms; lumbago, digestive and respiratory derangements are frequently noted amongst them. Attention has likewise been called to localised and general troubles (af- fections connected with cold, rheumatism) to which workers who themselves gather
the reeds and willows required for their occupation are liable.

There should likewise be mentioned in conclusion possible injuries due to burning of sulphur in the process of bleaching certain fibres or to the use of turpentine, and of various solvents or lacquer and varnishes and of colouring materials for decorating certain basketwork articles.

As regards prophylactic measures in relation to the lesions mentioned, the use of gloves to prevent cuts and cracks is advisable; many workers however declare that precision of movement of the fingers is hindered by gloves. Men who, as has been stated, mostly handle coarse vegetable fibres protect their hands with bits of cloth and skin, placing a kind of digital palmar lining on the parts most exposed to rubbing with the raw materials.

Benzene (Benzol)

Benzol is given off during the distillation of coal in a closed vessel. It is formed partly in the tar deposited in condenser boxes or towers (see articles “Gas Works” and “Pitch”) and another — the most important — part remains in the gas. There are, therefore, two means of recovering benzol: (a) tar distillation; (b) stripping the gas.

(a) Distillation of tar.— This has been for long the sole source of benzene. The first fraction in the distillation of tar constitutes the light oils containing water and benzol, given off up to 170° C. After separation of the water by decantation they are brought into contact with dilute sulphuric acid which removes the basic substances (pyridine and homologues) liberated subsequently by treatment with lime, then with concentrated sulphuric acid which combines with the ethylene hydrocarbons and the sulphur impurities. They are then washed with soda lye to eliminate the phenols, leaving the crude benzol which is rectified in a continuous apparatus made up of three fractionating columns allowing of methodical separation, on the one hand, of the lighter products and, on the other, of the pure benzene and pure toluene, while the residue (solvent naphtha) falls back into the lower part of the last column.

Colourless, mobile, very refractive liquid with an agreeable, characteristic smell. Burns with a luminous but very smoky flame. Distils completely between 80° and 81° C. Density 0.874 at 20° C.; boiling point 80.4° C. If cooled below 0° C. it crystallises in large rhombic crystals.

Extremely volatile, especially if slightly heated. The vapour is three times as heavy as air; easily explosive in proportions of 2.6 to 6 per cent. of air (optimum 2.7 parts to 63 parts air).

Slightly miscible with water, more so with alcohol (ethyl, methyl), ether, acetone, chloroform. Easvly electrified, it is self-inflammable. Textile materials in baths, if benzol is set in motion or agitated, become positively charged and the benzol negatively.

Never chemically pure in the commercial state; even when purified it contains traces of xylene, phenol, toluene, etc. Obtained pure by freezing or by distilling benzol acid (distilling with lime according to the reaction

\[ C_6H_6 + CaO \rightarrow C_6H_5Ca + CaO \]

washing the distillate with caustic soda, drying with chloride of lime) or synthetically starting with acetylene or other aliphatic hydrocarbons (by passage through a glass tube heated to redness).

Manufacture

Benzol is given off during the distillation of coal in a closed vessel. It is formed partly in the tar deposited in condenser boxes or towers (see articles “Gas Works” and “Pitch”) and another — the most important — part remains in the gas. There are, therefore, two means of recovering benzol: (a) tar distillation; (b) stripping the gas.

(a) Distillation of tar.— This has been for long the sole source of benzene. The first fraction in the distillation of tar constitutes the light oils containing water and benzol, given off up to 170° C. After separation of the water by decantation they are brought into contact with dilute sulphuric acid which removes the basic substances (pyridine and homologues) liberated subsequently by treatment with lime, then with concentrated sulphuric acid which combines with the ethylene hydrocarbons and the sulphur impurities. They are then washed with soda lye to eliminate the phenols, leaving the crude benzol which is rectified in a continuous apparatus made up of three fractionating columns allowing of methodical separation, on the one hand, of the lighter products and, on the other, of the pure benzene and pure toluene, while the residue (solvent naphtha) falls back into the lower part of the last column.

The term "Benzol" is generally confined in French to the mixture of benzene and its homologues obtained from the distillation of tar. Petroleum essence is sometimes erroneously called "benzine".
(b) Stripping the benzol from gas.— In coke ovens the extraction is carried out by means of towers where a great surface is provided with several layers of wood laid cross-wise. The gas travels from below upwards, while the heavy oil, coming from the distillation of the tar, trickles down in the apparatus. The benzol dissolves in the heavy oil and is separated from it then by a current of steam.

The benzol caught in the steam is carried to the top of the fractionating column at a temperature of about 100° C. and then into a condenser where it is cooled to the ordinary temperature.

The heavy oil can be used again, but after several operations the tarry products with which it has been enriched have to be distilled out.

In gas works recovery of benzol from the gas is not carried out, as to do so would mean removing too much of the heating value and especially of its illuminating power. However, many circumstances have rendered this procedure profitable (enrichment by carburetting, use of incandescence mantles for lighting, extension of electric lighting with, as a result, almost exclusive use of gas for heating purposes).

Traces of benzol are found in the tar and still more in gas from the distillation of peat, and also in American and Caucasian petroleum. The petroleum of Burma, Borneo, Java, Sumatra and Japan are mixtures of aromatic hydrocarbons that can be easily separated. The fatty hydrocarbons of petroleum can yield benzol and toluene by the process of "cracking" (see article "Petroleum"): treatment by heat at 500°-1000° C. under pressure and in presence of a catalyser.

In commerce different types of benzol are distinguished:

(a) Crude 90 per cent. benzol (density 0.86-0.88), which distils up to 100° C. and contains about 84 per cent. benzene, 13 of toluene, 3 of xylene;

(b) refined 90 per cent. benzol;

(c) 50 per cent. benzol (density 0.88), of which 50 per cent. distils at 100° C.

These benzols contain also other products such as bisulphide of carbon (0.2 to 1 per cent.), thiophene (0.1-0.2 per cent.), ethylene and other impurities: olefine, naphthaline, paraffin, etc.

A benzol is also found in commerce which contains no benzene and of which the composition is about as follows: toluol 25 per cent., xylol 70, higher homologues over 5; and also a heavy benzol which is composed only of higher homologues (95 per cent.) and xylol (5 per cent.).

CAUSES OF INTOXICATION

These represent a very important practical problem, because the majority of the acute and subacute cases are fatal.

A. In the course of manufacture (gas works, coke ovens, distillation and purification of benzol).—Intoxication is rather rare in modern installations. The construction and working of the apparatus are so closely supervised that practically there is no danger either of fume or of contact with benzol. In regular working, leakage or defects in upkeep of the apparatus become evident immediately by headache and slight vertigo among the workmen. The severe and fatal cases are nearly always the result of mistakes in working or of work carried out hurriedly (workmen engaged in emptying or cleaning, painting, or repairing boilers or other apparatus that has served for the preparation or transport of benzol in the absence of sufficient ventilation) or to pure accidents (explosion, the upsetting of quantities of benzol, etc.). Hence the absolute necessity of taking indispensable precautions under the responsibility of a manager and organising staff carefully trained in the carrying out of regulations designed to prevent accidents.

Because of its aromatic smell many workers do not regard benzol as poisonous, associating the idea of danger rather with a smell at once irritating or unpleasant. Cases are reported of workmen drying their hands soiled with benzol on their clothes, which thus provide a large surface for the evaporation of the poison in closed or small workrooms. There should be borne in mind also, as sources of danger to persons employed in the making of benzol, carbon monoxide, hydrogen sulphide, etc.

B. When used industrially.—Despite its toxicity, benzol is largely employed (a) as a chemical product (preparation of the aromatic derivatives), (b) as a solvent (it often replaces less powerful solvents of the fatty series), (c) as a fuel or carburetting substance.

(a) As a chemical product: Manufacture of the derivatives of benzol (nitro-benzene, etc.), phenols, anilin, anilin colours, and other colouring matters (where it is purified by fractional distillation), pharmaceutical products,
permanences, explosives, etc. (see the corresponding articles).

(b) As a solvent for iodine, phosphorus, etc. Industries for the extraction of fat: Dissolving fatty substances, oils, etc., for extracting fat from bones, coconuts and soya beans, etc. Artificial manures, Glue factories. Textile industry (manufacture of silk ribbon, finishing department). Cementing and finishing of shoes. Artificial leather and feather industries. Spreading textiles with "fabrikoide".

Manufacture of straw hats.

Indiarubber industry: Preparation of solutions for "rubber cement" (making of pneumatic tyres). Substances for waterproofing tissues. Aviation industry: doping the wings of aeroplanes with acetate of cellulose dissolved in hydrocarbons (solution containing 40 per cent. of benzol (see article "Tetrachlorethane"). Industry of impermeable rubber goods: 250 grm. of rubber solution containing about 200 grm. of benzol. Every person employed uses on an average 300-350 grm. of benzol or benzene per day. A solution of rubber containing 30-35 grm. of benzene and 65-70 grm. of carbon tetrachloride is also used in the making of ladies' hats as a cement in place of needle work. Manufacture of cardboard boxes, etc.

It is used further in the linoleum, celluloid and lacquer industries, in factories for making electrical fittings, in painting, in decoration (e.g. pottery), in bronzing and gilding. It is combined with tar paints or in the making of quick drying paints widely sold commercially under fantastic names; it is used in varnishing the interior of reservoirs, vats, special apparatus, interior of ships, etc. It is used in accumulator works, bronzing, decoration of pottery, gilding, lacquering, in varnishing (especially of motor cars) and even for the removal of paint (e.g. church benches) (see article "Painting"). It replaces also turpentine, as a solvent of asphalt.

In the dyeing industry benzol is used for degreasing, mordanting and dry cleaning. In the most varied undertakings (mechanics' workshops, optical glass manufacture, printing and allied industries, etc.) it is used in the place of pure benzene for cleaning purposes.

(c) As a fuel. Motor propellant: as a carburetting agent in place of petroleum benzine; as an illuminant: used in lamps; its toxic action in this respect is like that of other gases giving off especially CO (see article "Petroleum"); as a carburetter of illuminating gas, of water gas (see articles "Carbon Monoxide" and "Gas-Works: Water Gas, Illuminating Gas"). It is mixed also with alcohol for lighting purposes which denatures it at the same time. In engineering, it is used to solder alloys (boxes of white metal, electrical apparatus).

It is used in place of acetylene for autogenous soldering and cutting up of metals, and as the constituent of certain anti-rust substances.

DANGER OF EXPLOSION AND FIRES

The mixture of air and benzol vapour in certain proportions is explosive. The heavy vapour sometimes travels along the ground to a point where a flame sets it alight and, forming a kind of bridge between the flame and the source of the vapour, gives rise to fires or explosions.

TOXICITY, ABSORPTION, ELIMINATION

The light oils come on the market under the commercial name of "benzine", and too frequently this leads to confusion with petroleum benzine, so that even in toxicological literature confusion between the two products is not unknown (see article "Petroleum"). The divergencies are probably due to the nature and quality of the impurities of the two substances (carbarylamines, carbon bisulphide, thiophene) and especially to the differing conditions under which intoxication has taken place. But it is very much to be desired that, as far as possible, essence of petroleum (benzine) should not be confused with benzene (or benzol).

Benzol has action on cellular protoplasm, the blood, on the haematopoietic organs (characteristic and dominant in the acute cases); the central nervous system (very striking: narcotic action analogous to that of chloroform and dominant in the acute cases); on the heat-regulating mechanism of the body (lowered temperature, sensation of cold in those intoxicated), and on the oxidation processes of the organism (limiting them). (For the local action, see below.)

The toxic action of benzol in subacute and in chronic cases is said to be as follows: degenerescence of the constituents of the blood and haematopoietic organs (the liver, kidneys, etc.); atrophic action on the bone marrow (on the leucoplastic portion and especially the granulocitogenic or erythroblastic tissue), on the spleen and the lymph glands, causing leucopenia (as a result of the destruction of the leucocytes and
noted long ago; coagulation is retarded.

progressive

involves even 600 per cubic millimetre (an early and may even disappear. After a short time showing important morphological changes or young and immature forms.

840,000 and 600,000 without at the same time showing important morphological changes or young and immature forms (only in experimental massive intoxication has an intense excessive cell formation been observed and shown to be genuine by the formation of new elements). Blood plates are diminished and may even disappear. After a short period of leucocytosis (excitation of the leucoepoietic organs) characteristic leucopenia sets in down to 1,100-850, and even 600 per cubic millimetre (an early sign, if accompanied by diminution of the red blood cells and haemoglobin); colour index is sometimes above unity, (anaemia of pernicious type), sometimes below (chlorotic type). The leucopenia involves especially the polynuclear neutrophiles which may disappear (tendency to or existence of an inversion of the leucocytic count with relative lymphocytosis). Methaemoglobin is absent. Clinical data, therefore, do not justify a picture of pernicious anaemia nor of haemorrhagic aleucaemia (as certain German writers maintain), because the blood is damaged in toto and the picture left is that of a grave progressive anaemia of aplastic and haemorrhagic type.

The blood is markedly fluid, a fact noted long ago; coagulation is retarded and the blood has a pink colour as in poisoning by carbon monoxide.

Toxic dose.— Experiments on animals go to prove that benzene vapour is toxic in the proportion of 0.015-0.016 per litre of air (Ramboseux). Chronic poisoning is said to result from daily dose of 9 mg. per litre of air in the course of 23-25 days (Lehmann). With benzol (commercial) this author has shown that 20 mg. of the vapour per litre of air was fatal to the animal in two hours, that 40 mg. produced the same result in 30 minutes, 60 mg. in 15 minutes, and 120-140 mg. in a few minutes. In order to induce narcosis of moderate intensity, i.e. to bring about diminution of the reflexes, a dose of 20 mg. of the vapour per litre of air for six hours is sufficient; 40 mg. for two hours and 60 mg. for one hour.

In man a dose of 10 mg. of the vapour per litre of air (in volume a proportion of 3 to 4 per cent.1) causes marked discomfort; 15 mg., after 30 minutes, sensation of fatigue, discomfort and mental confusion; 20-30 mg. after some hours can induce loss of consciousness. Fatal cases, nevertheless, are described in persons working in a room where analysis has shown only 1 part per 1,000 of benzene, and severe cases, with loss of consciousness where a proportion of 2-3 parts benzene to 100,000 parts of air has been found.

Heated vapour is the more dangerous, especially in a badly ventilated room.

As has been said above, benzois include very different products (hydrocarbons both of the aromatic and acyclic series). The most important practical point, still much discussed, is that relating to the difference in toxicity (if any) between pure benzene and commercial benzol.

Researches into this point are not numerous but the results are very different. According to some writers intoxication is more marked and more pronounced with minimal concentrations of the vapour in air of crude benzois than with commercial benzois, and with these than with the pure product. Other writers have not noticed perceptible differences in the action of different benzois. Some attribute the toxic action to the toluenes, the thiophenes, or the substitution products containing benzois; others again (Kobert) to the presence of cyclopentadiene (C, H) contained in crude benzo; and yet others to the benzol itself. But some authorities have found in animals signs of toxic action with benzene (chemically pure, which is not the case with benzol as ordinarily used in industry) earlier than with common benzol. This paradoxical result can be explained by the fact that volatilisation is the more rapid the purer the product.

No opinion beforehand can be expressed as to individual idiosyncracy or degree of susceptibility in regard to the poisonous action of benzol. Even in animals of the same species susceptibility to the poison varies very much. It should be borne in mind that slight poisoning can have grave sequelae.

1 That is 10 grm. of benzene per cubic meter: 3.3 grm. of benzene vaporised at ordinary pressure and temperature occupies a volume of one litre.
Recent experiments show that animals subjected several times to the vapour of benzol become hypersensitive and display symptoms of acute intoxication from small doses of benzol which were readily tolerated at first. This is a fact of prime importance as explaining intoxication in persons who had not before shown symptoms.

Susceptibility to intoxication is increased by well-recognized conditions, but especially by respiratory maladies (tuberculosis), kidney disease (which hinders elimination of the products of oxidation of the poison), by pregnancy, and youth.

Note the kind of respiration of the person, former intoxications, sex (women are very sensitive), the fact that the vapour is less well borne on days following a rest and in sultry weather, or when rapid weather changes occur, because of the defects in natural ventilation existing as a result of these conditions.

Absorption takes place especially by way of the respiratory tract (inhalation of the vapour); this is the case with the acute and subacute forms. In chronic cases absorption by the skin may be accepted. In the opinion of some writers this does take place and, at any rate in part, even in the form of vapour. But this channel really plays only a secondary role, and the quantity of vapour thus gaining access to the system must be minimal as compared with that inhaled. Absorption by the skin evidently is facilitated by abrasions, scratches, etc., either pre-existing or set up by benzene itself (remember the property of benzene of dissolving fatty substances and so altering the epidermis). In practice skin absorption is generally very restricted. Intoxication by way of the digestive tract can also be considered.

According to Lehmann, the proportion of the poison retained by the human system is very high, namely 80-84 per cent. of the benzene contained in the atmosphere.

Elimination.— Benzene is mostly eliminated unaltered by the respiratory tract. It is easy to detect the characteristic smell in the expired air. Benzene has never been discovered either in the organs or the urine; recently, however (1923), in America it is said to have been found by a special method in the cadaver. It must, therefore, undergo changes in the organism (very different in different subjects) as to the nature of which very little is known. The products of its oxidation are represented especially by phenol (30-40 per cent.), pyrocatechol, hydroquinone, products which are eliminated by the urine as sulphates. Elimination proceeds usually very slowly.

The urine may contain further albumin, cylinders, droplets of fat, and haemoglobin.

Statistics

A complete account of the acute and chronic cases of benzene poisoning cannot be given. It is possible, however, to recall the majority at least of the cases recorded in medical literature. Rambousek (1911) describes 34 cases of acute poisoning, of which 22 proved fatal. The Factory Inspectors reported, in 1911, 2 fatal cases in Austria; 2 cases (1 fatal) in Switzerland; in 1912, 3 cases with two deaths in Germany; 3 cases with one death in 1913. Chronic cases are not reported to the Factory Department in Great Britain. Include also cases due to petrol and naphtha, which numbered 6 in 1913 (with 2 deaths), 4 in 1914 (2 deaths), 4 in 1917 (2 deaths), 7 in 1918 (4 deaths), 9 in 1919 (3 deaths), 12 in 1920 (1 death), 10 in 1921, 25 in 1922 (1 death), 55 in 1923 (3 deaths), 26 in 1924, 3 in 1925, 4 (1) in 1926 and 7 (2) in 1927.

In 1922, in a German factory for the manufacture of rubber shoes, 22 persons showed symptoms more or less acute; 16 workers were affected three days later. In the same factory in September 1923, 27 persons showed the same symptoms of acute benzene poisoning. In January 1924 two workers in a cardboard box factory, after being exposed to a solution of cement were also intoxicated by benzene.

The National Insurance Office of Lucerne in Switzerland reported 37 cases of poisoning and 11 of eczematous ulceration due to benzene (and its compounds) in 1918; 4 of poisoning and 1 of ulceration in 1919; 12 cases and 1 respectively in 1920; and 7 and 2 in 1921.

In Bavaria 10 cases from use of lacquer (of which the solvent was benzol) came to the knowledge of the Medical Inspector of Factories in 1914-1918.

During and after the war the production and use of commercial benzol became so important that cases of poisoning became more and more frequent and severe. Inspectors of factories drew attention specially to the danger of intoxication among painters applying colours dissolved in benzol heated to 60° C. in confined spaces on board ship, to the use of benzol in washing optical glass (Austria), and especially among workmen engaged in the manufacture of rubber goods where a number of cases of subacute poisoning occurred.

Chronic Poisoning.

The first cases were described by Sanning in 1897 in Upsala among nine women between the ages of 15 to 20 employed using benzol as a solvent for rubber (for periods varying from three weeks to four months). In 1910 Selling...
described 3 cases affecting girls between 14 and 16 years of age employed in a factory in Maryland, U.S.A., and in 1911 two other cases. Holtzmann has studied the cases in men, but it is especially women who are most exposed to intoxication from benzene.

In 1916 McClure described 3 cases in a Maryland factory; in 1917 Harrington, of Boston, reported 5 cases (with 3 deaths); 2 fatal cases after three months' use of a benzol solution occurred in Edinburgh; a third fatal case in the same factory occurred in 1918. The New York Commission on Compensation for Accidents in 1920 reported 2 fatal cases in the manufacture of “fabrikoide”; in 1922, 5 fatal cases came to light among persons making rubber goods in Milan (Ronchetti Meda), and 10 cases among women described by Starr; 2 other cases were described in 1923 by Brücken (Germany), who had also reported 2 industrial cases in 1922. Further cases have been described by Gerbis (Germany), Flandin and Robert (France), 2 fatal cases by Hamilton (U.S.A.), and others in the reports of the inspectors of factories of different countries (see also the report published in 1922 by the Department of Labour of Massachusetts: Cases of Benzene Poisoning in the Manufacture of Rubber).

SYMPTOMS

Poisoning presents itself as acute, subacute and chronic.

(a) Acute or fulminating form.— Fatal issue at the end of a few minutes, due almost always to inhalation of massive doses of benzene vapour. Profuse sweating, hyperaesthesia, hallucinations, delirium, coma, death.

The clinical picture varies much according to the quantity of vapour inhaled and the predisposition of the subject: vertigo, headache, excitement recalling the first stage of acute alcoholism, cough, dry skin, flushed face, subnormal temperature, etc. In severe cases there follows a stage of depression, with general malaise, nausea, vomiting, somnolence, mental hebetude, loss of consciousness, tremor, respiratory and circulatory troubles, sensory and motor paralysis, pink mucous membrane. The narcotizing action of the poison can reach a high degree with complete general anaesthesia, abolition of reflexes, and death in a state of coma.

If the person has inhaled massive doses, death ensues in a few minutes or fairly rapidly (30 minutes to 1 hour). Recovery from severe intoxication, however, can take place rapidly and without sequelae, but on the other hand slight cases may recover and yet be associated with very severe and prolonged sequelae.

(b) Subacute and chronic form.— At first the individual tolerates the poison easily, or at least seems to do so, over a period of weeks or months. A time comes, however, when he complains of headache, malaise, somnolence, gastralgia, vertigo, feeling of cold, rapid onset of fatigue, formication, anorexia. These are the signs in slight cases. Next, or in the more severe cases, are noted: need for coughing, shortness of breath, fever (sometimes high), remarkable anaemia, livid skin, and, what is characteristic in these cases, multiple haemorrhages underneath the skin (localised on the upper and lower limbs as in purpura haemorrhagica, more or less extensive according to the gravity of the case and the individuality of the victim) and in the mucous membrane (nasal, intestinal, gastric, renal). In women there is very abundant menstruation, especially during the extra-catenal period or during pregnancy (very frequent and early symptom, often the only one). Scorbutic lesions occur in the mouth: a bluish line, deposits of sphaecele on the tonsils (of great diagnostic importance according to some writers, but rare). The anaemia is more or less severe, and after reaching a certain degree may progress even if the cause is removed.

Cases are reported with symptoms of toxic polyneuritis, retrobulbar neuritis, retinal haemorrhages, and lessened resistance to infectious diseases. Further, local action on the skin and mucous membrane is frequent, more or less severe, according to individual susceptibility. These skin appearances are: roseola, swelling, erythema, and eczema; the patient complains of discomfort, sensation of dryness, especially of the uncovered parts of the body (face, neck, arms). The action is more noticeable on the mucous membrane: frequent conjunctivitis, blepharitis, and even keratitis. It is of importance practically because commercial benzois are always mixtures (petroleum, benzine, petrol, etc.).

DIAGNOSIS

When it is known that exposure to the action of benzol is in question, the headache, vertigo and distress (which often obliges the person to stop work) serve already as very important aids to diagnosis.

In the subacute and chronic forms the cutaneous and nasal haemorrhages, the meno- or metrorrhagia is women, the examination of the blood, the pink colour of the mucous membranes, with
absence of signs of cyanosis, are useful signs in the diagnosis of effects of benzene vapour and for differential diagnosis from nitro and amidodervatives.

Examination of the blood is useful: delay in coagulation and neutrophil leucopenia are of primary importance in diagnosis, but the trained medical man will not depend solely on these.

In cases with raised temperature the history should be carefully examined, because wrong diagnoses have been made from failure to consider or recognise the occupation of the sufferer.

**PROGNOSIS**

Prognosis must be cautious; recovery is possible with or without sequelae (often of a chronic nature). But severe and even slight cases with slow development have in general a fatal result. In these cases frequently haemorrhages can be found over large areas of the skin early in the course of the intoxication.

**DEMONSTRATION IN THE AIR**

More than 1 milligram of benzene per litre of air is necessary before the smell is distinctly perceived. Aspirate the air to be analysed through a wash bottle containing a mixture of sulphuric and nitric acid which fixes the vapour as a nitroderivative; extract with ether; add an excess of stannous chloride (the derivatives are converted into amino products); estimate the excess of stannous salts added by titrating with iodine. This method is said to detect a thousandth part of a milligram (Heim and Herbert). According to Ogier and Kohn-Abrest it is sufficient to make the air bubble through some cubic centimeters of fuming nitric acid, afterwards diluting with water to separate the nitro-benzene; neutralise with soda; extract by shaking with ether which removes the nitrobenzene, evaporate the ether off and weigh the residue. Use of white mice has also been suggested in workrooms, as they are very sensitive to percentages of benzol which have no effect on man.

**PROPHYLAXIS**

(a) **First aid** (see that article).

(b) **Manufacture of benzol.** — Supervision of the installation and processes and careful watching of the apparatus (prevention of escape of vapour).

Smear the cocks with glycerine which, being insoluble in benzol, ensures air tight joints.

When cleaning, repairing or emptying, etc. the reservoirs it is necessary to make sure that the apparatus is cold, that it is ventilated as fully as possible, that work is done under the supervision of a competent person who is made responsible, and that the workmen wear breathing apparatus. Experience has shown that even these precautions have sometimes not been sufficient.

The safest method would appear to be to let down a cage containing white mice into the receptacles and vats. If they become poisoned, cleaning with water and steam should be repeated before the workmen enter.

(c) **Contact with benzene.** — Generally speaking benzene and benzol are used in industry as a solvent and the solution is often applied to large surfaces (e.g. in waterproofing materials, painting, walls, ceilings, etc.). In such cases prophylaxis becomes very difficult, because the industrial processes are not finished until evaporation has taken place and the solvent has passed into the air.

The fundamental principle should be to catch the benzene vapour at the point of origin; but in most processes this solution of the problem meets with almost insurmountable difficulties, because the surfaces covered by benzol or solutions containing it are so large that no mechanical localised exhaust can be installed in such a way as to capture and remove the toxic vapour.

Further, cases are shown to be more frequent in cold weather because of defective ventilation then. Closed or warm workrooms favour evaporation of benzol and concentration of the fumes in the air. The action of other gases, such as carbon monoxide and carbon dioxide, which may be present at the same time, may aggravate the situation.

In cases where merely to instal mechanical ventilation is not sufficient, as it is necessary also to heat the incoming air — a matter it is difficult to insist on with small occupiers.

As a result of an enquiry made by the British Ministry of Labour into a number of fatal cases which had occurred in a factory in Edinburgh, it was found that a minimum of 2.1 parts and a maximum of 10.5 parts of benzene vapour per 10,000 parts air were present in the workroom in question. The ten machines could, it was calculated, give off 0.420 of a cubic metre of benzene vapour per minute in a room of 1,540 cubic meters capacity. Were the air renewed thirty times an hour, and the diffusion of the vapour uniform in the room (remembering that benzene va-
pour is heavier than air), the room would contain 0.065 per cent., i.e. 3.5 parts of benzene vapour per 10,000 parts of air. The same room if unventilated would contain, after an hour, 168 parts of benzene vapour per 10,000 parts of air. It was therefore necessary to solve the problem either by prohibiting the use of benzene or requiring good artificial ventilation of the kind adopted for the ventilation of doping rooms in which tetrahydroethane had given rise to serious cases of illness among the workers.

With this system of ventilation applied, the benzene vapour could be reduced from 28 parts per 10,000 to 5 parts, and the Home Office Regulations for india-rubber require that in workrooms where benzene is used as the solvent the air shall be changed thirty times an hour. Under these conditions very rarely can as much as 0.6 mg. of benzene vapour per litre be present. Lively discussion has ensued in different countries as to the practical possibility of effecting such a frequent renewal of the air without increasing the evaporation of benzol and without setting up draughts annoying to the workers. It has been suggested that 10 changes of air per hour is already ample and that the suggested new conditions of ventilation, the toxic vapour at their job is not excluded. Indeed fatal cases have been described in persons who had worked in well-ventilated rooms and with the windows open. Whether it is so or not must be left to the test of experience, hoping that it may not be absolutely necessary to demand "excessive" ventilation, which may be inapplicable in practice, but only a change of air such that the content of the air in each particular case shall not exceed 0.6 mg. of benzene vapour. Others consider that the ventilation should be such as to prevent a proportion of benzene vapour in the air of 1 part per 10,000 parts of air.

Protection of the skin of the fingers against contact with benzol during work is difficult, and up to the present no complete solution has been found.

Benzol should be kept, and the solution prepared, in places isolated from other premises (danger of explosion and fire). (See article "Petroleum").

As far as possible benzol should be replaced by toluol, xylok or their compounds, carbon tetrachloride, and even petroleum benzine (see these articles).

**INDIVIDUAL PRECAUTIONS**

Eliminate persons recognised to be specially susceptible (those suffering from heart disease, arteriosclerosis, alcoholics, neurotic subjects, young persons, especially girls). Periodic medical examination (blood examination, determination of the time of coagulation of the blood, prevention of infectious diseases, precautions before admission of convalescents, especially from infectious diseases) is a useful guide in vocational selection, and it permits of temporary or permanent suspension of subjects showing premonitory symptoms of benzene poisoning. Onset of epistaxis in a worker in contact with benzene (metrorrhagia outside the catamenial period in women) should be sufficient to warrant suspension from work of the persons in question.

**LEGISLATION**

Exclusion of children, women, and young persons from work exposing them to benzene vapour. (See articles "Poisonous Gases and Fumes" and "Nitro-Amine Derivatives").

**Children up to 15 years.**

*Italy.* Manufacture of carbon compounds and their derivatives, premises for the distillation of tar, for preparing solutions of rubber (india-rubber, ebonite, gutta-percha) and for applying them to substances to make them waterproof.

*Japan.* In workrooms in which toxic gases are given off.

*Poland (formerly Russia).* In rubber factories and chemical works.

*United States.* Manufacture of toxic dyes (Delaware).

**Children up to 16 years.**

*Argentina Republic.* (See below: women.)

*Belgium.* Tar distilleries: degreasing, dyeing, dry cleaning, and workrooms where naphtha or toxic substances are used; extinction of fat by benzol.

*Canada (Quebec).* Rubber and varnish works.

*France.* Manufacture and distillation (on a large scale) of petroleum spirit, tars, hydrocarbons; manufacture of plasters by means of hydrocarbons in the workrooms where the solvents are used.

*Greecce.* All factories in which toxic gases are given off.

*Spain.* Use of varnish with rubber as a basis; premises in which benzol vapour is given off; use of hydrocarbons in rubber works; manufacture of mustard plasters; degreasing of skins, cloth, and wool.

*United States.* In the manufacture of substances giving off toxic gases (Alabama, Arkansas, California, Connecticut, Kentucky, Maryland, New Jersey, Ohio, Oklahoma, Wisconsin): in the manipula-
tion of toxic substances giving off fumes and gases (New Jersey).

Young Persons up to 18 years of age.

France. In workrooms and dye houses in which toxic substances are used.

Women up to 18 years of age.

Greek. (See above.)

Women up to 21 years of age.

Germany. (See article “Nitro-Amino Derivatives.”) Prussia (see the Ministerial Decree of 18 December 1908 concerning labour conditions in the extraction and storage of benzene).

Spain, Italy. (See above.)

Exclusion of women altogether.

Argentine Republic. In the refining and distilling of hydrocarbons; in processes giving off benzol vapour; manufacture of varnishes, impermeable goods; distillation of tar compounds.

France. In the manufacture of the derivatives of benzol (see article “Nitro-Amino Derivatives”); manufacture of rubber and rubber goods where benzene fumes are given off; dye works, varnish works, painted tiles, substances to be coloured by means of benzene derivatives, etc.

Norway. Pregnant women only, where toxic vapours are given off.

Regulations.

Storage depot (see article “Petroleum” for details).

In gas works the benzol should be conveyed to the carburetter by a metal pipe of small diameter placed underground. The service cocks should be placed in such a position as will allow of the feeding and regulation of the carburetter without entering the depot.

Germany. (See article “Painting Industry (ships).”)

Great Britain. The Chemical Regulations require exhaust ventilation or every other means for preventing the escape of toxic vapour and heavy gases; breathing apparatus for those likely to be exposed in any place to toxic gases: compressed oxygen cylinders for first aid. (See article “Nitro-Amino Derivatives.”)

Compulsory Notification.

Great Britain. (See also article “Nitro-Amino Derivatives.”) Netherlands: list “A” of the Act of 1921; list “B” requires the notification of lesions of the skin and mucous membranes (bucal and nasal) occurring in persons engaged in refining tar derivatives and handling such substances. Duration of compensation: 7 days for lesions of the skin and mucous membranes, and 6 days for those of the eyes (cornea and conjunctivitis). Bavaria, Saxony, Switzerland (benzene did not exist in the list of 1916). New York: The very wide formula adopted by the legislature of Missouri (toxic gases, Ohio, and Massachusetts (“every indisposition or malady due to the occupation”) would cover notification of cases of benzene poisoning.

Recent experience would, however, make it desirable to notify cases of purpura haemorrhagica with profound anaemia, nervous symptoms and weakness with bleeding from the nose, gums and uterine, and to allow at least two months as the period for compensation.

Assimilation of benzene poisoning to accidents of work: Austria (cases of benzol poisoning “can” be regarded as accidents), Great Britain, Switzerland, Minnesota, New York, Ohio.

Benzene Derivatives

Detailed review is not necessary here relative to the question of the composition and internal structure of the benzene molecule. It will suffice to say that the formation of new derivatives takes place by substitution in the hexagonal formula of benzene and of its homologues, of atoms of H and that, whatever may be the complication of these substitutions, the six original atoms of carbon of the ring remain unchanged.

Benzene has the formula C₆H₆; one of its homologues, toluene (C₆H₅CH₃) (see that article), is a methylbenzene, and another, the m-xylene C₆H₅(CH₃)₂ (see that article) is a dimethylbenzene.

If the substitution only affects a single atom of hydrogen, the substitute
may occupy any one of the six atoms; but if more than one atom is replaced, the isomers thus produced, whilst having the same number of atoms, have varying properties and a degree of toxicity which differs according to the position of the substitutes.

The disubstituted isomers may be either "ortho", "meta" or "para" derivatives; these terms are explained according to numbers given to the position in the ring, as follows: 1-2 = ortho; 1-3 = meta; 1-4 = para.

The number of isometric forms is greater when there are more than two substitutes, as is shown by the number of the angle: 1, 2, 3; 1, 2, 4; 1, 3, 5; etc. The number of isomers is still greater when one substitute differs from the other two.

In the benzene radical is united to an alkyl or to another radical, for example, C, H, CH, or C, H, CH, CH, CH, etc., one speaks of a lateral chain, and the benzene radical is then described as a nucleus.

Although there is no rule for judging the toxicity of isomers, the para position is, nevertheless, according to Fraenkel, more poisonous than the ortho position. However, according to the researches of Lewis, the meta position, for example for nitrauniline, is more toxic than the para. In the same way, for the nitrochlorobenzenes, the ortho isomer is more toxic than the meta and the para. But as regards phenylenediamine, experts do not agree, some considering that the para isomer is the more toxic and others the meta. The products obtained by substitution of an H atom of the ring are more toxic than those obtained by substitution of an H of a lateral chain (Hamilton).

If nitro groups take the place of H atoms of the ring, nitroderivatives of benzene and their homologues are obtained, which are dealt with in the article "Nitrobenzene".

If, on the other hand, the hydroxyl group (HO) is used, phenols are obtained (see that article); phenic acid or phenol is a hydroxybenzene; cresol is a hydroxytoluene; naphthol a hydroxy-naphthalene.

The introduction of the hydroxyl group makes naphthols (alpha, beta) more irritating than naphthalene. Any increase in the number of hydroxyls increases the toxicity of the product obtained. That is why, for example, trihydroxybenzene or pyrogallol is more toxic than monohydroxybenzene or phenol.

The introduction of the sulphonic group (SO, HO) into a derivative of benzene, weakens its toxicity; just as the same result often follows the introduction of a carboxyl group (CO OH). The introduction of an acetyl group (CO CH,) or a methyl or ethyl group gives a substitution product less poisonous than the original product.

This statement holds good when the substitution takes place in the lateral chain by the replacement of an H atom from an NH, group. But if the substitution takes place in the ring, then another product is obtained of a similar toxicity.

All aromatic compounds containing nitrogen are more toxic than those which do not contain nitrogen; but there is no fixed rule, increase in the toxicity of an isomer not being in proportion to the increase in the number of NO, groups.

The introduction of halogens into an aromatic compound does not cause any important changes, nor any definite increase in toxicity.

When chlorine or bromine has to be substituted for one of the hydrogen atoms of benzene or of its homologues, a catalyser (iron) must be added. In monohalogen compounds of benzene, the hydrogen atom only enters into reaction with great difficulty.

Chlorination is an operation which enables chlorine to be introduced into an organic molecule by substitution in a saturated compound, or by addition to a non-saturated compound. The halogen derivatives which are used in the modern dye industry are derived from the substitution of Cl for an H atom or for a hydroxyl in organic compounds.

Ferric chloride or pentachloride of antimony are active chlorinating agents for introducing chlorine into the aromatic nucleus. In the lateral chain, chlorination takes place without catalysers, by making chlorine act on the vapours of the hydrocarbon exposed to light, or by treating with cold chlorine the hydrocarbon very strongly illuminated by electric lamps.

When a halogen is substituted for the NH, group of the corresponding rings by an intermediary of their diazo compounds, some halogen derivatives are obtained.

Chlorobenzene or benzene monochlorate or chloride of phenyl (C, H, Cl) is obtained by making Cl pass into
benzene at 18-20° C, in the presence of iron (in the form of metal sheets) as a catalyst. The hydrochloric acid given off is condensed in stone towers sprinkled with water.

Chlorobenzene is a colourless liquid with a faint smell, which boils at 131-132° C, without decomposing.

It is regarded as the least toxic of the benzene derivatives which do not contain Cl. But, although the experiments of Mayer prove it to be less toxic than benzene, several serious cases of poisoning are known: ten cases were reported by Mohr in 1902, due to chlorobenzene and dinitrobenzene; in three cases chlorobenzene only was concerned; the workmen showed symptoms after drinking beer. Rambousek mentions a case of poisoning after contact lasting three weeks with this product, and four cases among workmen who had upset some of this substance on their clothing.

Lehmann's experiments with animals show that chlorobenzene has a stronger narcotic effect than benzene. An atmosphere containing 1-3 mg. per litre is tolerated by cats for several hours without injury; an atmosphere containing 3-5 mg. produces deep narcosis; and one with 11 mg. causes at the end of an hour uncertain gait, at the end of an hour and a half midriasis, violent muscular spasms, and tremor, and at the end of three hours respiration with the Cheyne-Stokes character. However, even at the end of seven hours' exposure to the poison, these symptoms do not get worse. An atmosphere containing 17 mg. per litre kills an animal at the end of seven hours, causing pulmonary haemorrhages; and an atmosphere with 37 mg. causes deep narcosis in half an hour to follow at the end of two hours, even if the animal is carried at once into the open air.

The symptoms observed among men are headache, vertigo, dyspnoea, cyanosis, and a formation of methaemoglobin. The lesions occur chiefly in the blood, urinary passages, and nervous system (peripheral and central).

Among the polyhalogen derivatives, the paradihalogens are solid: the ortho and meta isomers are liquid.

By nitration of monohalogen benzene, the ortho and para isomers are obtained exclusively and may be isolated from the mixture by crystallisation, the para isomer alone crystallising on cooling. As a rule the ortho isomer occurs in the liquid state. Nitration of chlorobenzene at ordinary temperature gives in the benzene solvents 70 per cent. of para and 30 per cent. of orthochloronitrobenzene. Taking integral chloronitrobenzene at a high temperature as starting point, metachloronitrobenzene can be prepared.

A mixture of ortho and paradichlorobenzene is more toxic than the monochlorobenzene, but it acts in a similar way.

From mother liquors containing paradichlorobenzene, a mixture can be easily separated by fractional distillation which boils at 175° C., due to the presence of 75 per cent. of ortho and 25 per cent. of paradichlorobenzene. This mixture is used as a solvent of resins and lacquers. No cases of poisoning have been reported in the course of its preparation.

In the same way as monochlorobenzene, the para product is used as a disinfectant for clothes and furs, and as such has given rise to accidents; a fatal case occurred in a chemical cleaning works in Germany in 1920, and another, moderately severe, affected a person living on a floor above a fur workshop where a product, known under the trade name of "Global", was used which had, as a base, paradichlorobenzene. This product has been recommended as a substitute for napththalene for the preservation of clothes and furs.

These mono-, di-, and trinitrochloro-compounds are very poisonous products which, according to Von JakSch, have caused and are causing more cases of poisoning than are recorded in the literature on the subject.

Paranitrochlorobenzene (C₈H₇ClNO₂) has caused cases of poisoning in the course of its reduction to paranitrochloranilide. According to Fischer and Sturmann, the ortho isomer is very volatile and, in consequence, very toxic. It causes among animals, symptoms of poisoning even in a dilution of 2-10 mg. per litre of air. It is more toxic than the para isomer, which is an intermediary product in the manufacture of sulphur blues, whilst the ortho is intermediary in the manufacture of anisidine.

During the preparation of nitrophenol, starting from nitrochlorobenzene, some cases of poisoning have been observed which have been attributed to this last product. Likewise it is blamed for nervous and psychic symptoms exhibited by a chemist and his fellow-workers who were employed in centrifuging nitrochlorobenzene.

The symptoms reported were headache, vertigo, more or less marked cyanosis, pains in the gastric, hepatic and splenic regions, optic neuritis, coma, collapse and cardiac paralysis.
Hunziker and Koechlin, of Basle, in 1922 reported a case of poisoning by paranitrochlorbenzene in a small boy who had swallowed some crystals of this substance picked up in the vicinity of a chemical works. Symptoms appeared an hour later; marked cyanosis, localised chiefly in the mouth and eyes; attacks of dyspnoea; pulse, 200; temperature normal; headache; fits of excitement; troubles of co-ordination; jaundice on the second day; nephritis on the following days; eosinophilia in the blood on the tenth day; recovery was very slow and took several months.

Generally these products can enter the body through the skin — a very important point in industrial practice — and by the inhalation of their fumes. Although these products are employed nowadays in the dye and explosive industries, the number of cases of poisoning is not very great, perhaps because the meta and para isomers are only slightly volatile.

In industry mixed poisonings are most frequent; they are notified under the vague name of anilism or poisoning by nitro- and amino-derivatives.

Thus, for example, in 1920, 17 cases of anilism were reported in two German factories, most of which had been caused by nitrochlorbenzene. The duration of these cases never exceeded five days on an average, except for one case. In Bavaria 10 cases of dermatitis and eczema caused by dinitrochlorbenzene and other aniline colours were reported.

Lehmann, Müller, Sturm, Dressler, and others who have studied these products experimentally, have shown that the inhalation of 0.05-0.08 mg. of ortho-nitrochlorbenzene per litre of air prolonged over three days and including a total of seventeen hours and a half, caused among cats characteristic phenomena and death. Sturm, in 1908, and Dressler, in 1910, investigated acute and chronic poisoning by vapours and vapourisation either of the product in question, or of "Tropsol".

According to these researches it would seem that the para isomer is a little less toxic than the ortho.

Bourquinet has described two cases of poisoning by nitrochlorbenzene which occurred in a Swiss explosive factory in 1919. But the number of cases of industrial poisoning by this product is not high; it was quite important during the war, on account of its use in the manufacture of explosives and where necessary precautions were not taken.

Dinitrochlorbenzene, C₆H₄Cl(NO₂)₂, which has been very little studied, is still more toxic than the mono. It is an irritant to the skin and to the mucous membranes and also causes digestive troubles (Lehmann). When used in the dye industry (sulphur blacks) it frequently causes dermatitis, which is characterised by itching of the skin confined chiefly to the elbow, the popliteal spaces, the interdigital spaces and the internal surface of the thighs. The skin is covered with small red points which become confluent and then change into vesicles and pustules.

The patient complains of a violent sensation of burning. It is well to note that these products take effect even through a layer of vaseline. Sometimes the dermatitis affects the face and eyelids.

General symptoms often appear from 8 to 24 hours after contact with the poison: headache, vertigo, vomiting, cyanosis, cramps, heart spasm, and ocular troubles. In serious cases, improvement is, very often, a premonitory sign of a fatal issue.

Dinitrochlorbenzene ("Parazol") has been studied by Macclure and Lussky (1920). When applied to the skin (of animals) it exercises an irritant effect, which shows as hyperaemia, followed by oedema and necrosis, depending on the length of the application (two hours). Oedema and redness may continue, even after the poison has been removed, lasting for about twenty-four hours. When applied to the human skin, parazol gave no reaction at the end of an hour, but hyperaemia appeared two hours after, accompanied by small vesicles. At the end of three hours and a half, pronounced itching occurred and later oedema.

The sublimated product, obtained by cooling the vapour of the hot crude product, is not as active as crude parazol; nor is its effect so great when it is mixed with lanoline.

Inhalation during three minutes (animals) of the vapour of parazol crude or melted, is not fatal.

Chloride of benzyle (C₆H₅Cl) is obtained by passing a current of chlorine into vapour of boiling toluene, exposed as much as possible to light, or by treating toluene, very strongly illuminated by electric lamps, with cold chlorine. This substance is toluene, with an atom of Cl substituted for an atom of H in the group CH₃.

Generally the simultaneous production of chloride of benzylidine and of phenylchloroform is unavoidable.

Chloride of benzyle is a liquid with a pungent smell, strongly lachrymatory, which boils at 176°C. It is used in the
preparation of green colours (Malachite green), and of benzoic acid.

According to the experimental work of Lehmann, exposure to about 1-2 mg. per litre of air for 30-60 minutes causes either at once or later on, serious effects or death; 0.4 to 0.6 mg. for 30-60 minutes either does not cause any symptoms or at least no serious symptoms; whilst 0.1-0.2 mg. per litre can be tolerated even for six hours' exposure.

The same author says that 0.2 mg. per litre causes pronounced irritation, and 0.5 mg. violent irritation; 0.9 and over may, after an inhalation of several hours, cause results sometimes fatal. Similar products, such as bromides of benzyl and xylene, the chloride and iodide of xylene, etc., are all lachrymatory gases. Bachfeld considers that the chloride of benzyle can cause dermatitis (eczema). Hamilton has reported a case of poisoning (see further on).

Chloride of benzylidene (C₆H₅.CH Cl.) is similar to the preceding, but with two atoms of Cl. These two products of the lateral chain are not so toxic as the chlor-toluenes, where the H of the ring is replaced by Cl (C₆H₅.CH Cl.).

Hamilton mentions a case of poisoning by a mixture of chlor-toluenes: chloride of benzyl and xylene. This was the case of a chemist employed for nine months in a dyeworks, who was exposed to the vapours in question, and had become very thin and presented a cyanosed coloration of the skin, with serious loss of strength, conjunctivitis, troubles of vision which became worse as the air of the place became charged with vapour of chloride of benzyl, pains in the hepatic region, and insomnia. It was not, however, possible to make an exhaustive examination of the patient.

Chloride of benzoyle (C₆H₅.CO Cl) is a liquid with a disagreeable odour which boils at 194° C.; it is strongly irritant and has up to the present been very little studied.

It originates from the action of pentachloride or oxychloride of phosphorus on benzoic acid or by the action of phosgene gas on benzene, in the presence of chloride of aluminium. Industrially it is prepared by making Cl act on benzaldehyde. It is used for introducing a benzyl group into a compound. Its irritant and violent action on the mucous membranes is due to its decomposition into hydrochloric acid and benzoic acid.

The other halogen derivatives, the bromides, iodides of benzene, such as benzene monobromate, moniodate, bromide of benzyle, and iodide of benzyle, have no practical importance in industry. Generally speaking, this applies to such lachrymatory gases as bromide of xylene and bromide of toluene.

As regards hygiene and legislation, the measures and instructions given in the articles "Nitro-Amino Derivatives," "Benzene," "Toluene," "Nitrobenzene," etc., are valid.

The Swiss legislation enumerates in the list of substances, injuries from which are compensated as accidents, the chloride and bromide of benzoyle, the nitrochlorate derivatives, the oxy-bromide and oxychloride of benzene; whilst other legislation class these substances under the general heading "Nitro-amino derivatives of benzene and homologues" (see that article).

***

**Benzidine**

French: Benzidine (Paradiaminophényl).

— German: Benzidin. — Italian and Spanish: Benzidina.

**Properties**

Benzidine is represented by the formula

\[
\text{NH}_2\text{C}_6\text{H}_4\text{NH}_2\text{C}_6\text{H}_4\text{NH}_2\text{NH}_2\text{C}_6\text{H}_4\text{NH}_2\text{NH}_2\text{C}_6\text{H}_4\text{NH}_2 = \text{NH}_2
\]

— NH₂. It crystallises in the pure state in an aqueous solution in large colourless shining flakes, whose melting point is between 197.5° and 198° C. and boiling point 400-401° C. (at 740 mm. of Hg.).

It dissolves with difficulty in water (1 part in 244 parts at 17° C. and in 106.5 parts at 100°); it is comparatively soluble in ether (1 part in 45 parts); it dissolves readily in alcohol. It is not taken up by ordinary steam. As a commercial product it takes the form of a finely crystallised powder, of a shade passing from a light reddish-grey to white; it is slightly irritant to the nasal mucous membrane and possesses a bitter taste, similar to that of pepper. It melts at 123-124° C. and boils in the open between 380° and 450° C.

With oxidising bodies benzidine gives a series of very delicate colour reactions, which makes its examination quite an easy matter. In alcoholic solution it gives, with chloride of iron, a magnificently green colour, which soon passes off. A solution in sulhide of carbon, in chloroform or ether, gives with bromine water an intense blue colour tinged with green; with chlorine water it forms a red precipitate.

Ferrocyanide of potassium and bichromate of potassium give, in the most dilute solutions, a pale blue precipitate. The reaction used as a test for haemoglobin, with the formation of a blue or bluish-green product, is based (according to Adler) on oxidation of benzidine by oxy-
Benzened water in the presence of catal-
yzers. (For its use in the examination of
urine, see further on.)

Benzenized has a slightly alkaline reac-
tion and, like the other aromatic bases,
such, for example, as aniline, it forms
directly, on the addition of acid, crystalli-
sable salts which correspond to the for-
mula \(-\text{NH} - \text{HCl}\). In acid solution it
forms with nitric acid tetranitrate bodies
(tetranitro-derivatives), by the transforma-
tion of two amino groups \(-\text{NH}_2\) into
diazro groups \(-\text{N=N}-\).

Among the salts of benzenized the sul-
phate is almost insoluble, even in boiling
water and in alcohol; use can be made
of this fact to isolate benzenized. The di-
chlorhydrate which is more important from
the technical point of view is the following:
tolazine, which corresponds to toluidine, a ben-
zenized derivative, can be isolated and, like the other aromatic bases,
its homologues which have just been men-
tioned, and dichlorbenzidine, vice chlor-
benzine.

Among the homologues of benzenized,
the most important from the commercial
point of view are the following: tolidine,
which corresponds to toluidine, a ben-
zenized derivative, can be isolated and, like the other aromatic bases,
its homologues which have just been men-
tioned, and dichlorbenzidine, vice chlor-
benzine.

Benzenized was discovered in 1845 by
Zinin by making sulphuric acid react on
benzidine. Hoffmann, Fittig (1861),
and Schultz (1874) determined its composi-
tion in preparing dinitrodiphenyl by the
process of reduction.

Benzenized and its homologues have only
acquired a technical importance since the
development of synthetic congo dyes, for
they are very largely employed for mak-
ing direct dyes for cotton, which are em-
ployed without using mordants.

Since the preparation of congo red by
Boettcher in 1884, through the tetranitra-
tion of benzidine and combination with
naphthonic acid (acrid x naphthylamin-
sulphonic), there has been discovered a
whole series of cotton dyes which belong
to this group, the principal of which are
the following: the congo dyes, chrysamine,
diamine blue, diamine red, diamine black,
benzopurpurin, diaminide blue, and many others.

**Preparation and Use**

In consequence of its extensive use in the
manufacture of dyes, just referred to,
the industrial preparation of benzenized takes place on a large scale
exclusively in the coal-tar dye industry.

It is prepared by starting with hydrazo-
benzene \(\text{NH}_3\) \(\text{NH}_2\) \(\text{NO}_2\) \(\text{NO}_2\)
from which it is extracted easily by
the transposition of this product by an
acid solution.

Hydrazobenzene is prepared, starting
with nitrobenzene, by alkaline
reduction by means of soda lye and
zinc powder; for the rest the technique
is similar to that of aniline by
reduction in an acid solution (see that
article). Reduction by the electrolytic
method has not yet been applied in
industry. The apparatus used for the
reduction is composed of a receptacle
of sheet iron, fitted with a revolving
screw, a cooling coil, and a steam pipe:
the whole apparatus is generally
smaller than that used in the prepara-
tion of aniline. When making on a
small scale, the reduction is carried out in alcohonic solution; it can also be
conducted in an aqueous solution with
energetic stirring at boiling point.

Iron filings can be used instead of
zinc powder, as in the manufacture of
aniline, once the reduction is finished;
the contents are diluted with water
and the alcohol is separated by dis-
tillation. Then, after cooling the zinc
powder, which is not changed and is
contained in the crystallised hydrazo-
benzene, the residue, consisting of
oxhydrate of zinc, is passed through
metal gauze. The hydrazobenzene is
retained on the gauze and then isolated
in an almost pure state by washing.
Using this process of reduction, the
quantity of hydrazobenzene obtained is
relatively small; however, a fraction of
nitrobenzene, from about 4 to 5 per
cent., is changed into aniline (and, for
that matter, it is the same when the
process of acid reduction is used),
which is eliminated partly by combina-
ting with the alcohol and partly by
reuniting with the hydrazobenzene
during the operations which follow.
Further rectification is not necessary.

The second phase in the preparation
of benzenized, the transformation of
hydrazobenzene, is carried out by heat-
ing this product with hydrochloric
acid in closed receptacles, first to 55° C.
and then to boiling point. Thus is
obtained an impure solution of chlor-
hydrate of benzenized, with a small
residue of chlorhydrate of aniline.
After the addition of sulphuric acid or
sulphate of soda, the base is separated by
filtering the precipitate in the form of
sulphate. Where as the aniline
present in the solution takes the form of
a salt of a mineral acid (sulphate of
aniline or chlorhydrate of aniline),
the sulphate of benzenized, transformed by
means of a warm solution of soda or
of soda lye which precipitates it, is separated from the mother liquor by aspiration and washing; the aniline salt (sulphate of aniline or chlorhydrate of aniline) is in this manner entirely removed.

When sulphate of purified benzidine is not immediately put on the market in the form of a moist paste, as was formerly done, but is used in the manufacture of nitric dyes, it is heated in a dilute solution of soda or in soda lye. The solution is concentrated, filtered and cooled. The base liberated takes the form of shining colourless flakes. This product, which is already very pure, is again purified by distillation in vacuo at 300°-400° C. While warm and fluid it is run into iron vats, then it is crushed after cooling and solidification. The quantity of sulphate of benzidine obtained represents about 90 per cent. of the nitrobenzene employed.

Tolidine is prepared in the same way by reduction of ortho-nitrotoluene in an alkaline solution, and the transposition of orthohydrazotoluene is obtained by acting upon it with hydrochloric acid. Orthodianisidine is prepared in the same way, starting from ortho-nitroanisol, by reduction and transposition of hydroazoanisol. In the two cases the quantity obtained is small, amounting in the case of dianisidine to only 40-44 per cent. of the crude product used. In the case of the reduction of ortho-thiazolic anisol a very large quantity of the corresponding mono-amine is formed (0-anisidine).

Benzidine and its homologues are only manufactured in view of their use in the coal-tar dye industry, and that almost exclusively for the preparation of numerous nitric dyes used for dyeing cotton, some of which have been mentioned above.

Benzidine is also obtained, but on a much smaller scale, in the course of the manufacture of thiazolic colours (for the details, see article "Aniline"). The technique for the manufacture of nitric colours is as follows: dinitration of the base by means of nitrite of soda in acid solution and combination, in an alkaline medium, of the dinitrite formed with the appropriate compounds. The compounds employed are generally naphthal, naphthylamine, the meta phenylendiamine and its sulphonic acids.

Instead of the base itself, its salts are also sometimes submitted to dinitration, in particular the sulphate; and these are also used in the manufacture of some of the colour derivatives, of which the chief are the sulphonic acids which are prepared in the following way: the sulphate is heated with sulphuric acid to 170° to 210° C.; the purified mass is treated with a lye wash (an alkaline lye wash) and taken up by the acids. Like all sulphonic acids they are insoluble in alcohol and ether; they do not dissolve the lipoids, and are not poisonous.

Sources of Danger

The handling of benzidine and its homologues usually presents less danger than that of the mono-amines with a single nucleus, e.g. aniline and its homologues. Theoretically, according to the results of experiments on animals, the toxicity does not seem to be sensibly weaker; that can be explained by the less complete volatilisation of benzidine, especially by steam, and because it is less easily accompanied by impurities. The danger is much smaller when sulphates are used instead of the base.

1. During the making of benzidine and its homologues, the risks of injury are greater with the starting products (especially nitrobenzene or nitrotoluene) and with the aromatic mono-amines (aniline or toluidine) which form by secondary reaction, although in smaller quantity during their reduction than with the final products, the boiling point of which is high and which are not carried off by steam.

The danger of poisoning is especially great during the actual reduction or during the evaporation of benzidine, still containing as impurities the by-products mentioned, if these operations are carried out in apparatus which is not hermetically sealed.

2. During its use for the manufacture of nitric dyes, it is not always possible to avoid the liberation of dust while filling the receptacles for dissolving and denitrating with powdered benzidine (the sulphate of benzidine is usually used in the form of paste). Dust comes off chiefly when filling is done with a shovel. In the same way during the making of sulphonic acids, volatilisation of the free base may occur.

Toxic Action

It is generally agreed that benzidine and its homologues, by analogy with the other aromatic bases, enter the system, notably in the form of dust, not only by the respiratory passages and digestive organs, but also through the intact skin. Nevertheless sufficient evidence is not yet available to enable
it to be said which of these ways of entrance is the most important from the hygienic point of view; but it is thought that the principal path of entry is the respiratory apparatus. However, that many of these cannot be absorption by the skin during the handling of sulphate of benzidine.

The toxic effect and the final exit of the benzidine has only been ascertained by experiments on animals. According to the researches of Adler, which are, however, disputed by other experts (Klingenberge, Kuchenbecker), benzidine, like the other aromatic amines, is oxidised in the body and transformed into a diamino-dioxydiphenol, which is eliminated as such.

The urine is of a dark colour which seems to be due in part to derivatives of haemoglobin, among which are the bile pigments, and in part also to products of the transformation of benzidine.

According to experiments made upon animals (Adler) benzidine acts on the nervous system, on the blood, and on the metabolic exchanges. On the nervous system this action shows itself by fatigue, vomiting, and motor excitement, which with larger doses reaches paralysis; the fatal dose is lower than 0.2 grm. by mouth for dogs; it is higher for rabbits.

On the blood the action of benzidine shows itself by morphological changes in the red blood cells whose resistance is increased. Diminution occurs in the number of red cells; and sometimes methaemoglobinaemia with brown coloration of the blood. With rabbits pronounced haematuria is frequently observed. In acute poisoning cases the effect on metabolic exchanges is manifested by a serious glycosuria.

**SYMPTOMS**

Cases of acute poisoning by benzidine or its homologues have never been reported in human subjects, neither have injuries, acute or chronic, corresponding to toxic effects noted during experiments made on animals. From the point of view of industrial practice the toxicity of these products is, then, so slight, that it is not possible to draw a clinical picture of an acute case of poisoning in man. [The cases of poisoning reported by Hamilton, concerning two men who worked in a benzidine department, are not very clear and could have been slight forms of anilism.] Nevertheless, dust of benzidine and its homologues exercises a certain irritating action on the skin (eczemas: Bachfeld), and on the nasal mucous membranes, which is manifested, especially with dianisidine, by very violent sneezing. On the other hand, these products have, from the viewpoint of occupational pathology, a much greater importance as regards the onset of diseases of the bladder, which are met with among workmen manipulating benzidine and its homologues over several years. In the same way as aniline and other aromatic bases, these products cause haemorrhages and tumours of the bladder; papillomata and cancer (see articles "Aniline", "Naphthalylamine", "Tumours", "Occupational Diseases: Urogenital System").

Nassauer, who has himself observed quite a series of tumours of the bladder among workmen occupied in making benzidine, especially at the evaporation and distillation, is not of opinion that this affection is due to benzidine itself, but to aniline vapours which are set free, although in small quantities, during its manufacture. However, the observation of this author, as well as that of other experts, scarcely leave any doubt that benzidine and also its homologues are a cause of tumours (Schwerin).

As is the case with all the other aromatic bases, it seems that the inhalation of the smallest quantities in the form of dust or fumes is sufficient to cause, when prolonged for years, the onset of diseases of the bladder.

**HYGIENE**

In the same way as for all the other aromatic amines, the preparation of benzidine, and especially the precautionary measures of reduction of the raw product and of distillation, must be carried out in closed receptacles, especially provided with an exhaust system either general or local. The separation and washing of the by-products, and particularly their evaporation, must be done in covered receptacles fitted with an exhaust system. Emptying distilled benzidine into open tanks or vats, not supplied with an exhaust system, must be strictly prohibited. Similarly, the greatest precautions must be taken while emptying the pipes of the distilling apparatus, in order to prevent the inhalation of vapours. The same precautions must be taken during sulphonation. The liberation of dust must be prevented while the products are being crushed and packed (see article "Naphthaline"). To the manufacture of nitric colours care must be taken to avoid the formation of dust and splashings which fall on
the floor while the tanks for dissolving and dinitrating are being filled.

**Legislation**

See also the articles "Aniline" and "Nitrobenzene".

In Germany regulations are in force in Prussia and Bavaria controlling the starting and carrying on of businesses for making and recovering nitro- and amino-aromatic compounds. The regulations are concerned with the construction and technical equipment of the works, with changing rooms, baths, lavatories, and dining rooms; with the exclusion of women and children; with medical examination on engagement and periodically every four weeks. Injuries caused by benzidine are compensated in Switzerland and in all countries which have included in the list of industrial diseases the nitro and amino derivatives of benzene and its homologues.

**Bibliography**

Meyer. Ibid., 1925.

Schwerin. Ibid., 1920, p. 64.

Dr H. Engel (Berlin).

**Bismuth**

Bismuth is found in nature as native bismuth in argentiferous strata in Saxony, Bohemia, France, and Bolivia; it occurs in the form of lamellar or granular masses, and sometimes in the form of rhombohedral crystals of a reddish or silver-white colour containing traces of sulphur, arsenic, tellurium and selenium. Its density is from 9.7 to 9.8, and its hardness from 2 to 2.5. It is also found as: the sulphide, bismuthine, in Bolivia, Sweden, Australia, and Saxony; the oxide, bismuthoxhre or bismutile, in Saxony, Bohemia, and France; the carbonate, bismuthoferrite and bismuthite; or in combination with lead.

**Industrial Processes**

Metallic bismuth (symbol, Bi) is of a greyish white colour and is easily crystallised; its melting point is 267 to 269° C., and its atomic weight 208. It almost always contains arsenic, sulphur, iron, nickel, cobalt, copper, antimony, and silver.

It is obtained from the native metal by simple melting, but this process has now been given up because the extraction is incomplete, and it has been replaced by processes similar to those used for antimony (see that article).

The extraction of bismuth from minerals may be carried out by dry or wet processes. In the first the ore is roasted and smelted with coke and a fluxing agent which is often iron. The reduction process is not infrequently combined with a precipitating process. By the wet method bismuth is precipitated from hydrochloric solutions by means of iron. The bismuth so obtained is always impure and has to be purified by melting with 10 per cent. its weight of potassium or sodium nitrate. The sulphur, arsenic and foreign metals become oxidised and form a dross which can be easily removed. Although purified it still contains in small quantities the substances mentioned above.

Bismuth is chiefly used for the preparation of various metallic alloys of low melting point, which are used particularly in the making of safety valves, printing type, stereotyping, and in making illustration plates.

The salts of bismuth are of no importance from the view-point of industrial hygiene.

It must be recalled furthermore that, in association with nickel and cobalt, bismuth occurs with arsenic and sulphur in the ores obtained from the mines of Schneeberg (see article "Cobalt").

**Toxic Effect**

No figures are available relating to the risk of poisoning for workmen who manipulate bismuth or its compounds. The possibility of poisoning is provided against when ores containing it are dealt with; but in that case impurities, such as lead, arsenic, copper, or antimony, may play the more important part in the origin of any trouble.

Among persons who have absorbed large doses of bismuth, the appearance of a blue line has been noted, exactly similar to that caused by lead (Oliver). After swallowing bismuth, Bresgen reported redness and inflammation of the buccal mucous membrane, then a bluish-black coloration of the borders of the gums, the tip and sides of the tongue, uvula and palate. The coloration of the mucosa of the cheeks corresponds with that of the teeth; it appears usually after disappearance of
the inflammation and may be attributed to the formation of sulphide of bismuth. Dubinsky is of opinion that this inflammation resembles that caused by chronic mercurial poisoning. It is helpful to bear in mind that bismuth is eliminated not merely by the urine, but also by the salivary glands. A study of the blood reactions in bismuthism was made by Sabrazes and Grailly in 1923 and compared with the reactions in lead poisoning.

Soluble salts of bismuth are poisonous. The neutral nitrate which decomposes into the sub-nitric and acid nitrate may give rise to serious accidents; the latter exercises a corrosive action. The sub-nitrate often contains as impurities, lead, chlorine, and arsenic.

Administration, over a long period, of small doses of the oxide or acid nitrate of bismuth produces in animals wasting and a peculiar cutaneous eruption (Meyer).

Cases of bismuth dermatitis of industrial origin are unknown. On the other hand, the literature on the subject records the case of a German chemist who, in 1907, while separating bismuth from a solution of chloride of bismuth in hydrochloric acid, was poisoned by the arseniuretted hydrogen which was evolved.

**DETECTION**

Inorganic liquid: among the recognised methods proposed, the best is that of Aubry, which is characteristic. There are, however, certain possibilities of error which must be carefully avoided. The method need not be given here as it lies within the province of the chemist and the clinician.

**LEGISLATION**

No special legislation.

* *** *

**Bleaching**

**TECHNICAL DATA**

The bleaching of different products such as fibres (animal and vegetable), materials, oils, and fats consists, in effect, of the removal of darker parts or rendering the same invisible, so that the whole becomes as far as possible uniform in tint or whiteness.

Bleaching is carried out with a view to immediate use or as a preliminary to printing with colours.

Substantially, all bleaching processes consist of oxidation or reduction by the employment of certain physical or chemical processes.

**Vegetable and Animal Bleaching**

Vegetable fibres are bleached by other methods than animal fibres: for the first (cotton, artificial silk, flax, jute), the process consists of conbustion of the colouring parts by oxidation; for the second (wool and silk), of reduction of the darker tint, while retaining the uncleared parts.

Bleaching may be (1) natural or grass bleaching or (2) chemical.

**Grass or Natural Bleaching**

The material is first boiled in soap and water (bleaching of cotton and linen). It is then spread out on a field of grass in a wet state to undergo oxidation by means of the oxygen in the air. This continues for some weeks, and the article is afterwards rinsed in chlorine water.

This process may be accelerated by pouring chlorine water over the article from time to time while it is lying on the grass.

**Chemical or Workshop Bleaching by Various Processes**

(a) Impregnating the fibre while boiling with 2 per cent. natron lye and chlorinating with natron hypochlorite (cotton bleaching).

(b) Boiling with or without lime, treatment with soda solution and chloride of lime, and afterwards with dilute sulphuric acid.

(c) Diluted chlorine lye solution (chlorine lye is an article of commerce) at 38°-42° C. (linen bleaching).

(d) Diluted chloride of lime solution (1-2 per cent.) and formaldehyde solution in weak solution (½ per cent.; jute bleaching).

(e) Special dilute hydroxosulphite compound containing Na₂S₃O₆ in a 1½ per cent. solution as found in the commercial preparation "Decroline, Burmol, Rongalite"); this is a reducing process.

(f) Diluted sulphur natron solution, chlorine, hydrochloric acid and sulphites (artificial silk bleaching).
(g) Electrolytic chlorine bleaching — the bleaching fluid electrolytically prepared.

(h) Sulphurous acid steaming — burning sulphur (wool bleaching).

(i) Electric bleaching, in effect, ozone action.

(j) Hydrogen superoxide solution, suitable for all fibres.

Special Methods for the Bleaching of Different Fibres

Wool bleaching.— The bleaching of wool is preceded by the removal of grease, for which various chemical grease-removing appliances are employed, among others the commercial preparation "Hexoran", which contains carbon tetrachloride. In the Netherlands certain workers in a woollen blanket factory contracted serious stomach complaints through the employment of this preparation.

For the purpose of bleaching, sulphur powder is burned in a brazier in a chamber, for the formation of SO₃ or sulphur vapour is released from cylinders, also producing SO₂.

The hanging and removal of woolen blankets, in spite of the ventilation of the chamber, gives rise from time to time to difficulties in breathing.

In dyeing wool fibre, this is previously lightly bleached by the reducing preparation Na₂S₂O₄ at about 70° C.

The hydrosulphite compound is brought into the factory in the form of powder, under the name of Burmol. Another much used compound is Decroline, which is a zinc hydro-sulphite formaldehyde compound.

Cotton bleaching.— The process here is as follows.

The woven pieces are sewn together, laid over gas-flames (generator-gas), and the finish removed by washing; they are then treated in the impregna
ing machine with 2 per cent. natron lye at boiling heat. Thence they go to the so-called revolving trucks or revolving boilers, in which they are boiled under pressure with a strong lye solution. The distribution of the cotton sliding down from above on the floor of the revolving boiler, carried out by boys in an atmosphere of hot steam, is unhealthy work. Clothing becomes wet through, which gives rise to colds and their consequences.

The boiling is followed by chlorinating (generally so-called, by means of natron hypochlorite, with subsequent chlorination, with natron sulphite in closed apparatus.

Alternatively the goods are boiled with or without lime; caustic soda solution and chloride of lime solution are afterwards employed, and the lime is then removed by the addition of a diluted sulphur acid solution. Finally, the material is rinsed several times with water and wrung dry, processes which are carried out mechanically.

The caustic soda is brought into the factory in a molten state in closed boxes, is broken into pieces with hammers, and afterwards opened, so that the danger of getting splinters of caustic soda in the eye is avoided. The natron hypochlorite in strong solution is introduced in closed earthen vessels, drawn out of them by an iron pipe into reservoirs, and from these by tubes into the cellars, where the chlorine basins stand. This involves no touching with the hands.

Sulphuric acid, 66° B., is extracted from the tank-wagons under pressure by cast-iron tubes internally covered with cement.

Linen bleaching.— This process, both for threads and woven pieces, is carried out with commercial chlorine lye (natron hypochlorite and watery solution) at 38°-42° C. in diluted solution.

Artificial silk bleaching.— After the viscose process artificial silk is successively treated with sulphur natron solution, water, chlorine, hypochloric acid water, and antichlor natron sulphate. Until recently the rigid artificial silk was hung on staves and shifted with the hand, while the vessels of solution were poured over it one after the other. The hot sulphur natron solution gave rise in a number of cases to loss of epidermis from the fingers; the strong hydrochloric acid fumes from the buckets used in filling the hypochloric acid bath produced an inclination to cough, and catarrhal symptoms in the upper air passages. The hand-bleaching process has been replaced by a mechanical process, by which the staves of artificial silk are propelled through a bath and rinsed with various solutions.

Jute bleaching.— Jute fibre for sacks is not bleached, in order to prevent weakening. For colouring fibres the rigid jute is hung in a vessel containing diluted chloride of lime and formaldehyde solution, and is then placed in a centrifugal machine and rinsed.

Flour bleaching.— For flour bleaching sulphur dioxide is used; for starch bleaching hydrogen peroxide; for potato flour sulphur dioxide. Sugar is bleached
by means of animal charcoal (see article "Sugar") in filter presses furnished with a mixture of sawdust and other materials (coke, pumice stone, etc.; this process even succeeds when carried out without heating); another method consists in adding to the final clearing syrup a little ultramarine blue or methyl violet, or better still, by means of indanthrene. In certain factories, in order to effect immediate bleaching the last boiling is decolorised with a bleacher or hydrosulphite.

**Bleaching of fats and oils.**— Oil is heated to 60°-80° C., and white or grey "Florida bleaching earth" is added to it in a copper. This is a fine powder with a greasy feeling to the touch, and producing little dust, analysing as follows: silicic acid, aluminium, magnesium, iron, and calcium oxide. The bleaching depends on the colloidal character; colouring parts are taken up by adhesion. "Lucidol", a commercial product with a peroxide of benzoyl basis, is also used. In linseed oil bleaching an alkaline lye is used in solution, with danger from spluttering when pouring a warm (40° C.) alcoholic solution into the oil. A solution (see article "Bleaching") of indanthrene, with danger from spluttering when pouring a warm (40° C.) alcoholic solution into the oil.

Bleaching of skins and feathers.— This is carried out by means of hydrogen peroxide. In the case of hair, this is first washed with a warm 40 per cent. ammonia solution, rinsed, and then treated with H₂O₂. Feathers are first cleansed from grease and then bleached.

**Bleaching of ivory and horn.**— These are successively placed in diluted potassium permanganate solution after rinsing in water, in 10 per cent. oxalic acid solution, and finally in hot, slaked lime.

**Bleaching of calfskin.**— After cleaning with soap and water, the material is placed in a hydrogen peroxide bath at 34° C.

**Bleaching of skins and furs.**— For sheepskins bleaching with H₂O₂ and diluted sulphuric acid is preceded by treatment with alum, soda and soap solution (see article "Fur Industry").

**Leather bleaching.**— This is carried out with sulphurous acid after removal of grease with benzine.

**Glue bleaching.**— Glue is bleached in a copper at 105° C. with "Decroline" (basic zinc formaldehyde hydrosulphite).

**Bleaching of paper pulp.**— Lime with a pressure of 0.3 atmospheres is used for this. If soda or caustic soda be used, a concentration of about 0.1-0.2 per cent. is necessary. This type of bleaching is also carried out in successive stages, but two operations are substituted for four or five. In this process it is essential to eliminate not only the natural impurities of the fibre, but also the grease, sweat, and dressing in the rags.

Bleaching in this industry is easier than in the textile industry, and 0.2 grm. of chlorine per litre suffice in the washing trough. The action of increased pressure renders the fibres less resistant. Dressing is now eliminated by using malt, which does not affect the fibres; dilute sulphuric acid may also be applied. The use of emulsions such as oils, fats, soaps, favours the access of chemical reagents to the heart of the fibres and the elimination of material contaminating the rags.

Chlorine may be replaced by hydrogen peroxide. Permanganate of potassium and perborate may also be utilised, but this process is less common than the former.

**Straw bleaching.**— Wet straw is kept for hours in boiling water, then treated with sulphuric acid vapour, rinsed with water and dried. Hydrogen peroxide is also employed, or a combination of bisulphite, H₂O₂ and natron hydrosulphite; also chloride of lime in water — saturated solution.

**Bleaching of cane.**— For this purpose also chloride of lime and sulphur dioxide vapour are used; never sulphuric acid.

**Coconut fibre bleaching.**— The coconut fibre is placed in a diluted solution of chloride of lime and sulphuric acid, in iron or cement vessels in the open, or in SO₂ vapour of burning sulphur in an enclosed space.

**Wax bleaching.**— As in bleaching of oils and fats, this can be done with aluminium-magnesium hydrosilicate or with natron superoxide, etc.

**Shellac bleaching.**— Shellac may be bleached, among other methods, by pouring a warm (40° C.) alcoholic solution into fresh chloride water, stirring at the same time, sifting the separated lac, washing with distilled water and drying.

**Bleaching of bath sponges.**— Exposure successively to cold diluted potassium permanganate solution, potassium chlorate solution and hydrochloric acid in wooden tubs.
Sources of Danger

Even with the adoption of the most adequate precautions workers may be exposed to the harmful action of the products mentioned above.

It is chiefly a question of the irritating or toxic action of gases and fumes and localised caustic action of alkaline solutions. Often the products used give off fumes disagreeable for the workers and the neighbourhood. The risk of pollution of rivers and the subsoil by waste water must also be borne in mind.

The use of bleaching powders is very widespread; it is even common to see workers, cooks, general servants, etc., using them for cleaning their hands, washing dishes, clothes, etc.

Besides this local or general action must be recalled such further conditions of work as high temperature, humidity, steam from the vats and boilers, wet flooring, necessity for alternate work in and out of doors involving exposure to sudden changes of temperature. Amongst the products liable to cause harm may also be mentioned compounds of chrome hydrofluoric acid, etc.

In a quite modern bleaching powder factory Leymann found that 17.8 per cent. of the men employed and exposed to chlorine fumes suffered from respiratory troubles, whilst only 8.8 per cent. presented similar troubles in the other departments.

The use of a liquid for bleaching hats, and containing sulphur t alc, glue and formaldehyde had caused amongst the workers a persistent irritation, a burning sensation and skin eruption (see also article "Formic Aldehyde").

In a bleaching powder factory the use of manganese peroxide caused, according to Couper (1837), two serious and three slight cases of poisoning by manganese.

The increasing use of chlorine gas cylinders for bleaching flour had given rise to six cases of chlorine poisoning in Great Britain in 1922. Bridge visited several plants of this type and reports that the occupiers, happily aware of the danger, have posted up notice of the precautions required. As far as possible such apparatus should be kept outside the workrooms, as in the case of freezing plant. Good ventilation should be provided and the requisite precautions taken to meet all risk, either due to the production of a crack in one of the cylinders containing the gas, or connected with transport or neutralisation. The workers entrusted with the work

ing of this plant should be provided with respiratory apparatus and trained in its use.

The same expert recalls the necessity found for bestowing particular attention on elimination of fumes coming from sulphur stoves in bleaching and laundry establishments. Owing to the prevalent fashion for white, such sulphur stoves have been in constant use. The process, which consists of burning raw sulphur inside the stove, is extremely primitive; but when the stoves are isolated from the surrounding buildings, can be opened at both ends and cleaned by drenching with water before the workers are obliged to enter them, they present no cause for complaint. On the other hand, when such stoves are situated in the centre of the establishment, itself the centre of a dense mass of buildings and surrounded by workers' dwellings, the solution of the problem presents great difficulty. Employers should arrange for as rapid and complete elimination of the fumes as possible. However, if such elimination be effected either mechanically or by other means with liberation of the fumes at the height of the dwellings a new danger arises. The best solution would probably be the transference of the stoves far from such centres, but before the opportunity arises for putting this into effect, better methods of ventilation can and ought to be applied in co-operation with the local authorities so as to ensure dispersion of the fumes in the most practical manner.

Hygiene

In establishments for bleaching by chlorine and hypochlorites the flooring of the workrooms and courts should be impermeable; there should be installed in the workrooms a very effective system of ventilation, all vats, troughs and such apparatus should be constructed of masonry coated with cement and carefully treated with a bituminous cement; before opening the various chambers the chlorine gas should be forced into a hermetically sealed apparatus where it is passed over milk of lime, and any gas remaining after absorption should be made to pass into a high chimney with a powerful draught. The vats should be covered with wide hoods serving to draw off the fumes and steam towards the factory chimney. Stoves should be constructed of incombustible material, and each workroom should have at hand a carboy of ammonia to counteract the effect of the chlorine in case of sudden liberation of this gas.
Where bleaching of linen and woollen materials is effected by sulphur dioxide, the general hygienic measures provided for the establishments above referred to should be applied. Sulphur stoves should be of incombustible material and should be provided with a high door near the top which can be opened at the end of each operation, simultaneously with the other doors, in order to create a draught which will expel the sulphur dioxide. It is preferable to provide the sulphur stoves with ventilators which drive the gas into a very high chimney. When the dioxide is used in solution the work should be effected in a sealed apparatus.

Preventive measures against fire are called for, likewise precautionary measures in regard to liquid or solid residues, by prohibiting dispersion of these on public ground or in sewers. The workers must be protected against the action of toxic and corrosive substances by provision of gloves, suitable working clothes and respiratory apparatus.

**Legislation**

The employment of young persons under 16 is forbidden in Belgium in operations pertaining to the bleaching of woollen and silk yarn or materials by means of sulphur dioxide in workrooms where this gas is liberated; likewise during bleaching of yarns or materials made of flax, hemp, or cotton by chlorine and hypochlorites in places where chlorine is liberated. Young persons under 18 are excluded in France in operations connected with the bleaching of straw, cloth, or paper when chlorine and sulphur dioxide fumes are given off. In Spain under similar conditions young boys under 16 and girls under 21 are excluded from employment. For the Netherlands, see Labour Order, 1920, section 8 (e); section 33, subsection 20; annex, section 35; Safety Order, section 343 (b). In Great Britain Lord Brougham in 1860 drew the attention of the House of Lords to evidence on the subject given before the House of Commons Committee, and, in consequence, bleaching and dyeing processes were brought within the Factory Acts. The law relating thereto was later amended and consolidated, bleaching powder factories are now made subject to the Regulations applying to the chemical industries of 1922 (see article "Chemical Trades").

**Bleaching Powder**

(Chloride of Lime, Calcium Hypochlorite)

**Properties**

Solid chloride of lime is a white powdery substance, hygroscopic, smelling of chlorine or hypochlorous acid, and having a tart taste. The formula for chloride of lime has not been determined; according to certain authorities its essential component is $\text{Ca(OCl)}_2$, that to say, a mixed salt consisting of hydrochloric and hypochlorous acids. Other authorities believe it to correspond to a mixture of calcium chloride and hypochlorite of lime ($\text{Ca(OCl)}_2 + \text{CaCl}_2$). Partially soluble in water to which it imparts decolorising properties, it dissolves similarly in hydrochloric and nitric acid with effervescence. The chlorine element in the chloride of lime is easily replaced by acid and even by the carbonic acid gas of the air which explains its decolorising and disinfecting properties.

Bleaching powder is sold in wooden barrels lined with paper and having the bottom of the barrel plastered. In order to avoid explosions they must not be quite closed. The chloride generally contains 35 to 40 per cent. by weight of active chlorine (the theoretical maximum being 48.7 per cent.), which corresponds to 323.127° Gay-Lussac. It ought to be kept away from the light and kept cool to avoid decomposition. As a matter of fact, chloride of lime absorbs carbon dioxide and moisture from the air giving off chlorine. The substance decomposes and liquifies. The rapidity and completeness of the reaction depend upon the temperature and degree of humidity. crystallised chloride of lime contains 39 per cent. to 40 per cent. of chlorine; liquid chloride of lime, a limpid fluid smelling of chlorine, becoming turbid and changing readily on contact with air, contains 45 gm. of active chlorine per litre.

**Industrial Processes**

Solid chloride of lime is obtained by passing chlorine over slaked lime which has been carefully and slowly ground and sieved. This is carried out in completely enclosed apparatus, as in the Schultess apparatus. Lime of first quality shaken in a revolving drum is slaked, then falls in powder form into the external envelope of the apparatus in which it is collected.

The lime is conveyed to a hopper placed in the upper part of a chamber recalling that for the manufacture of
sulphuric acid. It is lined with vitrified bricks, or more frequently with lead. The inside lining is painted with a coat of tar-asphalt. The lime is placed in these chambers in layers 4 to 5 cm. thick on small horizontal shelves usually made of lava or lead arranged in stages. Where there are no shelves the lime is spread out on the floor of the chamber to a depth of about 20 cm. by means of a very long poker. The work is unpleasant, but not dangerous.

The chlorine is introduced by means of “lutes” into the upper part. Each chamber is provided with doors of iron or wood protected by iron and having peep-holes (glass panes) let in for observing the state of the reaction. If the chlorine contains carbon dioxide, the absorption of which by the lime gives off heat, recourse is had to cooling in order to prevent decomposition of the chloride of lime into chlorate and chloride of calcium. With this in view, leaden pipes, through which cold water circulates, traverse the mass of lime. The process of manufacture is continuous with at least three or four chambers in communication above, one of which is always either out of action or undergoing recharging.

The chlorine is introduced slowly until it ceases to be absorbed. It passes from one chamber to another, driving out the air in front of it. Although the lime readily absorbs the chlorine, it is necessary to distribute the powdered lime mechanically in the chambers in order to avoid escape of the gas into the atmosphere.

In the Gastner revolving furnace, which consists of a steel cylinder lined with vitrified brick, the manufacture is continuous, the chlorine and the lime circulating in reverse directions. Hasenclever’s apparatus, which diminishes the risk of inhalation of chlorine, consists of a structure containing horizontal iron tubes placed one below the other. Automatic devices distribute the lime. The mechanism can only function continuously with the gas rich in nitrogen and oxygen yielded by the Deacon process. With chlorine concentrated as it is in the Weldon process the reaction requires to be stopped from time to time, so as to prevent a too energetic reaction.

When the process is completed the chloride is received in wagons placed under the chambers, the bleach being pushed down by a shovel into the evacuation shoots. There are, however, automatic processes of removal. As stated above, the chlorine which has not been fixed is, at the moment the chamber is put out of action, carried by a current of air into another chamber so that the work of emptying can be done as far as possible without risk of absorption of gas.

The chloride of lime is then passed through metal sieves before it is packed to prevent formation of solid lumps. The dangerous processes of transport and packing are now done in closed automatic apparatus provided with means for the removal of dust.

Liquid chloride of lime (bleach liquor) is made by replacing the solid slaked lime by milk of lime, or more simply by dissolving lime in chlorine water and subsequent filtration, or again by electrolysis of chloride of lime and allowing the chlorine to combine with the chloride of lime into chlorate and giving off heat, recourse is had to cooling in order to prevent decomposition of the calcium hydrate formed as in the case of the hypochlorites of sodium and potassium.

Crystallised chloride of lime is obtained by saturating milk of lime with electrolytic chlorine, filtering and evaporating under reduced pressure.

**USES**

Chloride of lime is used on a large scale in different industries as a decoloriser and disinfectant. Generally it replaces chlorine in numerous applications because it can be easily carried: 1 kg. of chloride of lime freshly prepared gives off about 110 litres of chlorine.

As a decoloriser it is used in the bleaching of paper pulp, textile threads, etc.; as a mordant in printing tissues; in dyeing (preliminary treatment of the vegetable fibres — cotton, hemp, linen, jute, etc.); and for cleaning hands soiled by organic colouring matters. It is used as a disinfectant in industrial and town hygiene (tanneries, e.g. before any manipulation of foreign hides: Order of the Chancellor of the German Empire, dated 18 April 1891); in the manufacture of many organic compounds (chloroform, etc.), and in the purification of pure acetylene, etc. The irritating and caustic action of chloride of lime is due both to its content in free chlorine and its alkalinity.

**DANGERS**

In the course of manufacture,—The workers employed in the manufacture of chloride of lime are less exposed to occupational risks than would be supposed.

Danger to health occurs when the lime is pounded and slaked without taking precautions; from the chlorine especially in the leaden chambers.
when the lime is being shovelled at the same time that the chlorine is coming in, when insufficiently ventilated chambers are entered, or when emptying and packing are done without precautions. The risk is the greater the more concentrated the chlorine (chlorine produced by the Weldon process is more concentrated than by the Deacon process.) Lead poisoning has also to be considered than by the Deacon process).

Lead poisoning has also to be avoided by substituting hypochlorite of soda for chloride of lime as it has the same decolorising properties. At the same time that the chlorine is coming in, when the lime is being shovelled at the chambers. In packing there may be danger of explosion.

In the course of its use.— See above under "Uses".

STATISTICS

According to Leymann (1906), 1,941 workers employed in the manufacture of chloride of lime and caustic potash in German factories showed, during the period 1891-1904, the following morbidity per 100 persons: 2.3 for nervous diseases; 17.8 for respiratory; 12 for diseases of the digestive tract; 8.9 for infectious diseases; 11.3 for external injuries; 11.1 for diseases of the locomotor system; 8.1 for dermatosis; and 1.3 for organs of the special senses.

SYMPTOMS

Chloride of lime has a similar action to caustic alkalis, although less severe, and it has, further, a specific action on the sweat glands. Handling it or using solutions of the substance causes the eyes (lachrymation, conjunctivitis, etc.) and the respiratory tract (perforation of the septum of the nose, cough, asthma and sometimes bronchitis, etc.).

HYGIENE

The manufacture of chloride of lime, the object of which is to utilise chlorine in excess in the factory, requires that the chambers contain as little chlorine as possible when they are being emptied. The chambers should be in series and communicate one with another to secure a complete absorption of chlorine. The last one should not smell of the gas. All the chambers in series must be impermeable. Removal of the chloride of lime should be done mechanically and not by hand. Generally automatic mechanical methods, of which several kinds have already been proposed and applied, should be aimed at.

For cleaning the hands hypochlorite of soda should be used although it removes the colour less rapidly and does not remove completely methyl green, but it has none of the disadvantages of chloride of lime. According to Floret (1915), the substitute proposed by Greve (6.3 of hypochlorite of soda, 5 of sodium chloride, 1.5 of caustic soda to 100 of water) removes acid colours very well, but irritates the skin, makes the nails become brittle and fall out, and does not remove basic colours.

LEGISLATION

The work of adult women is forbidden in the manufacture of chloride of lime factories in Argentina and the Netherlands; employment of children under 16 years in Belgium (factories for the manufacture of dry chloride of lime and of the substance in solution); and under 18 years of age (in the manufacture) in the Netherlands.

In Great Britain the manufacture comes under the Chemical Regulations of 11 June 1922, section 20 of which reads:

No person shall enter a chamber for the purpose of withdrawing the charge of bleaching powder unless and until—

(i) the chamber is efficiently ventilated, and

(ii) the air in the chamber has been tested and found to contain not more than 2.25 grains of free chlorine gas per cubic foot.

A register containing details of all such texts shall be kept in a form approved by the Chief Inspector of Factories.

- 254 -
The lesions set up by the substance are included in the list of diseases scheduled under the Workmen's Compensation Act (1906) in Great Britain.

In Switzerland, similarly, chloride of lime is included in the list of substances injury from which comes within the compensation law.

The Netherlands require notification of skin affections (dermatitis, eczema), ulceration of the mucous membrane of the mouth in persons employed in the packing of chloride of lime.

***

Blood and Industrial Poisonings

The utilisation or liberation of poisonous products during trade processes presents special dangers to the blood. This "liquid tissue", as a matter of fact, penetrates every organ of the body, and comes into the closest contact with the atmosphere of the place where the work is carried on, through the mechanism of respiratory exchange. It can rapidly convey the poison with which it may be charged throughout the system, and more particularly to certain secretory or excretory organs where they may accumulate.

Poisons may simply pass through the blood without causing specific and peculiar lesions, or they may produce in it inorganic changes which reduce, as a preliminary effect, its function as a conveyer of oxygen and energy. It is essentially this last class that will be dealt with.

Morphological changes in the blood, which are easily recognised, like mass research work, are of value in proportion as they enable lesions to be early recognised. With this object the simplest processes are the best. Moreover, haematological methods have been studied these last few years as few others have, and are particularly designed for the conduct of periodical examinations into the state of health of workers.

Industrial hygiene in practice requires as rapid an examination as possible of workers in trades in which there are dangers of poisoning in order to determine the existence or non-existence of any sign, however small, of the action of poisons, so that aggravation may be prevented and the necessary prophylactic measures instituted.

In industrial life no one can escape from the influence of occupation, whatever it may be; but it is the duty of science to improve the methods for detecting any injurious effects brought on by the industrial life at a stage when recovery may be possible, or, at least, when no serious effect on the capacity for work or the duration of life has been incurred. As regards industrial diseases, prevention is far better, is easier, and is less costly than cure.

GENERAL REMARKS ON INDUSTRIAL POISONS

There is no doubt that, as concerns their action, the poisons are subject to the law of d'Arndt-Schulz, i.e. in quite small doses, below a certain strength, they act as excitors of new formation rather than as poisons. This is so with lead, arsenic, and phosphorus, very small quantities of which produce increased activity of the haemopoietic organs and increase the number of red cells (Meyer-Gottlieb). With a large dose and prolonged exposure, on the contrary, they cause anaemia and cachexia. Ammonia and sulphurous anhydride are considered by workers — and apparently with some justification — as tonics necessary to the system, and more particularly recognisably effective as prophylactic and therapeutic agents against colds, catarrhs, and tuberculosis. There always exists in the body a whole series of metals (besides iron, manganese, copper, zinc, phosphorus) which do not cause the least ill-effect.

Anyone who is not familiar with the proportions of metals normally present in human and animal organs is liable to make serious mistakes in chemico-legal analyses.

Knowledge of the action of metals is still incomplete, especially as regards the threshold of the poisonous dose for various organs and, more especially, for the kidneys. So there is no ground for surprise if, more often than not, it is not known in what form they pass into the blood and are deposited in the tissues. It is probable that they do not generally appear in the system in a completely dissolved state, but in the colloidal state, in combination with the albumens or acids (in the form of a salt of a fatty acid or of phosphoric acid). Neither is it surprising that they impregnate the bone marrow, so as to lead to the formation of new blood, and that they produce there toxic effects. But beyond what takes place in the case of lead and iron, nothing is known.

The influence of metallic and other poison on the structure of the blood plasma, as well as upon its physico-chemical properties, has been little studied up to the present. However, in the case of poisoning by lead and bismuth it is accepted that a displacement of the fractions of albumen towards the side of greater dispersion occurs, as well as an increase in fibrino-globulin, just as in infectious diseases (Kobert). V. Jaeksch has drawn attention to the analogy between acute poisonings and infectious diseases; and, although the mechanism of this action is quite unexplained, it is known chiefly from the work of the Danish Institute of Serology (Madsen) that small poisoning processes, that free haemoglobin becomes changed in the liver into globulin,
and that salts of manganese cause a very strong formation of antibodies.

It is probable that the influence brought to bear on the structure of the plasma does not occur without strong reactions, for changes of activity in the blood ferments may be looked for in consequence of modification in the dispersion of the albumens (see also "the activation of prothrombins" by protein bodies according to Weinhard). The foregoing ideas open extensive perspectives in the study of industrial poisons in the blood. In connection with this phenomenon must be noted changes in the ultra-filtrability of serum after mercurlal treatment (" Novasulur ").

A classification of blood poisons must of necessity have arbitrary limits. Of course the toxic effect — for instance, the haemolysis due to a single and special poison — need not be limited to a single process, and, in the same way, the fate of the haemoglobin can not be by a single and same poison need not always be the same. This is not surprising, considering the secrecy which is connected with most of the delicate processes which occur in the cellular laboratories of the animal body. Generous limits must be fixed to the evidence of observations as encountered in daily practice.

A. — RED BLOOD CELLS

I. HAEMOLYTIC POISONS WITH METHAEMOGLOBINAEAMIA AND HAEMATINAEMIA

This class includes all the poisons which have a destructive action on the structure of the envelope of the red cell followed by haemolysis. It is probable that this destruction is caused essentially by a reaction with the lipoids of the supporting substance of the cell stroma (the solubility of poisons in lipoids: Bechhold). Morphologically the condition is often indicated by the appearance of the so-called "internal haemoglobinemic bodies" (corpuscles intemnnes hemoglobi- biniques) of Ehrlich and Lindenthal, small spherical bodies of haemoglobin which are found in the interior of the red cells, and by the shadows of red cells described by Ponfick. Most of these poisons not only cause the discharge of haemoglobin from the stroma of the red cells, but a transformation of oxyhaemoglobin into methaemoglobin, that is to say, into a stable combination of haemoglobin with oxygen of such a kind that the haemoglobin, being firmly fixed, ceases to be available for the respiratory purposes of the cellular elements. Ehrlich, some time back, considered that these "internal haemoglobinemic bodies" constituted methaemoglobin. The blood, in this case, takes a dark venous colour, sometimes brown and blackish; there is cyanosis of the lips and extremities, deep coloration of the blood, which when bled is almost brown, and brown urination. Legge reports that, in practice, the blood in poisoning by aniline black is always of a chocolate colour with cyanosis.

Most of these particular poisons are met with in the chemical industry: aniline, nitro- and amino-derivatives of the aromatic and aliphatic series (e.g. nitrobenzene and, more particularly, dinitrobenzene, trinitrobenzene, trinitrotoluene and aniline), phenyl-hydrazine, pyrogallol, pyridine, picric acid, hydroquinone, nitrite of amyl, hydroxylamine, nitrous gas, chloride of lime, more rarely chloride of potassium, and chloric acid. With hydroxylamine there is, in consequence of oxidation, hydroxylamic acid at the same time as the formation of ematine (Kunkel). With nitrous gas, local action on the lungs, setting up oedema, and on the central nervous system is most important.

Benzene itself, by prolonged action of strong doses, causes the same effects. The female sexual organs are especially the seat of such lesions, chiefly at the time of menstruation.

Exact determination of the presence of methaemoglobin is made in the first place by spectroscopic examination of a very concentrated solution of blood (1:30), neutral or alkaline, which shows in the orange (from 634 to 602 μ ) a broad typical band. The other bands, which appear in a greater dilution and by the transformation of neutral methaemoglobin into alkaline methaemoglobin, and produce modifications characteristic of their composition, must be determined by the aid of the spectroscopic table of W. J. Dilling. It should be particularly noted that only when 40 per cent. of the oxygen is transformed into methaemoglobin do the bands appear and do clinical signs of poisoning become evident. Death occurs when 75 per cent. of the oxyhaemoglobin is transformed into methaemoglobin. It is evident that during this examination any oxyhaemoglobin which is present will always show itself by characteristic bands in D and E.

In the living the bands of methaemoglobin can be recognised in the orange by examining, with transmitted light, the external ear intensely illuminated as Rost, Franz, and Heise have strongly recommended. Methaemoglobin acts in relation to reducing agents, such as sulphide of ammonium, in the same way as oxyhaemoglobin does, and con-
sequently bands of reduced haemoglobin appear (see below).

O. Schumm was the first to establish the production of haematin with or without methaemoglobin in numerous cases of poisoning, caused by cyanides, dinitrobenzene, acetic acid, and chloride of potash, but not by lead and its compounds. Haematin is the pigment of blood; it contains iron, but is free from albumen, of which it is the first product of disintegration. As Schottmuller has recommended, it is advisable to proceed first to the spectroscopic examination of serum which, more often than urine, and even than blood solutions, contains methaemoglobin and haematin. This is shown by a band in the orange red (615 or 627 μμμ) to the right of the red band of haemoglobin and by two small bands in the yellow and green. Treated with sulphide of ammonium the bands change into those of haemochromogen (550 and 525 μμμ), whilst methaemoglobin becomes reduced into haemoglobin without oxygen, distinguished by a large dark band at the site of the two bands of oxyhaemoglobin at 560 μμμ.

Naturally there will be found in the serum oxyhaemoglobin, methaemoglobin, and bilirubin, but, according to Schumm, bilirubin, the pigment of jaundice, is almost always associated with oxyhaemoglobin and not with haematin, so that difficulties of diagnosis are rare. According to the observations of Schottmuller, there is found in haematinæma a coloration of the skin passing from yellow to brown, resembling slightly the jaundice coloration. The shades of coloration of the skin in poison, unfortunately, only have been slightly studied up to the present from the clinical point of view, although they may not be without their practical value.

From the anatomical and pathological points of view, this group of blood poisons causes very serious lesions of the organs and especially fatty degeneration of the liver and renal cells, sometimes even of the muscular fibres of the heart. There also occurs a formation of pigment and an accumulation of iron in the liver, kidneys, and bone marrow. The urinary canaliculi are completely filled with an accumulation of red cells, to such an extent that the clinical picture of oliguria and anuria is present. That may also be produced without blocking the canaliculi, in consequence of serious lesions of the renal parenchyma. The pronounced hyperaemia of the organs must also be noted, showing the existence of lesions of the capillary walls in consequence of which cutaneous haemorrhage or violent metorrhagia are produced, as, for example, in chronic poisoning by benzene, pyrogallol, and aniline. If the system recovers from the poisoning, a process of regeneration in the bone marrow takes places rapidly. All the blood cells which indicate such regeneration are then found: normoblasts, polychromat, and basophilic erythroblasts.

From the biochemical point of view, facts recently acquired on poisoning by nitrobenzene and aniline are of great interest, for they have shown that, until the definite elimination of sulphoconjugates and glucuronic acids takes place, intermediate products, such as phenylhydrazine and chinonine, complete the change into methaemoglobin by activation of oxygen in the processes of both reduction and oxidation (Heubner and Rhoden; Engel).

Besides this, a blood picture of strong degeneration may occur, without any sign of regeneration, such as polycytoysis, anisocytosis, micro- and macrocytosis, a picture which resembles that of pernicious anaemia. Depending on the state of the bone marrow, whether bone marrow or lymphoid tissue predominates, the picture obtained will be that of either regeneration or degeneration. In poisoning by benzene, according to Zanger, there occur, above all, leucopenia and thrombocytopenia in consequence of degenerative processes in the marrow. According to this author, the nuclei are in a state of pycnosis, easily stained, with preservation of protoplasmic structure.

In poisoning by aniline, Helm, Agasse-Lafont, and Feil have quite recently (1926) reported the presence in the blood, although rare, of red cells with very fine basophilic granules, seen in a third of the cases examined, with predominance among aniline workers.

**Acute Haemolysis by Arseniuretted Hydrogen and Organic Volatile Arseno-Derivatives**

Although it rarely happens, some poisons such as arsениuretted hydrogen and organic arsenical derivatives, the chemical composition of which has not up to the present been sufficiently investigated, may explain the occurrence of industrial processes of acute haemolysis. According to the amount of arsениuretted hydrogen inspired, the haemolysis will vary in intensity, and the
clinical manifestations which follow will vary, from the slightest blood changes which only appear at the end of 8 to 24 hours on blood in urine, but the serious sequelae, up to the most acute manifestations with destruction of red cells, which occurs in a few hours or even less, and reduces the percentage of haemoglobin in the blood to fatal limits (about 15 per cent.).

Even when danger of serious collapse is passed, there remains, as regards the kidneys, danger from anuria and uraemia in consequence of the urinary canaliculi in the kidneys becoming blocked by the debris from the red cells. Early detection can be carried out in an excellent manner by means of the simple micro-chemical methods which Erwin Becher has introduced into medical practice and only requires a little blood.

It was an accepted fact in days gone by that in poisoning by arsenuiuretted hydrogen there occurred a pure haemolysis with haemoglobininaemia and pure haemoglobinuria. G. Joachimoglu has recently established the fact that the formation of methaemoglobin also occurs in vitro and in the frog. In general many of the cases the determination can only be made in the serum (see below). It must not, however, be forgotten that spectroscopic examination succeeds only with a content of 40 per cent. of methaemoglobin.

Quite recently an occupational disease ("Gulf disease") was observed among the fishermen of a German port, a disease which, according to the latest researches, was not due to arsenuiuretted hydrogen but to organic arsenical compounds, which after prolonged inhalation during work have a similar action. These cases were characterised by haemoglobinuria and methaemoglobinuria (L. Lewin), with violent muscular pains and stiffening of the whole body. It was considered within the range of high probability that a micro-organism (for example, Penicillium breviculae) could cause, during the high temperature of summer, by processes of reduction of the mud of the port which contained arsenic, the liberation of organic arsenical combinations. Arsenic was present in waste water from a cellulose factory making use of pyrites, the waste water from which was discharged into the port (C. Lentz). It is interesting to know that, according to Lewin, methaemoglobinuria alone was found spectroscopically in the patients and not methaemoglobininaemia (see article "Arseniuretted Hydrogen").

From the viewpoint of the practice of industrial hygiene, it is interesting to note that, according to Zangger, poisonous combinations of arsenuiuretted hydrogen and nitrous vapours may be produced, for metals are often arsenical.

It is evident that the poisons under consideration may have a twofold seat of action. In the first place the circulating blood, where the poison directly attacks the mature red cells. At the same time action also occurs on the haemopoietic centres in the red marrow where, however, the attack is apparently a secondary one. As a matter of fact, debris of erythrocytes are found in the circulation, and it often takes some time before signs of blood regeneration appear.

According to the interesting experimental researches of Rous, Peyton, and G. O. Broun, destruction of red cells may occur as the result of violent muscular effort, especially if it occurs after a long rest. Broun is of opinion that in normal conditions a state of equilibrium is set up in which the destruction of the red cells acts as a regenerating stimulus to the bone marrow, which immediately forms new elements to replace the old ones.

These facts enable numerous forms of stubborn anaemia wherein athletic activity is a definite help to be classified in the same group. There is no doubt that this activity may accelerate the elimination of numerous poisons, e.g. lead in particular. From the point of view of industrial hygiene the development of sports for the working classes is to be recommended. Schmidt rightly estimates that physical training, rationally indulged in, is often much better and more beneficial than costly balneological treatment.

It is probable that the reticulo-endothelial mechanism of the liver and spleen plays a special part in the destruction of red cells, as it is in these cells that an increase and accumulation of the poison occur, and later it is there that phagocytosis of the debris of the red cells takes place.

The reticulo-endothelial system is stimulated in lead poisoning. This fact is proved by extensive development of the connective tissue in cultures of tissues in the presence of animal plasma, as well as by recent research carried on in Biondi's laboratories.

The reticulo-endothelial system is also stimulated, although to a less degree, in mercurial poisoning. The large macrophages of the spleen in rabbits suffering from lead poisoning engulf mature red cells, but not, it
seems, red cells which are not yet mature. The reticulo-endothelial system, thus stimulated, fills a haemopoietic function, of which material expression is found in myeloid metaplasia and in the appearance of cellular elements (Bianchini).

Very great scientific interest is afforded by the recent experimental researches made by Madsen (Copenhagen) and his pupils, in particular by Reymanns, who have shown that during haemolysis the liberated haemoglobin is probably transformed in the liver into fibrinogen and later into globulin. This increase of fibrinogen is not only caused by haemolytic poisons of bacterial origin, such as staphylo- ysin and diphtheritoxin, but also by chemical poisons, such as pyrodine and pyrogallol, so that it can be spoken of as a general law. Probably a defensive arrangement of the body is set up, more particularly of the liver, the action of which in the face of bacterial damage is sufficiently well known, whilst it is still obscure for chemical poisons. It may be that defence against metallic globular poisons lies in the envelopment and putting out of circuit of material exchanges, in so far as no destruction or transformation into a non-toxic form occurs.

By processes of disintegration, haemoglobin is separated into an albuminoid part, globine, and into a part containing iron, haematin.

This latter subsequently loses its iron and becomes changed into haematoxid and haematoporphyrin which, by passing through unknown intermediate forms, becomes bilirubin, which is reduced in turn to urobilin in the intestines and reabsorbed in this state, only to be oxidised in bilirubin once more in the healthy liver, while in a diseased liver the urobilin passes as such into the blood and into the urine. This same process of separation of urobilin occurs when the liver, in course of haemolysis, is flooded with haemoglobin or haematin. This is why urobiliniauria and even urobilinogenuria (a more advanced degree of reduction) represent a symptom of great value for detecting anomalies of haemoglobin metabolism and functional disturbances of the liver.

II. Haemolytic Poisons without Methaemoglobinæmia and without Haematinæmia (e.g. Lead)

(a) Modifications of Blood Formula

Things are different with such a blood poison as lead, which is very important and very common in daily life. Here the new blood formation after the inhalation of fine dust or vapour follows so rapidly the first onset of the poisoning caused by the metal that it may be attributed to a previous attack on the cells of the bone marrow, with karyokinetic excitation. However, according to the researches of Schmidt, the invasion of the blood by new polychromatophile cells and cells with basophilic granules appears when it can no longer be a question of a diminution of haemoglobin. That has been established in the case of animals, as well as in the case of man; and Schmidt has even seen the appearance of elements of blood regeneration among women employed at the work of decorating articles by means of transfers after only five days and without there having been any signs of previous anaemia. Schnitter has reported among white lead workers, often after only two days' work, a proportion of 100 basophilic granular cells per million. The conditions here are quite analogous to those caused by inorganic iron, which, according to Abderhalden, does not act directly on the structure of haemoglobin, but through a haemopoietic action by stimulating the bone marrow.

Further, according to Schmidt, in the development of lead poisoning there are two methods of attack upon the circulatory apparatus: at the centre of the reticulo-endothelial apparatus and of the marrow.

While, at an early stage, the action on the former is of greater importance, destruction of red cells in the blood stream, continued for a long time, and concomitant damage of the haemopoietic centres cause great diminution in the number of red cells and even sideropenia of the haemoglobin as themselves, to such an extent that the colorimetric index falls below 1. These lesions are probably explained by the fact that lead, as well as most of the poisonous metals, is not found in the circulation in a state of complete solution, but in a fine colloidal state as carbonate, phosphate, or salt of a fatty acid. In this form it is of course fixed in the erythrocytes, and slowly exercises its destructive action in the circulation, by which the reticulo-endothelial apparatus, as in the case of aromatic blood poisons, terminates the process. But at the same time the poison is introduced with the blood stream into the bone marrow, where, in consequence of the diminution of the speed of the circulation, it accumulates and affects the mother haemopoietic
cells. The haemolysing action of lead seems, according to recent researches of American authors, to be due to a change in the elasticity of the red cell in consequence of the formation of phosphate of lead and acid phosphates.

According to the researches of Biondi, not only does lead incite phagocytic activity, but it also exerts a complex stimulus, which gives to the reticulo-endothelial system a haemopoietic function and perhaps directs it also towards the formation of fibroblasts—which may explain the kidney and hepatic lesions of lead poisoning.

(b) Formation of the Granular Material

The observations of Schmidt indicate that the first manifestation of the toxic action of lead takes place on the nucleus of the normoblasts of the bone marrow; after that, or perhaps before, an elimination of poly chromatophile red cells appears as the first sign in the blood. The old conception of a pure degenerative state (Grawitz-Pappenheim), in consequence of destruction of the protoplasm of the red cells, has practically been abandoned, while the theory of W. Schilling, Rauch, and Michaelis of a degeneration of the young polychromatophile red cells lacks support of the facts.

This is how Schmidt explains the process of the formation of granules. The structure of the nucleus breaks up; derivatives from the nuclear substance pass out of the membrane (karyosecretions) and mingle together, part as very fine elements detectable by staining with basic colours (polychromasy), and part as elements in a coarser state known under the name of "basophilic granules". Smears of blood from a guinea-pig poisoned by lead, examined by the method of Kreibich, show all forms of granulation and lesions of the nucleus, protuberances on the nuclear membrane, and intermediate forms between the granulations and the nucleus. With the ultramicroscope can be seen varieties of the particles up to the finest polychromatic granules, so that according to Schmidt there is no longer any doubt as to the genesis of the formation of these elements. The rapid action of lead is due to the stimulus which it exerts on the nuclei of the mother cells of the marrow. After precipitate regeneration, sooner or later a slowing down of the regeneration may occur. But a condition may be established in which the nucleus becomes so accustomed to lead that the blood formula resembles morphologically that of the normal.

In fact, there can be no doubt that a certain amount of "salting" occurs among many lead workers.

According to the researches of Bianchini, punctuate red cells will sometimes be the only expression of an apparent reduction in the granules of basophilic substance which is usually spread uniformly over the whole element, following an autolysis of rapid evolution. In this case the appearance of punctuate red cells would be considered as an artificial phenomenon. The process which, so to speak, transforms the basophilic substance into granules might, under special conditions, also take place in the blood stream. Thus it can be understood why, starting from basophilic substance, the stage of the punctuate red cell through the polychromatophile can be reached.

The alterations in the circulating blood, especially the polychromatophile red cells and those with basophilic granules of new formation, and finally the consequent anaemia, are factors resulting from stimulation or regeneration in the red marrow, which can cause, by flooding the blood with new cells, a clinical picture comparable to that of anaemia. Quite a number of cases occur where, with a normal strength in haemoglobin and a normal number of red cells, a great artefactual of cells with granules have been noticed, as occurs in favourable cases. Evidently, it is a question here of a special reaction and a particular form of anaemia, and it is quite incorrect to regard the granules simply as a manifestation of anaemia. Simple forms of anaemia are not so often removed from these changes as is poisoning by lead.

Chlorosis is not characterised by the appearance of basophilia, not even when serious cases show a certain number of red cells with coarse and even with fine granules. The same thing may be said of posthaemorrhagic anaemias, of those caused by the above-mentioned poisons, and infectious diseases.

According to Schmidt, in lead poisoning a specific condition occurs, due to changes in the cells of the marrow and their nuclei. This nuclear state is not characteristic of other secondary anaemias in which only an indirect stimulation of the marrow is produced.

Estimations of blood lesions can be made by different methods of staining, depending on the object in view. Double stains, e.g. Giemsa and May-Grunwald, are quite unsuitable, for the red colours conceal part of the
nucleus, a fact upon which Schnitter has already insisted. In the opinion of Schmidt, the methods of staining most to be recommended are as follows:

(1) Staining with borax methylene blue (Manson’s method).

(2) Staining with the azure blue 11 of Giemsa modified by Schmidt-Koch (not to be compared with the double staining of Giemsa).

(3) Staining by Schwarz’s method (modification of the method of Manson).

(4) Staining by toluidine blue by the method of K. B. Lehmann.

These four methods (see further on for the technical part) cause a slight staining of the red cells, against which foundation the basophilic granules stand out much better. Deep staining with too concentrated solutions, as well as double stains, conceals the delicate granules. Schwarz has eliminated the defects from the various means of staining by Manson’s alkaline solution by keeping separate the methylene blue and the alkali (see further on). By his research in collaboration with E. W. Koch, Schmidt has increased the duration of the staining with azure blue 11 of Giemsa from ten seconds to two minutes (Schmidt-Koch method), in order to show up polychromasia in conjunction with granules.

The recent work of E. W. Koch shows the expediency of taking into consideration, in the course of a health examination of workers, the polychromatic elements as described by Schoenfeld, especially since advantage accrues from detecting the first signs of lead absorption industrially. In fact, if, after having found a normal blood, one suddenly detects the presence of numerous polychromatophile red cells, it can be ascribed to absorption of lead during work, if there is no question of other causes of injury, as, for example, haemorrhages. But polychromatophilia in this case only constitutes, as does basophilia in minor intensity, a danger signal or warning, and nothing more.

(c) The Blood Formula and Diagnosis of Lead Poisoning

With regard to workers in lead industries it is necessary from the start to make a choice among the men exposed to the risk (Carozzi), in order to be sure that the blood changes are not due to other causes, such as malaria, tuberculosis, carcinoma, haemorrhages, or poor nutrition. If comparison with the normal or anaemic blood is desired, a limit should be fixed to start from, so that blood examinations which are found positive may be accepted with greater confidence. A careful count of red cells with basophilic granules has shown that their limit should be fixed at 100 per million of normal red cells. But naturally the certainty of the results increases with an increase of this limit, Trautmann fixing it at 300 and Schnitter at 500 per million. These counts, however, call for withdrawal from unhealthy work.

Schmidt constantly recalls, and does so rightly, as much from a humanitarian as from a prophylactic point of view, that it is much better to stress too much the occupational origin of a case than too little. With indefinite subjective symptoms, when the doctor has to decide between shamming, hypochromadriasis, or occupational disease, the decision should incline — according to Schmidt — in favour of an occupational origin if repeated examinations show in the blood a count of 100. In these conditions a diagnosis of “lead poisoning” is not strictly justified, but “in dubio pro aegroto” — in case of doubt find for the patient. This conception is justified by the statistics of Schmidt and other experts. By way of example, it is fitting to quote here the tables of Schmidt (1907), of Trautmann (1909) and of Schnitter (1919):

<table>
<thead>
<tr>
<th>Limiting count</th>
<th>110 workers with no industrial contact with lead</th>
<th>546 workers with industrial contact with lead</th>
<th>15 cases of lead poisoning confirmed clinically</th>

</tbody>
</table>

TABLE 1 (SCHMIDT)
For cases of poisoning well marked from the clinical point of view, A. Sellers also gives a count of 100 per cent. positive results, and so does Koelsch.

Beyond doubt the count in many cases shows a parallelism between the blood changes and the degree of lead absorption and the damage done. Determination of the risk caused by an industrial installation is of great importance, a point upon which Carozzi has insisted when speaking of the kind of control to exert. For example, the industries which give most positive results are those where there is most dust (Schmidt), which demonstrates the correctness of Legge's conception of the importance of lead dust. This is why persons occupied in the transfer department of the pottery industry show counts which are definitely and clearly high when compared with those in other industries (especially in the polygraphic industry), and why women show great differences compared with men. There are in consequence possibilities of appreciable differentiation, which fact is supported by quite a rich literature (see following tables, Sellers, etc.). That applies not only when diverse industries are compared, but also when different departments of the same factory are compared, when the percentage of the distribution of workers who show positive results, as well as when the value of the results obtained is compared.

The proof is supported by some statistics supplied by P. Schmidt:

<table>
<thead>
<tr>
<th>Occupation</th>
<th>Number of cases examined</th>
<th>Positive results (above 100 per million)</th>
<th>Percentage</th>

There are no other operations which show in such a certain and simple manner the risk of danger from lead poisoning. One can understand that objections are raised from many quarters to such a numerical determination of defects in the hygienic arrangements of factories. But, in the opinion of Schmidt, there is no further doubt that the blood formula can be of very great use for determining the danger risk and the hygienic standard of workshops.

The examination of the blood naturally calls for thoroughly successful preparation of the blood smears. The red cells should be isolated one from another, and not be piled together as occurs in bad preparations. The technique for spreading the films is as follows (Gilbert process):

1. Prick so as to obtain a good drop of blood from the pulp of the finger or the lobule of the ear without having to exert any pressure.

2. Collect the drop upon the narrow edge of a well-cleaned slide.
(3) While the slide is held obliquely at 45°, place the edge carrying the drop of blood upon the surface of a second slide which has been well cleaned and slightly warmed.

(4) Wait for the drop to spread out uniformly on the slide along the width of that edge.

(5) Then effect the spreading out by extending the smear.

Only too often, out of a number of smears prepared by doctors who are not experts, there is a large percentage of absolutely useless ones. It is in this way that the numerous negative results recorded in lead poisoning can be explained, quite independently of differences in staining and expert opinion (Schmidt).

It must once more be emphasised that, even under the above-mentioned conditions, the limits of count, fixed at 100-300 and 500 per million, are only probable counts; but they are sufficiently accurate from the prophylactic point of view. Still it need not be a question of exclusion from work when dealing with the lowest figures. If, however, an examination carried out on the whole personnel of a factory shows thousands of red cells with granules per million of red cells, the value of this examination will obviously be much increased.

It is known by experience that the blood formula in lead poisoning may exhibit variations, in that basophilia and polychromatophilia may be present or may disappear. The explanation lies in the fact that the marrow, like all other glands, especially in conditions of sickness, acts irregularly. If, for various reasons, it loses its activity, few or no altered red cells may be expected to be found. But the fact must be emphasised that complete absence of polychromatophilia and basophilic granules in the red cells is exceptional in lead poisoning. This phenomenon is more frequent in old, chronic cases than in acute cases. The bone marrow reacts in the former less promptly and less intensely to the action of the poison than in recent and acute cases. Besides, it is not known at the start if, in chronic cases and elderly subjects, some parallel changes due to vascular sclerosis do not exercise a favourable action on the haemopoietic organs.

Hence arises the necessity for making numerous investigations at frequent intervals.

It is of some practical importance to observe that blood changes, in the majority of cases, are the first sign of a reaction of the blood to lead, even in the absence of subjective or objective symptoms. Such symptoms may, however, be associated from day to day, due to some excess, with intercurrent diseases, or be caused by quite different unknown reasons. It is in the highest degree desirable to acquire further proof of such a state. At all events, blood changes, even when deviating only a little from the normal, are a warning note to the doctor in charge. And, as a matter of fact, how many more times has it been observed that workers presenting blood changes fall sick clinically than those not showing any such lesions of the blood (Engelsmann)?

The idea of there being healthy carriers of lead should then be accepted cum grano salis, and Schmidt, in consequence, adopts a division, proposed by Teleky, into three groups, which include gradations up to the most serious forms:

(1) Lead absorption.

(2) Reaction to lead without clinical symptoms or with some blood changes.

(3) Poisoning by lead with clinical and objective symptoms. With the object of detecting red cells with basophilic granules in case there are only very few, Schwarz has recently recommended preparations with a heavy drop, in which distilled water is used to dissolve the haemoglobin; they enable a much larger number of cells to be examined than is possible in ordinary smears. Schwarz prefers this method as a means of selection when investigating large numbers. In suspected cases recourse can then be had to the method of the normal smear in order to determine the number of granulated red cells, which cannot be done by the method with the heavy drop.

Quite recently (1925), Schwarz has drawn the attention of experts to the value of examining smears, stained by the Manson method, in a darkened field. It is certain that by this method the finding of red cells with basophilic granules is rendered much easier and quicker.

Bianchini and Sestini have shown that basophilic red cells found in a
smear from a heavy drop, but absent in an ordinary smear, represent an artificial product. In reality, as has been said above, rapid autolysis, such as is found in the heavy drop, causes the formation of basophilic substance in small grains, which otherwise would be scattered over the whole element. Thus the results obtained with the heavy drop are regarded as erroneous, rather than as an advance in haematological technique (Biondi).

According to Schilling, the finding of a basophilic network in polychromatophile red cells is quite an easy matter for an experienced doctor, and also enables him to detect cases of anaemia. Schiff, with the same object in view, has used Hoffmann's method of illumination, which had already given good results in the detection of Koch's bacillus. This process is to be recommended in cases where there are only very few granular elements.

By means of this method, Schmidt has been able to demonstrate polychromatophilia, as a very fine granular appearance, through all transitional forms up to basophilic granulation properly so called.

The determination of red cells with granules is greatly facilitated by their splendid colour, which is a golden yellow, the complementary colour to methylene blue. However, it is essential to have a good condenser adapted for changing, so that one can pass easily and without effort from a dark field to a light field and vice versa. In doubtful cases, or rather in threshold cases, the ultramicroscope is certainly most useful, whilst it appears to be superfluous in positive cases.

Researches with the ultramicroscope, made in Italy by Cesarini Demel at Pisa and by Bianchini at Sienna, prove that the change from polychromatophilia into punctate, detected by oblique illumination and by the appearance of the complementary colour, do not justify accepting that red cells with basophilic granules are present with their specific diagnostic significance, unless they can be detected by ordinary methods. Examination with the ultramicroscope may be used to demonstrate, if it is so desired, a fact detected by other methods of investigation, viz. that the basophilic red cell passes uniformly and by degrees to the polychromatophile and the punctate (Biondi).

B. — THE LEUCOCYTES

As regards quantitative alterations in the leucocytes, a diminution of white cells, especially of the polynuclear type, occurs in chronic lead poisoning and chronic mercurialism, and an increase, chiefly of polynuclears, in the acute forms of these poisonings.

It should, however, be mentioned that the leucocytosis varies much according to the type of animal experimented upon, the age, the special condition of the poisoning, and the path by which the poison enters. The leucocytosis also presents a different formula according to the different poisons, which generally cause a neutrophilic polynucleosis. Basophilic polynucleosis is seen most frequently in poisoning by pyridine; eosinophilia in poisoning by carbon monoxide, phosphorus, mercury, aniline, nitrobenzene, benzene, and, practically always, in the final phase of any toxic leucocytotic reaction. In ankylostomiasis, leucocytosis and eosinophilia have been found, which may reach even 40 to 53 per cent., according to Berck, Simon, and Boycott, and only 15 and, more rarely, 20 per cent. in the opinion of such other experts as Bruns and Lieffmann. But generally the rates are from 5 to 7 per cent. In the serious cases alone is anaemia found, which can, however, be very serious and even fatal. Haemoglobin may sometimes fall to 18 per cent.

Lead Poisoning

As in most chronic anaemia, the white cells present, during lead poisoning, changes which betray themselves by an increase in the polynuclear forms and lymphocytes. Naegli speaks of a “moderate leucocytosis” in cases of slight lead poisoning and of pronounced leucocytosis in cases with pronounced anaemia.

Lymphocytosis is also mentioned. What was formerly called the mononucleosis of lead poisoning should be interpreted, according to the researches of Bianchini, as an endotheliosis, that is to say, as an introduction into the blood stream of hyaline corpuscles of reticulo-endothelial origin.

Recently A. Seitz failed to find among typefounders changes in the red cells, but, on the contrary, has found a relative increase of lymphocytes and a diminution of blood platelets. He has ascribed this finding to chronic poisoning by antimony rather than to lead poisoning. Antimony collects and accumulates on the scrapers of furnaces in typefoundries and dust easily forms. Similar results have been obtained in Saxony by Thiele. According to A. Scitz, in consequence of toleration by
the bone marrow of the action of lead, products of this pathological and sudden regeneration are no longer found, whilst a hyperproduction of lymphocytes still occurs. But, since the latest clinical researches allow of the possibility that a mononuclear or basophilic leucocyte, the presence of mononuclear or basophilic leucocytes, although this picture is not characteristic of antimonial poisoning. In mercurialism, Biondi and Giglioli have reported the presence of mononuclear or of basophilic leucocytes.

In anilism, there has recently (1926) been noted by Heim, Agasse-Lafont, and Feil an abnormal increase in small lymphocytes. In a case of serious poisoning by nickel, anaemia was accompanied by an increase in the number of platelets.

The Elements of Diagnosis

The presence of a large quantity of porphyrine in the urine, according to Teleky and Goetzl, is of great importance in the diagnosis of lead poisoning, and more especially in connection with what is called "the lead complexion". According to recent studies of Hans Fischer and O. Schumm, the porphyrin present in urine and faecal material in cases of lead poisoning is not haematoporphyrin, as was formerly supposed, but a koproproporphyrin, for it does not originate from blood haemoglobin, but from myo-haematin by disintegration. The two can be distinguished very easily by spectroscopic examination: acid haematochromoporphyrin has its principal absorption bands at about 593-550 mμ, but not by trional which gives haematoporphyrin, due to poisoning by lead and sulphonal, but not by trional which gives haematoporphyrin, has its bands at 593 and 550 mμ. Alkaline porphyrin is characterised by four absorption bands.

If, according to Garrod's researches, small quantities of porphyrin are present in miscarriages — it is necessary to decide on a standard limit, so that diagnosis may be reliable from a practical point of view. This standard can be easily arrived at by diluting an acid extract until the absorption bands disappear (see further on). Never-the-less, the presence of porphyrin after extensive dilution is not in itself an absolute indication of lead poisoning, for Garrod has found it in a great variety of diseases.

In conclusion, if in the changes in the red cells specific phenomena do not occur — in the sense, for example, of the formation of agglutinins, since polychromasia and basophilia, but specially the first, can be detected in such other forms of anaemia as malaria, pernicious anaemia, leukaeimia, nitrobenzenism, and haemorrhage of long duration, for example, haemorrhages in the mouth, nose, and lungs, and in the injection of the blood in the diagnosis of lead poisoning must not be minimised, more especially when it is a case of detecting the injurious effect on the body in an early stage among certain predisposed individuals with the object of protecting them against more serious injurious effects (Schmidt).

As a simple and objective means of investigation among a number of women workers, nothing can take the place of examination of the blood, and the same thing applies to cases of differences between employers and their
workpeople, between factory surgeons and public health doctors, especially since it can be maintained with complete confidence that, with irreproachable technique and some practice, 90 per cent. at least of new cases of poisoning give positive results on repeated examination. Schmidt has learned from repeated experience that the workers themselves agree readily to a decision, even when it is incomprehensible to them, if it is based on impartiality and science without any subjective taint.

Without wishing to admit that questions of sentiment may arise, it is advisable to demand that decisive examinations shall be done in a central laboratory, where the best methods of investigation are carried out or can be learnt. This idea was recently developed by C. Biondi (see article “Lead Poisoning”), who considers blood investigations of an incontestable value in all doubtful cases, or even in cases not notified, and also when a decision has to be taken as to eventual suspension from work. From this point of view, examination of the blood has a special value, even when the objective signs of the line and anaemia are wanting (Carozzi).

The experience of A. Sellers (1921) among the workmen in an English accumulator factory convinced him that the number of basophilic red cells among those affected by lead poisoning is greater than is generally accepted, and that it is quite easy to find a proportion of 10,000 and even 20,000 basophilic red cells per million. According to his expert, this clinical investigation is simple and can be applied on a large scale. Nevertheless, in counting basophilic red cells difficulties may be met which are not always easy to overcome. But the search for basophilic red cells affords a valuable method in the diagnosis of lead absorption. It is of great use to the clinician, who is enabled to make a diagnosis in slight cases which would otherwise escape notice if the diagnosis had to be based on known symptoms.

Of course suspension from work must not be based simply on an examination of the blood, but on all discovered facts; and regard must be had to the general state of the individual. According to Schnitter, the standard rate of 500 cells with granules per million represents a danger signal, which makes it advisable for workers to leave their work, when industrial lead poisoning is considered as a compensatable accident from the legal point of view; he also says “that the highest pension is a poor consolation for the loss of health”, and suggests in consequence early suspension from work with, of course, compensation. If and in what limits this measure is practically applicable is not a question for discussion here. Examination of the blood provides a supremely important means for early detection of the first effect of the poison on the body, as well as for continuous observation of the features of the blood formula, especially during the early period of exposure to lead risk which is particularly critical.

For all legal decisions, as opposed to prophylactic measures, Biondi undoubtedly does not consider blood examinations as conclusive, even when high rates are present. However, according to Schmidt, the combination of isolated results, especially a high degree of basophilia, for example, more than 500 cells with granules per million, when it is associated with the presence of lead in the urine and the blood, can be considered as conclusive.

It may perhaps be necessary to take into consideration higher rates, for example 1,000 per million, and also the presence of polychromatophilia (Koelsch).

Examination of urine for casts is described by certain authors (Engelsmann, for example) as a means of very great value for controlling the health of lead workers; but it cannot be considered to give better results than examination of the blood. As a matter of fact, experienced clinicians warn us against drawing too rapid conclusions from the presence of hyaline casts, or other similar findings, with regard to the diagnosis of renal disease. Schmidt, for example, has no belief in any parallelism between renal lesions and the results of urinary examinations.

It is necessary then in this important practical question, to accept the opinion of the best qualified experts, who take into consideration the whole clinical picture in addition to isolated symptoms, or require isolated symptoms to be particularly well marked.

It is a fact of great scientific interest that lead may circulate for a long time in the body without causing even the slightest subjective symptoms, or even diminishing the working capacity of those affected. There are many other diseases, especially infectious ones, syphilis for example, which act in the same way. But one day there suddenly appear, while the victim is in full health, the most serious illnesses, often with a fatal issue. It is so with renal diseases and arteriosclerosis, which
may remain latent for a long time and then suddenly cause a catastrophe. Doctors do not possess in these cases any means for foretelling the future; and there is no cause for complaint if investigation for red cells with granules does not enable one to make such a prophecy.

It is probable that the cause of certain phenomena lies in anatomical changes which are caused by the lead in the nerve or muscle cells, but escape notice. Perhaps certain morbid inter-current conditions, such as affections of the circulation, of nutrition or other causes, influence these changes. This is not known. Or perhaps in certain cases of crisis the troubles should be attributed to an unstable nervous system, caused by internal factors completely unknown.

C. — Non-Haemolytic Poisons with the Formation of New Combinations with Haemoglobin

A series of blood poisons exists characterised by the formation of new combinations of the poison with haemoglobin, without, however, leading to destruction of the red cells.

Of these combinations the most important and best studied is certainly carboxy-haemoglobin, while sulphurated methaemoglobin (sulphomethaemoglobin)\(^1\), and particularly cyanomethaemoglobin, are of less importance and so have been less studied from the theoretical point of view. The newly formed chemical bodies are of so stable a character that haemoglobin is deprived of its proper physiological function of carrying oxygen — take, for example, methaemoglobin in its most stable form of oxidation (see article "Carbon Monoxide"). The normal course of oxidation and disintegration processes is so disturbed that combustion of carbon into carboxic acid is prevented or retarded. Dextrose and intermediate products of exchange of various kinds, such as acetone, oxybutyric acid \(\beta\), acetaldehyde, acetic acid, and bodies of the aliphatic series in the urine and the expired air, which are formed in the blood, not only exert a decided influence on the structure of the plasma, displacing the distribution of globulin and changing the strength of fibrinogen, but still more affect the process of disintegration of albumen. The nerve centres suffer chiefly, and suffer first from want of oxygen and exhibit disturbances which may advance to fatal coma.

In view of its great practical importance from an industrial point of view, accurate detection of carbon monoxide must be insisted on, and in particular by simple processes which are available to the factory surgeon (see articles "Carbon Monoxide" and "Air Testing in Workrooms").

The scientific and practical findings of J. and H. Barcroft have shown that the spleen, in consequence of its special vasomotor functions, is in a position to retain carboxyhaemoglobin for a longer time than the circulating blood. According to Nicloux, the amount of carbon monoxide fixed by the blood is not strictly proportioned to the percentage in the air, but it is governed by the mass action of a system where the oxygen and carbon monoxide have an inverse influence on the blood, the curve possessing a parabolic character.

An increase in the number of cells has frequently been found, but it is not constant. Roth is of the opinion that eosinophilia is always absent. From the point of view of the progress of the poisoning, a slight leucocytosis should be considered as indicating a bad prognosis.

Complete elimination of carbon monoxide occurs in the course of five to six hours partly by oxidation into carboxic acid and partly by dissociation and replacement by oxygen (Bolognini, 1912). Administration of pure oxygen causes a dissociation of carboxyhaemoglobin five times greater than when air is used. Still more favourable results are obtained by the addition of 5 per cent. carbon dioxide to the oxygen, for it stimulates more active respiration and the dissociation is by so much the more rapid.

It should be added that red cells of oxycarbonated blood have a greater rate of sedimentation than those of normal blood.

It is an established fact that carbon monoxide is completely displaced by oxygen introduced naturally or artificially without the red cells being destroyed (Bolognini, Lewin). It can at least be said that there is no certain proof of anaemia having been observed after poisoning by carbon monoxide. The chronic forms are said to lead to anaemia; but it is not yet known whether the cause is a destruction of the red cells, or, more likely, a lesion of the haemopoietic organs in consequence of changes of fatty degenera-

\(^1\) See the article "Sulphurated Hydrogen". Howard and Longard is of the opinion that the direct action of this gas does not, in the living body, lead to the formation of sulphohaemoglobin or of sulphomethaemoglobin.
tion, caused by a continuous or even partial want of oxygen.
Next to carbon monoxide, sulphur- 
etted hydrogen plays an important part as an industrial poisonous gas. The only path of absorption which

Spectrum of blood according to Walter J. Dilling (Liverpool)

need be considered is inhalation. for absorption per os by a solution of sulphur- 
etted hydrogen in water is comparatively without danger even in large doses. Sulphur- 
etted methaemo-
sulphohaemoglobin is of a dirty green to brown.

Spectroscopically this substance is characterised by a broad band in the orange at 622 µµ near the bands of oxyhaemoglobin which is always present, whilst neutral methaemoglobin presents a broad band at 634 µµ and alkaline methaemoglobin presents a band at 602 µµ (Rost, Franz, and Heise).

Cyanhaemoglobin, due to poisoning by hydrocyanic or prussic acid, is characterised by a broad band in the yellow-green up to 540 µµ. Cyanhaemoglobin, as well as cyanaemia, which presents an absorption band at the same place, have not up to the present been detected either in the living or dead body, but only in vitro. It is obvious that during life a cyanised combination cannot be produced, for the toxic action is too rapid, paralysing the respiratory and vaso-motor centres before the formation of detectable quantities of cyanhaemoglobin.

Cyanhaematin, which is produced by the addition of hydrocyanic acid to an alkaline solution of haematin, is changed by means of reducing agents into cyanohaemochromogen, characterised by two bands which appear in the green-yellow. If one adds to the blood red cyanide, a body capable of forming methaemoglobin, it does not cause any change in coloration, although this last body may have reacted.

In the same way cyanhaemoglobin, oxynitrated haemoglobin and fluorised haemoglobin, the first a purple red and the second a carmine red, have only been obtained as products of laboratory reactions. Oxide of nitrogen, present in the nitrous fumes which are given off when nitric acid is reduced by means of organic substances or of metals, acts, according to Kunkel, as a nitrite, with a similar formation of methaemoglobin. The red colour of the blood in poisoning by hydrogen cyanide arises, not only from the formation of cyanised haemoglobin, but finally from complete arrest of nutritional exchanges in consequence of paralysis of the cellular enzymes, the cells no longer being able to use the oxygen with which they are supplied. A deep asphyxia of the tissues results, followed by respiratory and cardiac paralysis, long after the nerve cells have ceased their work. Alkalinity diminishes; it is replaced by lactic acid, which can no longer be burnt into carbonic acid.

In all these poisonings repeated exposure, even to small quantities, always leads to anaemia, even though no haemolytic action can be detected; this anaemia undoubtedly arises from fatty degeneration and paralysis of the haemopoietic organs. But as yet no accurate data on these reactions are available.

It should be added that different spectroscopic results are possible owing to variations in concentrations. As some concentrated solutions (1 in 30) completely extinguish the spectrum from the D-ray up to the violet, it is necessary to employ concentrations as weak as 1 in 100, or even lower, in order that the part of the spectrum with the short wave lengths may show up with all its bands.

In a whole series of industrial operations such as the manufacture of acetic acid, soap, margarine, and candles, workers are quite often exposed to the inhalation of acid fumes at an ordinary temperature, but most often at a raised temperature. In some circumstances this danger is very great, both as regards the concentration of the acid fumes, particularly of acetic acid, as well as the length of the exposure. Local lesions, such as ulcerations of the mucous membranes of the eyes and respiratory passages, monopolise the foreground of the picture, for a possible influence on the red cells has up to the present only a theoretical interest. As a matter of fact, in industrial practice cases of haemoglobinæmia and haemoglobinuria have only been noted from accidental absorption of acetic acid by the alimentary canal (Kunkel).

In the same way inhalation of volatile bases, e.g. ammonia and trimethylammon, causes an enrichment of the blood by these products. It is evident that concentration in the blood of bicarbonates and phosphates and of albuminoid bodies causes first of all combinations with and neutralisation of the acids, then follows concentrations of bases rapidly leading to a displacement of the concentration in hydrogen ions. Hober has clearly shown that ammonia can straightforwardly penetrate into the blood stream, but any direct acute effect on the red cells seems not to occur even when the exposure is most pronounced, as, for instance, in the manufacture of ice due to defects in the piping.

The most serious lesions of the system are due to asphyxias or to such local action as spasms of the glottis or pulmonary oedema.
CONCLUSIONS

From this general survey it can be concluded that, while examination of the blood in the domain of industrial hygiene still presents quite a number of problems, it has, on the other hand, given a harvest of obtained results. Speaking generally, it may be said that the methods for examining the blood described above have already gained the full confidence of employers and employed. These methods do not furnish accurate results in 100 per cent of cases, that is to say, not with absolute precision. Such accuracy, however, is unknown in medicine; biology is not mathematics. But confidence can be placed in them, for in 90 per cent. of the cases these methods give a sure result. In the opinion of Schmidt, the time is not far off when the establishment of research institutes for industrial hygiene will not only be asked for but will be insisted on, including in them all the methods of analysis mentioned above carried out by bacteriological methods. These laboratories will not only be for the purpose of detecting injuries already caused, but chiefly for establishing protection against more serious injuries. They will only fulfil this duty when their directors offer adequate and guaranteed skill, as well as a disinterested outlook. Schmidt has given up hope of entrusting to factory doctors such difficult tasks, on account of the time they are obliged to give to the numerous examinations of the personnel of a factory. The work requires such centralisation and unification that the laboratories ought to be State institutions. That no state has so far looked into injuries of this nature and a right of hygienic control is proved by the fact that several of the services for medical inspection of labour, e.g. in Bavaria, Belgium, and Italy, possess laboratories for these practical investigations.

The blood poison which, in the industrial domain, has the greatest importance is lead; it has still a particular significance for the community on account of its influence on the generative organs and the next generation. But the dose of the poison and the duration of its influence to bring about this result are not yet known.

This point alone, according to Schmidt, ought to be carefully studied, since determination of the extent of risk in an industry plays an important rôle, as well as other questions, that is to say, the degree in which, in the course of chronic poisoning by lead, a direct or indirect stimulation of the reticulo-endothelial system is caused with phagocytosis of the damaged red cells and the passing into the blood stream of cell elements. The question arises as to whether this lesion occurs in healthy carriers of lead, or only among those persons affected with poisoning to an extent which can be detected clinically. It may be that there will be found here traces of organic weakness in the hereditary constitution. The way in which such research institutes are linked up to bacteriological laboratories already existing requires explanation. Chemists should clearly be associated with bacteriologists, since the ulterior development of these studies is tending not only in the morphological and clinical direction, but also towards chemistry. Only in this way can an industrial research laboratory be complete.

It is desirable, it might even be said it is necessary, that the study of such questions should be approached from an international point of view, even as is the regulation of the practical results from the point of view of industrial hygiene. With a one-sided, non-international control, apart from any question of narrowness in judgment, risk is run, as a matter of fact, that a nation may suffer from unfavourable competition on the point of industry, on account of the extent of its measures of protection. It is not necessary to insist further on the fact that special local conditions require special measures; the principal general regulations should be the same everywhere. Since it has been found that the social life and health of nations go hand in hand and are more and more interdependent, such postulates are readily understood.

METHODS OF INVESTIGATION

A. — Blood

Staining of Smears

(1) Azur II Giemsa, according to P. Schmidt and W. Koch (Archiv für Hygiene, 1907, Vol. 63, fascicule 1, and 1924, Vol. 94, fascicule 4-6).

Fix for ten minutes in methylic alcohol or twenty minutes in absolute ethylic alcohol.

Stain for two minutes with a solution of Azur II Giemsa (50 mg. per cent. of distilled water of neutral reaction).

Wash rapidly three times and dry.

Stain faintly, so as to bring out better definition in the light. Count
the cells with granules and finally the polychromatophile cells per million so as to establish curves (final determination of cells with granules and polychromatophiles at the same time according to Koch's method).

(2) Manson's blue, stock solution:

Medicinal methylene blue, Höchst
Borax
Boiling water

Grm. 2
2
100

Dilute with water until transparent in a glass reagent vessel and stain for twenty seconds. Wash rapidly.

(3) Manson's blue, modified by L. Schwarz (Klin. Wochenschr., 1st year, No. 49):

Solution I. — Methylene blue
Boric acid
Distilled water (neutral)

Grm. 1
2
100

Solution II. — Caustic soda
Distilled water

0.28
100

Mix in a graduated glass vessel six drops of solution I and eight drops of solution II and make up to 100 c.c. with boiled distilled water. Stain for five seconds, then wash with distilled water.

Preparation in heavy drop according to Schwarz (for rapid examination): stain for three minutes without fixation (see also V. Schilling: Deutsche Medizin. Wochenschr., 1924, No. 36).

(4) Methylene blue, according to Gilbert.

Stain after fixation by ethylic or methyllic alcohol with the following solution:

Ch. pure methylene blue
Bicarbonate of soda
Distilled water

Grm. 2
12
200

Wash until the smear is decolorised.

(5) Blue of toluidine, according to K. B. Lehmann (Archiv f. Hyg., 1924, Vol. 94, fascicule 1, p. 7):

Toluidine blue
Borax
Distilled water

Grm. 3
0.5
1.000

Stain for twenty minutes — twenty-four hours can even be allowed without fear of injury, for it does not cause over-staining. The staining is very delicate.

The double stains (Giemsa or May-Grunwald) are quite unsuitable for the diagnosis of basophilic granules, and polychromatophilia for part of the elements disappears.

B. — Urine

I. Chemical Detection of Blood

(See S. E. Spaeth: Untersuchung des Harns, 6th edition; Leipzig, Ambrosius Barth. — Brugsch and Schittenhelm: Lehrbuch der klinischen Untersuchungsmethoden, 3rd edition; Vienna and Berlin, Urban und Schwarzenberg.)

(a) Reaction of Heller. — Mix in equal parts urine and a 10 per cent. solution of soda; raise to boiling. Haematin is carried down with the precipitate of phosphate which is coloured a brownish red. There is a possible confusion after taking senna, santonic, etc.

(b) Examination by guiacum (Van Deen's test). — Dissolve in some c.c. of absolute alcohol as much resin of guiacum as will go on the point of a small knife; add some drops of oxygenated water or of old oil of turpentine. Make this flow drop by drop through a pipette down the side of a test tube; the reaction is zonal. At the junction of the two liquids a blue ring appears.

The method of O. Schumm enables a more accurate determination to be made: first of all shake the urine with acetic ether, then mix 50 c.c. of urine with 5 c.c. of glacial acetic acid and 50 c.c. of ether.

Allow the urine to flow away and wash with 5 c.c. of water; let that flow away; and use the ethereal extract for the guiacum reaction or for spectroscopic examination.

II. Detection of Urobilin and Urobilinogen

(a) Urobilin. — Mix 10 c.c. of urine with 10 c.c. of an alcoholic solution of acetate of zinc; then filter. The filtrate when the reaction is positive shows a green fluorescence against a black ground (reaction of Schlesinger). If bile pigments are present, eliminate possibly adding to 8 c.c. of acid urine 2 c.c. of a 10 per cent. solution of chloride of calcium. Add a weak solution of ammonia until the reaction is slightly acid; filter and use the filtrate for the test of Schlesinger.

In order to determine urobilin by the spectroscope, acidify 50 c.c. of urine with some drops of hydrochloric acid and stir with 25 c.c. amyllic alcohol. This solution when examined with the spectroscope shows in positive cases the spectrum of acid urobilin towards the F-ray: absorption band at 508-455 μμ.
'b) Urobilinogen. — To some c.c. of urine add some drops of Ehrlich's aldehyde reagent (a 2 per cent. solution of dimethylpara-aminobenzenaldehyde in 20 per cent. hydrochloric acid).

If urobilinogen is present a rose colour is produced, even when cold. This method can only be employed with fresh urine, because, when exposed to light, urobilinogen changes into urobilin.

(c) Biliary pigments. — (1) Reaction of Gmelin. Add to some c.c. of pure concentrated nitric acid some drops of fuming nitric acid. Make the urine run slowly into this mixture so as to obtain a zonal reaction. Oxidation rings are obtained which are, from above downwards: orange, red, violet, blue, and green.

(2) Rosenbach's reaction. Filter the urine several times, and spread out the filter paper on porcelain saucer. With a glass rod put upon the filter paper a drop of a mixture of nitric acid and fuming nitric acid used in the Gmelin reaction. It will cause at the point of contact coloured rings as mentioned in (1).

(3) Reaction with iodide. In a test tube dilute tincture of iodine with absolute alcohol (one part of tincture of iodine to nine parts of alcohol). Add this tincture slowly to the urine to obtain the zonal reaction. At the point of contact will be found a green ring. This method is very good and sensitive.

Biliary pigments can be detected in the serum long before they appear in the urine. They can be discovered by placing 0.1 c.c. serum in a test tube which is as narrow as possible, and adding 0.3 c.c. of physiological solution of chlorid of sodium and then 0.1 c.c. of diazo reagent.

In the presence of bilirubin a red violet colour is produced. In mechanical jaundice (emotional jaundice), the reaction occurs at once; in dynamic jaundice, it is retarded or occurs at the end of thirty seconds.

Diazoreagent is prepared by mixing 10 c.c. of diazo I (sulphanilic acid) with 0.3 of diazo II (nitrite of soda). The reagent when mixed only keeps a few hours. However, this formula has a composition which is slightly different.

(d) Haematochlorophyrin. Koproporphyrin. — The first of these is found in poisonings by trional and in constitutional porphyrinura, and the second in poisoning by sulphonal and lead (H. Fischer and O. Schumni).

Tests for haemoglobin by tincture of guaiacum and by Heller's reaction, and for albumen with heat and with acid, represent the direction investigations should take. In the cases of porphyrinuria the test for haemoglobin by guaiacum is negative, the reaction of Heller is positive and the test for albumen negative.

(1) A. E. Garrod suggests the following special reaction (Journal of Physiology, 1892, Vol. XIII, p. 596, and 1894-1896, Vol. XVII, p. 349): add to 500 c.c. of urine, 100 c.c. of 10 per cent. solution of soda, so as to obtain flocculation and sedimentation of phosphates.

If there is little phosphate of calcium, add a little of it in acetic solution so as to cause a good flocculation with the alkali. If porphyrinuria is present, most of the floccules are of a red colour. Filter the deposit, remove the alkali from the deposit, wash with distilled water, dissolve it in a 5 per cent. solution of hydrochloric acid in alcohol, and then dilute with acid alcohol till the total volume is 50 c.c.

For the spectroscope use a cuvette 4-5 cm. thick. According to Schmidt, only values above 1 in 100 are significant, for koproporphyrin is in small quantity a normal pigment of urine.

(2) Saillot (Revue de médecine, 16, 551) and H. Guntler (Deutsches Archiv für klin. Med., 1920, 134) advise acidifying the urine with acetic acid, making an extraction with acetic ether and adding 5 per cent. hydrochloric acid.

(3) Nebeltau (Neubaur-Huppert: Analyse des Harns, Wiesbaden, 1913) makes the quantitative determination as follows: to 100 c.c. of urine, add 5 c.c. of glacial acetic acid; allow to stand two hours until a deposit forms of impure porphyrin; take up this deposit with chloroform or weak hydrochloric acid. Evaporate to dryness and weigh.

(e) Carbon monoxide (see also article "Carbon Monoxide"). — (1) The tannin method of Kunkel (see L. Lewin: Die Kohlenoxid-Vergiftung, Berlin, 1920): mix one part of a 1 in 4 solution of blood with three parts of a solution of 1 per cent. tannin. Carry out at the same time a test with normal blood as a control. At the end of several hours the normal blood appears as brownish-yellow, and the oxycarbonated blood as pink. The reaction improves with time and will remain for months.

(2) For spectroscopic examination (according to Lewin) a 1 per cent. solution of blood in distilled water is
used with a thickness of 1 cm. The absorption bands show as follows:

<table>
<thead>
<tr>
<th></th>
<th>Normal blood</th>
<th>Oxycarbonated blood</th>
</tr>
</thead>
<tbody>
<tr>
<td>Alpha ray</td>
<td>577 μμ</td>
<td>570 μμ</td>
</tr>
<tr>
<td>Beta ray</td>
<td>527 μμ</td>
<td>549 μμ</td>
</tr>
</tbody>
</table>

Differentiation is made by adding to the solution of blood some drops of sulphide of ammonia. After a delay of some eight minutes or so a large pale band of reduced haemoglobin appears in normal blood having a wave length of 599 μμ, whilst with oxycarbonated blood there is no change; or when, carboxyhaemoglobin being excluded, there is ordinary oxyhaemoglobin, the absorption band of reduced haemoglobin appears between the alpha- and beta-rays. The presence of carbon monoxide can also be detected by means of white mice.

(i) Methaemoglobin (neutral nitrite-methaemoglobin). — Prepare a solution of blood diluted thirty times. With a dilution of this strength the spectrum is extinguished on reaching the D-ray, whilst a large absorption band is seen in the orange having a wave length of 634 μμ. If the solution is further diluted to 1 in 60, or 1 in 100, the bands of oxyhaemoglobin appear, for, practically, oxyhaemoglobin always remains. Further, a large band appears in the blue at 500 μμ and then the bands in the orange are completely effaced (Rost, Franz, and Heise: Arb. aus d. Katsersl. Gesundheitsamt, 1909, Vol. 32, p. 263).

(g) Sulphomethaemoglobin. — This is very rare according to Kunkel, and according to others has not even been determined with certainty in the living. Examine with the spectroscope a 1 in 60 solution of blood. In addition to the bands of oxyhaemoglobin a broad band appears in the orange red at 622 μμ. By the addition of sulphide of ammonia and potash lye the bands are changed into those of haemochromogen.

(h) Haematin. — According to Schumm, the serum is tested by the spectroscope, using a thickness of liquid of 1 cm. Three absorption bands of acid haematin are found in the red, yellow and green. The bands in the orange red of 633 μμ are characteristic; the others are the bands of oxyhaemoglobin (whilst the bands of methaemoglobin occur at 634 μμ).

The addition of four drops of sulphide of ammonia causes the three bands to disappear, but, on the contrary, causes to appear a broad band of reduced haemoglobin and two bands of haemochromogen at 555 and 525 μμ. Detection in the serum is often possible when the urine is negative, just as in the case of methaemoglobin and bilirubin.

BIBLIOGRAPHY

Among the numerous publications on the subject may be mentioned:

"Destruction of the Red Corpuscles in Health and Diseases." Studies from the Rockefeller Institute for Medical Research, 1923.

Blood (Changes Due to Occupation)

In this article will be examined briefly modifications in the blood which take place from causes other than toxic. Among the causes of such changes due to occupation the following may be enumerated:

1. Exaggeration of work (physical or intellectual) whether it be a question of continuous or intense effort.
2. Position assumed at work, and, notably, special movements or such as are methodically repeated.
3. Environment of work: surroundings, physical and chemical causes, etc.
4. Materials handled capable of exercising either a toxic or infectious action. (See articles "Blood and Industrial Poisonings", "X-Rays", and "Radium and Radio-Active Substances").

1. Blood in relation to fatigue

Either physical or intellectual fatigue makes its effect felt by all the elements which go to make up the blood. It seems as though the blood reaction is in relation with the kind of work done and the degree of fatigue (Palmulli).

Red Blood Corpuscles

Either an absence of changes (Ferrannini, Scalafatti) or a diminution in the number of the red blood cells has been observed (Wetzell, Broun, Palmulli). The slight diminution found during fatigue might be preceded, according to Palmulli, by an increase in the number of the red blood cells during the first hours of work. Other authorities, however, have found the red blood cells increased (Malassez, Tausk, Hawk, Dürrig), which is thought by one of them (Dürrig) to be the expression of the loss of water by the blood. Villemin, finally, considers that the blood reaction depends on the state of health of the individual. He is said, indeed, to have proved that there is a fall, the result of fatigue, among untrained schoolchildren and a rise among trained subjects.

Haemoglobin

A diminution in the amount of haemoglobin occurs (Dürrig, Broun, etc.), which, according to Conheim, may be 4-5 per cent. in slight physical work, and 10 per cent. in hard work. The same phenomenon is observed with intellectual work (Ferrannini, Graziani), from a long and tiring spell of mental toil. According to certain authors (Löwy), this diminution is in proportion to the number of red blood cells. On the other hand, an increase in the haemoglobin has been observed by Tausk and Palmulli.

Cellular Resistance

The cellular resistance is diminished showing itself in an increase of haemolysin in vitro of the red blood cells, and sometimes by haemoglobinuria in the course of physical fatigue (Manca, Feigl, Carpentieri, etc.) or intellectual fatigue (Graziani). Some authors, on the other hand, have noted an increase of the minimal resistance by exaggerated destruction of the red blood cells which are least resistant to toxic substances arising from brain work (Graziani). Similarly, Lieberman and Acel have shown that the diminution in resistance of the red blood cells to hypotonic salt solutions produced in physical work give place to an increase of this resistance as a consequence of the destruction of the less resistant cells.
Histological Modifications

Without entering into details as to the histological modifications which have been found, it will suffice to recall the fact that a slight increase of the granulo-filamentous material of the red blood cells has been found (Palmulli), as well as, in certain cases, the following changes: poikilocytosis, anysocytosis, punctate basophilia (Pretti).

Leucocytes

The majority of authorities agree in finding a real leucocytosis, which some would maintain had for its object the speedy removal of fatigue substances. The leucocytosis produced by standing upright after half an hour’s punting is well known. Rosenthal found a marked increase after ten minutes in the leucocytes (polynuclear neutrophiles), followed by a diminution and an increase of the neutrophiles.

Other authorities are said to have found only a mononucleosis (Burkhardt), but the majority is of opinion that a neutrophile polynucleosis occurs with sometimes a perceptible increase of the large monoriocellulars (Palmulli). A leucocytosis, described by Hochstetter, and a neutrophilosis would indicate a medullary reaction against auto-intoxication.

Wetzel, on the other hand, is said to have found no changes. Others again have detected a diminution in the number of leucocytes without any change in the differential count (de Sandro).

The phagocytic index is said to be lowered (Guerrini) by the presence of substances inhibiting the leucocytic phagocytosis.

Goldberg and Lepskaja (1927) studied the changes in the differential leucocytic formula during industrial work among 300 healthy individuals and among 134 workmen subjected to static effort. The enquiry covered also intellectual work.

During muscular and intellectual work they found that a neutrophilosis appeared which increased according to the duration and importance of the work; the neutrophiles even reach 80-81 per cent. The limphopenia is at first progressive and relative, but becomes absolute with increase in the intensity and length of the work.

When work is not hard the proportion of eosinophiles diminishes and disappears if the experiment is continued. The monocytes and basophiles increase both with intellectual and muscular work.

If the work is intense or long an increase in the neutrophiles occurs. Young forms appear as well as myelocytes, altered neutrophiles showing basophile, young granulations, plasmocytes and cells of Türck.

The process of regeneration of the white blood cells noted at the commencement of light work occurs in a typical way when the duration and intensity of the work increase.

The leucocytosis during intellectual and physical work, as well as the displacement of the differential leucocytic count to the left, are due to an auto-intoxication resulting from damage to the metabolism and the irritating action of toxic products on the haemopoetic organs.

Plasma

Discordant results have been made so far as the concentration, the viscosity and specific gravity are concerned, because by one observer a diminution and by another an increase is recorded.

The same remarks apply to the time coagulation takes.

An increase of the metrical index of refraction has been noted. The dry residue is also increased (Löwy).

The diminution in the alkalinity of the blood observed by numerous authorities arises from an increase in the hydrogen ions (Dürig) and is due to an augmentation of the circulating lactic acid, to modifications of the chloride exchange between the cells and the plasma, to an increase in the chlorides in the serum, and to the content of the blood in uric acid, total nitrogen and amino-acids.

An increase of the incoagulable nitrogen of the blood (by 20-25 per cent.) has been found as bearing on the value of rest; also of the ammonia in the blood. On the other hand, the proportion of sugar is said to be diminished, but this is less marked in the plasma than in the total blood.

The antitoxic, opsonic and agglutinating, etc., powers — that is to say, the defensive products of the blood — are said to be generally diminished, although some authorities have not found any change.

The blood diastases are themselves modified.

While in acute and chronic fatigue the lipase falls, there has been shown to be an increase of amylase, as well as catalase, which at any rate would diminish in chronic fatigue (Sereni). A hypoglycaemia of fatigue has been observed by Sereni, the glycolytic
Power apparently being increased in a constant way and even more remarkably in the chronic form. The proteolytic ferment is also increased (Sereni) and that increase runs parallel with that of the incoagulable nitroglycerin.

The antitryptic ferment is also increased as a result of fatigue (Preti). The activity in reduction of oxyhaemoglobin diminishes, while it increases during moderate exercise (Ferrannini).

Some authorities have found an increase in the oxygen concentration during work, almost parallel with the increase of the pulmonary ventilation.

Finally, an increase has been observed in the reducing substances of the blood (explaining partly the increase of the blood's toxicity), as well as of the lime circulating in the blood (due to a displacement of the calcium in the system following on the acidification of the muscles in physical fatigue).

It should be clearly understood that all these modifications of the blood are transitory. They last for twenty-four or thirty-six hours; then there is a return to normal.

II. — Position Assumed at Work

This can be a source of physical fatigue on the one hand, and on the other a cause of hindrance to haematosis as a result of an inconvenient position or of some special movement (Ferrannini).

III. — The Blood as Affected by Environment

The modifications due to temperature, pressure, radiations, etc., are very important.

Temperature

The action of high temperatures brings about the following changes:

(1) Diminution of the haemoglobin, especially residence in a warm climate: some authorities, however, have found an increase in the haemoglobin, while others have found an almost normal amount.

Increase in the ordinary temperature of the body, if maintained for a long time, would bring about tissue changes and consequently changes in the state of the blood; a diminution of the haemoglobin would then be found.

In some professions (bakers, mechanics, chauffeurs), changes in the state of the blood have been described; authorities, however, consider that the oligocromenia found (torpedo-boat chauffeurs: Belli) can be attributed to the influence of the absence of natural light and even to the action of certain toxic gases.

(2) In hot countries a diminution in the red blood cells has been reported (Maurel) which, according to some authorities, might be replaced by an increase.

A diminution in the red blood cells, accompanied by other symptoms of anaemia, is found in bakers, glassblowers, chauffeurs, etc. (Ferrannini).

Grawitz has found punctate basophilia occurring, running parallel with the diminution in leucocytes.

Further, high temperatures are said to transform in vitro the oxyhaemoglobin into methaemoglobin (Ferrannini).

The minimal cellular resistance remains within normal limits whilst the mean shows an increase. Lowenthal on the contrary has found a diminution of over 40%. In certain severe cases a profound cellular destuction has been found with jaundice from pleiochromia, haemoglobinuria and even anuria (from blocking of the urinary canaliculars), remarkable anisocytosis, with macrocytes and microcytes, etc.

(3) Leucocytes. — Ferrannini has described a hyperleucocytosis with hypermononucleosis and hypopolymorphonucleosis. The number of white blood cells varies rapidly as the result of excitation by heat (Naegeli). Some authorities are of opinion that the leucocytosis which is found is due to the retention of the leucocytes near the capillaries (Lówy).

Sweating in warm air and electric light baths sets up an increase in the number of white blood cells, which is not the case when a bath of hot water is taken. At the time of the increase in the temperature of the body, Naegeli has observed a reduction of the leucocytes to two-thirds of their normal number. Experimentally (on rabbits) Vincent has shown that at 41° C. no change took place in the leucocytic equilibrium, but that at 42° C. the animal dies with progressive hyperleucocytosis, affecting mostly the polynuclears and the larger mononuclears.

Diminution in temperature hinders the coagulation of the blood and weakens sensibly the activity of reduction of haemoglobin as well as the number of red blood cells.
Cold and humidity have a bad effect on the state of the blood: basophile granules appear; the corpuscular resistance diminishes, and at $-5^\circ$ C. haemolysis sets in (Löwenhail); the number of leucocytes diminishes (owing to vasomotor changes?), while, according to Rovighi, it would increase to double when the body temperature falls to $3^\circ$ C.

**Atmospheric Pressure**

When the pressure falls the effects are felt even after a short and repeated stay at a high altitude (aviators for example). While some authorities have observed a diminution in the number of red blood cells (reaching more than a third), others have not noted quantitative changes either in the arterial or in the peripheral blood. It should be said, however, that the majority of persons with experience are at one in agreeing that the number of blood cells is increased at high altitudes both among balloonists and aviators. Experimental investigations inside the pneumatic bell confirm the data obtained from the actual field of work.

The hyperglobulia, which reaches nearly $7,000,000$ at $1,800$ metres, and $8$ millions at $4,400$ metres, occurs at first quite quickly, then goes on more slowly to reach, in the case of a long stay at high altitude, its maximum on the fifteenth to the twenty-fourth day. Other authorities are said to have found an immediate and constant increase.

The hyperglobia ceases with the same rapidity when the individual descends to low ground. The return to sea level involves a rapid diminution, then a slow one, in the number of red blood cells, until there is a return to normal. While the return to normal takes some days to establish itself after a stay of some time at a high altitude, it does so immediately in the case of a balloon ascent.

Individual reactions play an important role in the production of the hyperglobulia, which is explained in different ways: a real hyperglobulia attributable to an increased activity of haemopoietic tissue with changes in the plasma increasing the respiratory surface of the blood; an apparent one attributable to a thickening of the blood from various causes. An unequal distribution of the blood in the central and peripheral organs may be considered, while the influence of the sun is accepted by some authors and rejected by others.

The amount of haemoglobin may also undergo changes: a diminution or augmentation according to various authorities. Others have not found any modification. Even while the majority accepts the view that there is an increase, they part company on the question of its extent: considerable in the opinion of some, less so in that of others. Whatever be the truth, the increase takes place more slowly than does the number of the red blood cells, and only Abderhalden has found an absolute parallelism between the two.

The activity of reduction of the haemoglobin increases with the climb and diminishes if there is a stay at a high altitude.

The variations in pressure cause the quantity of gases absorbed by the blood to vary. At high altitudes a diminution in the gases contained in the blood occurs.

Authorities are no more in agreement as to the morphological changes in the red blood cells. While some have not observed changes (Snell, Von Schröter), others have noted dwarf cells, an increase in the normoblasts, etc. The alterations in appearance in the opinion of Naegeli are always "artefacts". Further, this authority has never found nucleated red blood cells.

The concentration and specific gravity does not show change. The total volume of the blood on the contrary is said to be increased (Jaquet, Möög, etc.).

The alkalinity of the blood is said to be diminished by $36-44$ per cent. (Galeotti, Agazzotti), and is said to depend on a fall in the amount of carbon dioxide in the blood (Mosso, Marro), as well as to the formation of incompletely oxidised products.

Frenkel and Tissot are said to have found a diminution in the albumens of the serum.

Very different are the results as regards the number of the leucocytes. Generally speaking, a diminution in number is reported with mononucleosis or, as the majority of authorities agree, a marked lymphocytosis. Ruppauer has shown that in going from low ground to high altitudes an acclimatisation leucocytosis sets in lasting for some weeks, with increase in the number of neutrophiles and lymphocytes. It does not appear that there is any relation between the variations of the red and white blood cells.

*High pressures* do not seem to produce changes in the blood.
Luminous Radiations

Excess of light acts especially by the quantity of the radiations and in particular by the ultra-violet rays.

No morphological alteration of the red cells has been described, but, on the contrary, variations in the cellular resistance, which is greatly diminished.

The ultra-violet rays have a haemolyzing action — diminishing the oxidising power of the blood and changing the haemoglobin into methaemoglobin, then into haematin, and, finally, into haemochromogen. Similarly, the carboxyhaemoglobin is converted into reduced oxyhaemoglobin.

Artificial sunlight and light treatment produce an increase in the leucocytes, which, however, diminish in high mountain air. In this case an absolute diminution of the neutrophiles and a relative and absolute augmentation of the leucocytes occur.

Rays from the mercury vapour lamp are said to bring about, according to Bermer, a diminution in the leucocytes and, especially, in the polynuclear neutrophiles, without any increase in the amount of haemoglobin or the number of the red blood cells.

Diminution or suppression of light acts more slowly on the state of the blood. Here, again, the findings are very different because at one time an increase in the number of the red cells and at another a diminution and at another, again, no appreciable change have been described.

Generally speaking, a diminution in the amount of haemoglobin has been prominently stated, more rarely an increase. The oligochromaemia found is not distinguishable from that of ordinary workpeople (Carozzi). Some writers, indeed, speak of occupational anaemia (among photographers: Agasse-Lafont and Heim), which has not been confirmed.

It has yet to be proved that a hyposiderosis and a polynucleosis (slight) is found among night workers. Ferrannini admits a diminution of the morphological elements and of the haemoglobin as the result of complete and prolonged darkness as well as from general troubles.

The polar night causes anaemia (Flugge and Rubner), but only when the hygienic conditions are bad; in the contrary case there is no appreciable change (Nansen and Blessing). Some explorers show, during the polar night, a pale colour inclining to greenish-yellow without corresponding spectroscopic and morphological changes in the blood.

Electricity

The application of galvanic, faradic, or sinusoidal electricity is said, according to Stephens, to bring about a diminution of the leucocytes, which is the more marked the greater the number of white cells (for example, in the case of leukaemia). This diminution (transitory) affects mainly the polynuclears and myelocytes (Veraguth, Seyderhelm). On the other hand, some authorities have found a leucocytosis with relative mononucleosis. Ajello (1927) has taken up again the study of the blood of animals subjected to electrocution and has found a leucocytosis with inversion of the formula. The electric current gives rise, in guinea-pigs, to an alteration of the leucocytic count recalling that due to adrenalin perhaps by intense excitation of the spine.

As to the physical changes brought about in the blood by electricity, Ajello brings out the fact of an increase in the viscosity of the blood (except in fatal cases of asphyxia), a definite increase in the sedimentation rate, more accentuated than that found in fatigue (Sereni). This rapid sedimentation of the red blood cells presenting a curve parallel to those of the increase in fibrinogen, of the diminution of the electric charge, of the lability of the protoplasmatic proteids and of the viscosity, would appear to be due to a colloidal dis-equilibrium, set up by the brusque and intense passage of the current as well as of the prolonged muscular tetanic contraction.

Milan); the treatise by Næseli on the blood; the corresponding articles of this Encyclopaedia on "Rontgen Ray Operators", "Radium and Radio-active Substances", etc.

Boatmen

Though, in effect, Ramazzini speaks in his treatise of the working conditions of sailors and boatmen as well as their pathological conditions, venereal diseases, skin diseases, derangement of the circulation — it is nevertheless true that
no further attention was bestowed on this category of workers until 1906, at the time when the question of the working conditions of boatmen and gondoliers was raised during the first International Congress on Occupational Diseases.

The working conditions of boatmen and gondoliers, compared to that of other categories of workers, were seen in quite a favourable light. The occupations in question are effected in the open air—in sunshine and sea air, which is remarkably free from micro-organisms, excepting in the case of boatmen working on rivers, lakes or canals. The total mortality rate is not excessive; on the contrary boatmen and workers in docks, the latter are chiefly found amongst unskilled workers and dockers engaged in unloading.

The occupations in general shown by the census in the United States was as follows: 1890, 20 per 1,000; 1900, 18.8 per 1,000; 1909, 22.9 per 1,000. Out of 14,469 cases treated in the seamen's hospitals in the United States during the year June 1913-June 1914 there were 2,579 cases of general or local illness with 25 deaths; 11,890 cases of illness with 431 deaths; and of 33,757 dispensary cases, 6,816 were wounds, 31,941 diseases (8,601 of which were venereal diseases), 7,219 respiratory diseases, 2,731 cases of rheumatism, 1,361 diseases of the nervous system, and 679 of the circulatory system.

Shukowsky, of Leningrad, published in 1925 a study on the health conditions of canal boatmen of the north west of Russia. Before the war the health service on this network of canals covering 6,478 versts was absolutely inadequate. Since 1918 the problem of protection of the workers in question has been made the subject of a detailed study. The total number of workers and employers reached, in 1924, 16,562, or 71,313 persons in all, including the members of their families.

STATISTICS

From statistics collected in Italy in 1899 it would appear that 45 per cent. of the sailors and boatmen in question lived to the age of over seventy. According to statistics showing the cause of death amongst seamen, assembled by the Ministry of Labour and Social Insurance in Italy for 1917, it is seen that of 2,860 deaths of seamen (including boatmen, fishermen, etc.) 198, or 6.3 per cent., were due to tuberculosis, as against a proportion of 1,749 per million for the general population.

The sickness statistics established in Naples, covering a group of 300 working boatmen, show the following figures:

<table>
<thead>
<tr>
<th>Disease</th>

</table>

The working day is often nine to ten hours long and holidays often represent additional work. The only rest periods are the outcome of bad weather, which reduces the work. Because of crowding is counteracted, or at least attenuated, by the long hours spent in the fresh air.

A study made by Lowey has proved that sea air does not accelerate nitric metabolism, but that the activity of the circulation and of radiation increases the respiratory exchange, exerting a favourable influence on the digestive system and thus on nutrition in general.

When boatmen are obliged to work in very highly populated districts or near the mouth of sewers they do not, of course, derive the usual benefit of open-air work. As regards boatmen engaged in the transport of cargo, their loads vary from 80-90 kg. for a single oarsman and 300-400 kg. for several oarsmen.

PATHOLOGY

An analysis of the data relating to the diseases of this occupational group has revealed that diseases of the digestive system are the most frequent, followed by diseases of the skin and of the subcutaneous tissue. Whilst the former affect especially boatmen and workers in docks, the latter are chiefly found amongst unskilled workers and dockers engaged in unloading.

The second group comprises diseases of the respiratory organs found to be more frequent amongst boatmen, clerks, and workers. Next in order come infectious diseases, accidents, and, lastly, diseases of the eyes, bones, and muscles.

According to Shukowsky, the morbidity of boatmen is typical; there exists...
in fact for each group of boatmen a clinical picture or a special group of diseases. These characteristics may be explained by the objective conditions and the work of the occupational group in question.

The report of Vitali at the 1906 Congress dealt with the gondoliers and boatmen of Venice whom he had studied for several years. He must specially recalled that the economic position of the gondoliers is better than that of the boatmen, who are often obliged to labour arduously in carrying and unloading weights. The abuse of alcohol is the more frequent the lower the economic standard, and Vitali was often able to discover during post-mortem examination on these workers the existence of chronic leptomeningitis characteristic of wine drinkers, whilst he only rarely met with cirrhosis of the liver as encountered by Viola and typical of alcoholic subjects. However that may be, the harm wrought by alcohol on the system is not very serious, for gondoliers and boatmen show a remarkably small number of cases of digestive and kidney disease.

While the post-mortem findings point to changes due to leptomeningitis and while cases of cerebral hemorrhage and softening of the brain, etc., are fairly frequent, these facts might lead to the conclusion that the harmful effect of alcohol tends to take effect on the central nervous system, favoured perhaps by the action of the sun’s rays on the head or by other physical agents.

On the other hand, respiratory diseases are of very frequent occurrence, taking the form of bronchitis, pleurisy, and pneumonia; cases of articular rheumatism are likewise abundant. Emphysema, favoured by the fairly heavy work, is most often independent of bronchial and pulmonary infections. Rheumatical forms of disease are easily explained by work in all weathers (wind, cold, rain, etc.), wading in water is often the cause of articular rheumatism of the knees and ankles.

Venetian statistics for the period 1903-1905 show 110 deaths amongst boatmen and 71 amongst gondoliers; cases of nephritis only amounted to 9, one affecting a worker of 17 and another a gondolier aged 36.

According to observations made by Vitali, there occurs early development of alteration of the blood vessels (arteries), which are noted even at the age of 25. Yet amongst the numerous cases of atheromatous endocarditis studied the number of patients suffering from aneurism was very small (two cases amongst 1,157 patients). Similarly, the 67 cases of cardiac disease generally took the form of lesions of the myocardium in old patients. Mortality rates due to these lesions for the period 1903-1905 only affected 5 men between 30 and 50 years of age. In the other 33 cases of this trouble (amongst the 181 deaths), the age was always over 50. This proves that the work in question, though onerous, does not prevent boatmen from attaining an advanced age.

Mortality from tuberculosis, which is relatively high in comparison with the general average for the town, is explained by the bad housing conditions and overcrowding, which to a great extent counteract the benefits of life in the open air.

Visual troubles are more or less common. Amongst 2,596 sailors Tschrug found 57 (2.45 per cent.) cases of myopia. Granular conjunctivitis is not unknown. On the other hand, syphilis and venereal diseases are fairly frequent.

Vitali found fairly frequently amongst old gondoliers a characteristic curvature of the spinal column: more or less marked cyphosis of the upper part of the dorsal region, with a compensation curve and sometimes a slight lateral deviation to the right of the lumbar region. However this may be, marked deformity of the skeleton is rarely met with, and it is only amongst very aged boatmen that more or less serious lesions of the thorax are found connected with an emphysematous state of the lungs. A special characteristic deformity has been noted amongst the boatmen of the Rhine and the Rhone, consisting of a depression under the right clavicle and due to the fact that the boatmen press their long boat-hook against this part when pushing upstream. It is possible that this fact may lead to reduced resistance at the point in question, facilitating the development of tubercular infection.

In southern countries continual exposure to strong sunlight often causes hyperaemia of the skin, with redness, swelling and even formation of boils on the less protected parts, followed by desquamation and pigmentation, which disappears gradually or on the contrary becomes permanent if the patient remains exposed to the sun.

To the ultra-violet rays are attributed certain serious lesions and the Xeroderma pigmentosum of Kaposi, which has been noted amongst sailors, together with certain neoplasms which sometimes develop into ulcerated epitheliomata with fatal termination. The salt water as well as the strong light causes, for example, the well-
known affection of the Iceland fishermen, known as "Iceland flowers". Callousities varying in site and in number are formed on the hands of the oarsmen by pressure of the oars. Accidents are of more or less rare occurrence, though contusions of the hands or feet are sometimes met with. It must further be remembered that boatmen engaged in transfer of cargoes run the risk of infection transmitted by merchandise, such as anthrax. In Great Britain since 1920 three cases of epitheliomatous ulceration amongst workers engaged on boat mending and due to tar have been notified.

Bones Industry

TECHNICAL DATA

Bones differentiated as to their form — long, short, and flat — are composed of a solid substance, slightly elastic, and formed from a nitrogenous organic substance (ossein) and a mineral substance. The ossein may be isolated by treating the bones with dilute hydrochloric acid. It is in the form of a porous elastic mass, from which glue is obtained (see article "Glues"). The inorganic matter is chiefly formed of tricalcic phosphate, the remaining part being various mineral salts (phosphate of magnesia, carbonate and fluoride of calcium, traces of chlorides and of alkaline sulphates). Bones contain, further, water and fats, and in the crude state (before cleaning flesh is also present adhering to the bones in greater or less quantities. The average composition of bones delivered at the factories is as follows: organic substances, 28 per cent. (with 3 to 4 per cent. of nitrogen); phosphate of calcium and magnesium, 45 per cent.; water, 12 per cent.; fat substances, 10 per cent.; carbonate of lime, sand, etc., 5 per cent. It must be stated that the fat content varies according to the kind and condition of the bones, amounting to 8 to 13 per cent. for bones in a fresh condition (ribs, shoulder-blades) and 20 per cent. for long bones.

In the case of bones which have been kept for a long time and are approaching putrefaction, the quantity and quality of fats become reduced.

There are utilised in industry either bones which are, so to speak, local products coming from slaughter houses or knackers' yards, or more often foreign products coming from India and China. The most highly valued bones are those of the horse and of deer. There should also be mentioned bones from kitchens, more or less full of fat, flesh, and nerves, besides exhumed bones which are of much less value, coming from animals which have died of disease and have remained interred for a certain time.

Bones are distinguished according to the ultimate purpose to which they are to be put — bones for the manufacture of such articles as toothbrushes, buttons, rosaries, and numerous other items (such as notes of a piano, engraving tools, handles of sticks and umbrellas, ironmongery articles, turned objects, etc.), bones for the making of glue and manure, including those which are not suitable for the above purposes as, well as the residues of those so used. They are employed in the preparation of glue, animal charcoal, bone ash, bone powder, and artificial manures.

In the slaughter houses and knackers' yards the carcases after stripping are submitted to boiling, which allows of recovery of the fats and bones. Mention should here be made of the bad habit of removing bones from carcases of animals that have been buried, a habit still engaged in in numerous slightly civilised countries.

As soon as they are received in bulk, the bones are generally sorted out in order to separate the long bones (bones of the foot and breast bones, etc., generally intended for the manufacture of objects) from the short or flat bones (bones of the skull and spine, used more particularly for other branches of manufacture).

The removal of fat from the bones must be effected before any treatment of the bones from an industrial point of view. It is carried out by means of three processes: in extraction by water (giving a 50 per cent. return) the bones are placed in perforated receptacles suspended above boilers, the water in which is brought to 100° C. by circulating steam, the grease melts and floats on the top; well as the acidified by sulphuric acid with a view to decomposing the fat soaps containing lime. On the other hand, the action of cold water on the bones enables oil to be obtained (see below). In extraction by steam (return, 75 per cent.) bones are placed in autoclaves into which steam at a pressure of two to three atmospheres is introduced. In extraction by hot water (return about 100 per cent.) or by other solvents (carbon tetrachloride), the recovery
of the fats is effected in special apparatus (series of extractors).

The fats obtained according to the first two processes (natural bone fat, clear bone fat obtained by water or by steam), refined particularly for the treatment of fresh bones or bones in good condition, are of a syrupy consistency and yellowish white colour, with a sebaceous and not too disagreeable odour. The fats obtained by the last process (extraction fats or fats obtained by benzine), especially reserved for old or putrefied bones, are semi-fluid, granular, and clear or brown in colour, with a disagreeable odour. Fats are refined by exposure to light or by treatment with sulphuric acid. They are used in the manufacture of soaps, carbonates, lubricants for vehicles, or in the preparation of bone oil obtained by extraction at a suitable temperature from bone fat of good quality. It is a liquid, yellowish oil without smell and is used for the production of delicate manures and in the hides and skins industry.

For the manufacture of toothbrushes the bones, after removal of fat and drying, are dipped in water and then subjected to the following operations: cutting on a circular saw, washing with water, and drying. The bones (an operation usually effected wet and therefore not liberating much dust) are cut out with a special milling tool, which gives to the brush its definite form; shaping and finishing by hand; cleaning and bleaching by means of hydrogen peroxide. After drying, the brushes are subjected to treatment with pumice stone or Meudon white or borax and water. Thereafter, the brushes are pierced with a series of holes in a horizontal and vertical direction. After insertion of the bristles the latter are cut withippers and the final polishing is applied by contact with cotton buffers dipped in stearin and Meudon white. The waste and the bone dust are used for manures.

Manufacture of buttons involves operations somewhat similar to the above (see article "Buttons"). The same is true of the manufacture of rosaries (cutting in a wet state by circular saw, cutting out the heads, engine-turning on lathe, and polishing in a closed apparatus).

For the manufacture of glue, see article "Glues".

In the manufacture of animal black, the compact bones are carefully cleaned and freed from fat, and, excepting those which have already served in the manufacture of glue as well as the waste from the manufacture of articles made from bone, are ground into small pieces, then calcined in iron or refractory cylinders or retorts connected with condensing apparatus which recovers the products liberated during distillation (volatile organic substances, ammonia, carbon dioxide, water, cyanoxygenc, amoniacal sodium magnesium cyanide, and phosphatic gases, and their derivatives). Calcination can also be effected in a closed apparatus which involves combustion of the volatile gases, but at the same time furnishes an animal black richer in carbon and possessing a greater decolorising activity. After cooling the bones are ground and put through a sieve. The powder obtained is black, opaque, inodorous, and composed of mineral substances thoroughly mixed with carbon coming from the organic matter. The animal black possesses a very great absorbent power for organic substances, especially for colouring agents (decolorising capacity) and for certain inorganic substances (salts of calcium or potassium). Animal charcoal which has been washed (deprived of mineral substances) is obtained by means of washing with hydrochloric acid (increase in the carbon content by dissolution of the mineral salts), thereafter washing in water and drying. Regenerated or revived animal charcoal is obtained by submitting animal black which has been spent to a series of operations: fermentation, washing by acids, alkalis, water, drying, and roasting. The animal charcoal may be regenerated as often as twenty times before becoming unfit for use, when it is finally utilised as manure. It is used in industry for decolorising and purifying sugary syrups, decolorising numerous organic chemical products, and clarifying oils. It is utilised also as a black pigment in oil colours, varnishes and inks.

Ivory black, obtained by calcining in a closed receptacle residues from ivory work, is placed on the market in the form of fine powder with a velvet finish in a paste or small conical pieces. It has been washed and recalcined and to which there is added a small quantity of chrome green in order to neutralise the slightly reddish colour of animal black. It is chiefly utilised for oil paint.

Bone ash, obtained by calcination of bones, contains 67 to 80 per cent. of calcium phosphate, carbonate of lime, sand and water (up to 15 per cent.), oxides of iron, magnesia and alumina, and is used for the manufacture of phosphorous, phosphates, and phosphated manures (as a constituent).

Bone powder is obtained by removing the fat, drying the bones, and grinding them into a fine powder. It contains 3 to 4 per cent. of nitrogen and 19 to 21 per cent. of phosphorous anhydride. In order to obtain a bone powder free from gelatine, the bones, after removal of fat, are treated for eliminating the gelatine by the action of superheated steam. This powder contains nitrogen (14 to 15 per cent.) and phosphorous anhydride (20 to 25 per cent.).

In the manufacture of artificial manures the bones which have first been treated for elimination of fats are ground in a closed apparatus, and the powder obtained is mixed with sulphuric acid in order to render soluble the insoluble phosphates.
SOURCES OF DANGER

Apart from the odour given off either from the storing of bones or in the course of certain operations (elimination of fat, manufacture of animal black, etc.), the sources of occupational injury are represented by the risk of infectious disease due to bones from animals which have died of contagious disease as well as by the presence of dust and steam given off in the course of certain processes.

The danger of infectious disease due to septic cuts or pricks is chiefly of importance in certain operations: recovery of bones from buried animal carcasses, handling, preparation, sorting, and especially transport. In India, for example, 100,000 tons of bone are transported annually, and the very action of placing these in sacks may contribute considerably to the propagation of infection.

Bone dusts are not very harmful, for except during polishing they are not in a fine state of subdivision, which limits their capacity for dispersion, and they lack the harmful asperities which are met with chiefly in the operations of sorting, crushing, grinding, and especially polishing. Research carried out in 1924 in Russia in a bone factory showed, in the air of a polishing room, an atmospheric content of dust amounting to 1,200 mmgr. per c.cm. These dusts were almost exclusively composed (90 to 100 per cent.) of organic substances.

Account must also be taken of products liberated or utilised in the course of the various operations: benzine and solvents used for elimination of fat, liberation of hydrochloric, hydrofluoric, fluosilicic acids, carbonic and sulphurous anhydrides and sulphuretted hydrogen, in the course of the preparation of artificial manures, etc.

STATISTICS

Few statistical data are available. There may be recalled the cases of anthrax in Great Britain in 1913-1914 among workers who were engaged on repairing sacks having contained bone powder coming from Bombay and Egypt. In Japan, out of 9 cases of anthrax notified from 1897 to 1918, 2 occurred in 1913 in the bone trade. In the province of Kagoshima, out of an annual average of 10 cases reported between 1908 and 1919, the majority were similarly due to manipulation of bones. In Germany in 1924 a case of anthrax was reported as having occurred during the manufacture of bone meal. In Great Britain and France cases of poisoning by petrol or benzol used for the elimination of fat during the manipulation of bones have been reported.

PATHOLOGY

Septic scratches may lead to inflamed wounds more or less serious or to specific infections, especially anthrax, which is the most serious and extensive occupational risk in the bone industry. It is necessary also to take into account the possibility of such infections as tuberculosis and glanders, especially in the operations carried out in knackers’ yards and during the preparation of the bones.

Bone dust, besides causing irritating infectious conditions affecting the hands (button-makers’ disease), leads to injury to the respiratory mucous membrane (bronchitis). In the Russian factory above referred to, of 278 workers examined 30 per cent. suffered from lesions of the respiratory system.

The products liberated or manipulated may produce injury varying according to their nature (see articles dealing with such products).

HYGIENE

In the majority of countries, establishments for storing bones, factories for producing animal charcoal, artificial manures, etc., are subject to the general measures of hygiene applied in regard to the liberation of disagreeable odours. Among these measures should be noted: compulsory elimination at a distance (see articles referred to, of 278 workers examined 30 per cent. suffered from lesions of the respiratory system.

The products liberated or manipulated may produce injury varying according to their nature (see articles dealing with such products).

In the majority of countries, establishments for storing bones, factories for producing animal charcoal, artificial manures, etc., are subject to the general measures of hygiene applied in regard to the liberation of disagreeable odours. Among these measures should be noted: compulsory elimination at a distance (see articles referred to, of 278 workers examined 30 per cent. suffered from lesions of the respiratory system.

The products liberated or manipulated may produce injury varying according to their nature (see articles dealing with such products).
of suspected material as demanded in certain countries and recommended by the Advisory Committee on Anthrax (London, 1922), the Correspondence Committee on Industrial Hygiene of the International Labour Office (1924), and the International Labour Conference at its 1924 Session. Disinfection, already realised in certain industrial operations for the treatment of bones, can be carried out either by heat (boiling for at least fifteen minutes in water at 100°C. or during four hours at least in water at 80°C.) or by the use of chemical products.

Recent research in Japan has revealed the efficiency of disinfection of bones by petrol to which para-formaldehyde has been added. In regard to the recovery of bones from the carcasses of buried animals, certain precautionary measures are essential, and certain countries (Austria) demand boiling during an hour or exposure to heat until the outer layers become carbonised. Special regulations should be provided to safeguard the health of the transport workers who are called on to handle bones.

The wetting of bones prior to manipulation, as well as the execution in a wet state of certain processes, reduce the liberation of dust, but the principal means of prophylaxis consist in an efficient system for dust removal especially in the course of operations such as grinding, piercing and polishing, the apparatus for which should be furnished with local dust exhaust devices. The dust thus assembled is of further commercial value as manure.

As a protection against products liberated or utilised in the course of the various operations engaged in, ordinary measures of prevention should be adopted according to the nature of these.

The transport of bones in closed receptacles and the cleansing and disinfection of these after usage, the wearing of special working clothes, personal cleanliness and the provision of first-aid are equally important as effective preventive measures.

Legislation

Women are excluded from work connected with bones as well as from the manufacture of animal charcoal in Argentina; youths under eighteen years of age in France when dust is given off freely in the workrooms; youths under sixteen in Belgium in establishments where upwards of 25 kg. of bones are handled in a fresh state, and they are likewise excluded from the process of sorting bones, from the manufacture of animal charcoal by carbonising bones and from the regeneration of the same product in workrooms where fat is extracted by means of benzene, and from manufacture of animal black. Youths under fifteen years of age and women under twenty-one are excluded in Japan from workshops where very abundant dust is given off. Youths under sixteen and women under twenty-one are excluded in Spain from treatment in a very dry state of bones involving exposure to dust, and likewise from the manufacture of animal charcoal (en cleaned and passing through sieves) by crushing the residues coming from dried distillation of bituminous schist. Boys under sixteen are excluded from animal charcoal factories in France when dust is given off freely in the workshops.

Special prescriptions relative to the importation of bones have been issued in Austria, France, Italy, New Zealand, Spain, etc. In New Zealand, bone manure may not be imported except from Australia and India, and only then if prepared in certain special factories submitted to authorised inspection.

Importation in special receptacles is compulsory in the United States. Disinfection of bones which have not been cleaned is compulsory in Australia, Canada and the United States. Disinfection of bones can be effected by steam (Austria) or by leaving them fifteen minutes in water at 74°C. (Canada, United States). In Spain, disinfection by sulphur treatment of bones which have not been cleaned and which come from Morocco is provided for by sulphur treatment under certain conditions.

Disinfection for any industrial manipulation is provided for in Austria (Order, 3 August 1918). In France, such disinfection is merely recommended (Decree of 13 October 1913). Compulsory removal of fat from bones is required in Germany (Order, 3 August 1918).

In the Netherlands, in virtue of the Decree of 1916, flooring which can be disinfected is required in workrooms; disinfection of workrooms is required in all cases where it is deemed necessary.

Pulmonary infections encountered among workers engaged on sawing or turning bones are subject to compulsory notification in the Netherlands, as well as cases of tetanus occurring in animal charcoal factories.

Compensation for septicaemia contracted in handling animal by-products is provided in the States of Queensland and Victoria. For anthrax, see that article.

Boots and Shoes (Manufacture of)

TECHNICAL DATA

The erection of large factories, some of which are indeed model, has brought about a revolution in the boot industry during the last thirty or forty years. But in many cases this industry, and especially that of boot repairing, is still carried on according to primitive methods which favour the development of injuries to health, having their origin in bad conditions of work. Moreover, the industrialisation of the manufacture has led to the adoption of certain methods which are sometimes more injurious than the old ones.

In making by hand, after having cut out with the aid of zinc templates the top of the boot, that is, the leg and the upper — parts which the bootmaker can to-day obtain in the trade ready cut to various sizes — the bootmaker joins these various pieces with the lining by sewing either by hand (home work) or machine stitching. The workman fixes on a wooden last the internal sole which he has cut out and softened; he puts the upper on to the last and fixes it provisionally with tacks. After having stitched together the welt, attaching together the edge of the upper and the lip of the marked sole along the whole length at the edge of the sole, he fills in the inside with glue. He beats the second or external sole of strong leather hard in order to bend it, and fastens it on to the first by stitching or nailing. He then puts on the heel; he rubs the sole and heel with a rasp and glass paper and polishes with blacking.

Hand work is very often done at home (on the Continent by concierges) under very precarious hygienic conditions. The work is undertaken by men who are often old, or by women, but rarely by children.

Machine work was at first limited to stitching uppers and cutting out leather by stamping machines. But to-day the technique is so perfected that it is possible to make boots by machinery with the welt sewn as by hand. All hand operations are now carried out mechanically by means of an extensive set of machines, each of which is so distinct that to make a pair of shoes it is necessary to have the collaboration of a hundred workers and eighty machines.

These operations comprise: preparation of the sides and uppers; stitching the uppers together; preparation of the soles; preparation of the heels; putting together the boots and finishing them.

Women are usually employed on machines which sew together the linings and the uppers. The machines for putting in the eyelets are often worked by men, whilst women work the button-hole machines. The uppers are fixed to the sides by men and women, the lightest work being reserved for the women.

The edges of the uppers, the toe caps, and the sides may be stuck together with cement, which often replaces stitching; it is generally composed of cellulose or celluloid dissolved in a hydrocarbon (see further on).

The process of finishing, which is distinctly heavy work, and entails exposure to the inhalation of dust consists in smoothing and polishing, done by means of a padded wheel often covered with glass-paper or coated with a polishing powder like carborundum. The polishing, blacking and cleaning are also done by machinery.

SOURCES or DANGERS

The use of lead and cadmium for the preparation of footwear in order to give it a metallic lustre, and of barium, magnesia, and talc to increase the density, explains the presence in the atmosphere of workshops of small quantities of these products, which are mixed with copper, kaolin, phosphorus, and sulphur, arising from the pulverisation of debris containing these substances.

The workmen who use cement are exposed to the inhalation of vapours from the fluids used to dissolve India-rubber, cellulose, or celluloid, such as methylic or denatured alcohol, benzol, benzine, acetone, acetate of amyl, chlorinated and brominated hydrocarbons of the methane series, or sulphide of carbon. The same vapours mean a health risk for workmen manipulating blacking materials in which turpentine is commonly replaced by substitutes. The pitch is kept liquid by a small flame, usually of gas, which may expose the workers to risks of poisoning by carbon monoxide.

Some machine processes in assembling cause exposure to heat. The workmen who do the assembling of the boot may be exposed to mercurial poisoning from the fact that for stitching the soles a paste of mercury is used to lubricate the machine (for example, Blake's machine).

The same poisoning has been noted in Russia among felt bootmakers (see article "Hair Cutting"), who almost all work at home.

Gerbis draws attention to the heavy work carried on by men who smooth and polish; they have to hold their work with both hands against the polishing wheel; this position requires close attention and a certain amount of force; it exposes the workers to strong vibration and causes on their hands troubles analogous to those found among men
who work with pneumatic hammers (see article "Pneumatic Tools").
Sardi (1921) had an opportunity of analysing the air of a boot factory, and especially the dust which came off the finishing machines when leather polishing. This dust, which was very fine, impalpable, and slightly brown, gave on analysis the following results: moisture (humidity at 100°) 17.85 per cent.; ash — mineral matter — 0.44; fatty matter (Soxhlet) 0.88; organic extractive matter — from tanning 3.94, not from tanning 1.88; matter coming from leather: tannin 3.14, and dermic matter 43.35.
The ash should always be examined for the presence of lead, copper, kaolin, barium, magnesium, talc, soda, phosphorus, sulphur, and cadmium, which enter into the different industrial operations. But in Sardi's case, lead, copper, and cadmium were not detected.

### STATISTICS

The bootmaking industry can be considered a comparatively healthy one, except as regards tuberculosis. Figures on this point are fairly accurate for some countries. Thus, for example, the National Union of Boot and Shoe Operatives of Great Britain gives the following figures for the period 1913-1923:

<table>
<thead>
<tr>
<th>Age groups</th>
<th>Tuberculosis</th>
<th>Diseases of the heart</th>
<th>Chronic nephritis</th>

According to the report of the medical officer of health of Northampton, a bootmaking centre in England, the rate for tuberculosis for workers in this industry was 2.59 per 1,000 against a normal average of 2.08 for the whole population.

A report of the British Medical Research Council (1915) deals with the distribution of tuberculosis in the boot and shoe trade. In Great Britain there has been found a fairly large incidence of respiratory affections and especially of tuberculosis (Greenwood and Tebb), which is twice as high as in industry well organised on modern lines. The factories are as a rule overcrowded and the work is carried on in a badly ventilated atmosphere. The workers are seated all the time.

In the United States, at Lynn, information as to 297 deaths has brought out the fact that in 21.9 per cent. of cases death was due to tuberculosis and in 10.1 to other respiratory diseases. At Brockton (Mass.), out of 167 deaths among shoemakers, 42, or 25.1 per cent., were due to tuberculosis, and 10.1 per cent. to other respiratory diseases. Statistics collected by Hoffmann (1900), dealing with 1,300 deaths, bring out that 371 (19.2 per cent.) were due to tuberculosis and 14.4 to other respiratory diseases. According to the census of 1909, out of 225,435 persons working in the bootmaking industry, men showed 642 days of sickness and women 932, or 0.68 and 0.41 respectively per 100 members. The most important causes of death were as follows:

According to facts collected by the Prudential Insurance Company on the basis of 347 deaths it was observed:

<table>

### PATHOLOGY

Malpositions assumed during work, the pressure of the last and tools against the thorax, and long periods of standing or sitting are favourable to the production of certain deformities of the vertebral column and of the thorax, especially in the case of predisposed persons. According to some authors, the characteristic deformity of shoemakers is a marked depression of the sternum and of the cartilaginous extremities of the ribs. This deformity, commonly called "shoemakers' thorax", is accompanied by a hyperpigmentation of the skin of this region with numerous comedones and a folliculitis due to contact with pitch and the pressure exercised by the last or boot.

Pichler (1919) studied the question of shoemakers' thorax and after a very careful examination of all patients attended by him—several hundred, who carried on this occupation—never found proof that this deformity of the thorax exists.

---

1 These rates are higher than the average rates for all occupations.
While it is true that Oriander quotes it as specific, it is also true that Ramazzini, when speaking of certain occupational deformities of the skeleton among shoemakers, does not refer to what is known under the name of “shoemakers’ thorax”. Eichhorst in seven years only found the condition six times among 14,000 patients, and then among persons who were not shoemakers. According to this clinician, this deformity is very rare and is the consequence of work carried out according to a special technique by an individual predisposed by constitutional weakness of the sternum.

Toldt has come across it twice, in a painter and a common labourer, and in examining very closely the method of work he found that the shoemakers rested the last or boot against the lower costal edge rather than against the sternum.

As regards certain stigmata of shoemakers, Oppenheim, as recently as 1924, summarised them as follows:

1. Callosities on the palm of the hand and on the joints at places where the hammer or shoemakers’ knife rests.

2. Callosities of the external side of the right thigh immediately above the patella, due to the pressure of the cramp-iron and the strap on the ischium, when the workman is seated on a low stool. It is due to multiple injuries causing a new connective tissue formation of the subcutaneous cells and of the deep layers of the skin. This trauma arises essentially from blows of the hammer when beating the leather.

3. Deformity in the form of a groove in the folds of the skin of the fingers caused by the repeated passage of tarred and waxed thread.

Shoemakers frequently show injuries on the hands and forearm. Thus, for instance, out of 134,500 Austrian shoemakers during the period 1896-1900 such injuries were found in 10.38 per cent.

A typical lesion is found on the right thigh and is due to the shoemaker’s knife when used for cutting leather. This lesion has been noted from the time of Hippocrates as characteristic of this occupation.

Cutting out soles by stamping machines is a most frequent cause of accidents: in fifty-four Austrian factories employing 14,508 full-time workers, between 1897 and 1900, 77 cases of compensated injuries were caused by these machines.

Among the temporary stigmata, Oppenheim mentions brown and black coloration of the hands and nails caused by handling pitch. Jadassohn and Stahr have recorded that tuberculous verruca cutis and cancer of the thumb are not uncommon among shoemakers. This last statement, however, does not find confirmation in British statistics, for all forms of skin cancer were rare in those statistics, and cases of cancer of the hand do not appear in England and Wales in the period 1910-1912 among shoemakers.

Cases of heart disease are, according to Sternberg, particularly common among German shoemakers. Unhealthy posture, as well as intemperate habits, favour venous stasis, from which arise cardiac diseases.

The frequency of diseases of the heart and vessels among shoemakers has been already noticed by Lancisi and Morgagni. In Austria, from 1900 to 1904 among 124,000 members of the Sickness Insurance Institute the number of cases of incapacity from circulatory diseases was 4,907, of which 765 occurred among shoemakers: 15.5 per cent., as against 10.8 for the average of other occupational classes.

The incidence of respiratory affections and tuberculous infection among shoemakers has been already referred to, and this is favoured on the one hand by work in confined surroundings, and on the other hand by the considerable quantity of dust (animal, vegetable and mineral) which is set free, especially in the workshops for putting together and finishing the soles and heels, for stitching, smoothing and polishing, where the workers are further exposed to vapours from solvents and mastics.

The Austrian experts have noticed the frequency of itch among the shoemaker apprentices of Vienna, which is helped by bad social and hygienic surroundings; the conditions are the same as for baker apprentices. Out of 2,155 cases of itch, 38.9 per cent. occurred among shoemakers. But this affection is much less common to-day. Out of 395 cases of tetanus described in 1896 by Frankl Hochwart, 179 affected shoemakers. It caused a tonic spasm of the muscles of the hands and wrists, which sometimes took on an epidemic character, attributed, according to Koelsch, to lack of cleanliness and to bad hygienic conditions. Cramp or spasm of the muscles of the forearm is also rather common. Cases of lead poisoning and even of buccal syphilis are described in the literature of the subject, as well as...
caries of the incisor teeth caused by the bad habit of holding tin tacks in the mouth and between the teeth.

Too prolonged standing may cause flat foot and varicose veins. The sitting posture causes constipation, haemorrhoids, and disorders of the circulation well known in the pelvic organs of women.

Hygiene

The hygiene of home work by the shoemaker raises the question of general measures of hygiene laid down for dwellings. In the large factory measures to ensure healthy conditions of work are concerned with great cleanliness of the workplace, general ventilation, adequate exhaust of dust and fumes, a high standard for the system of lighting, both natural and artificial, provision of means for personal cleanliness as well as of first aid. There is good reason to believe that the risks incurred in this industry may be banished by means of these hygienic measures. The National Union of Boot and Shoe Operatives of Great Britain has similarly raised the question of a minimum superficial space for each worker. In the closing rooms, where the different parts are sewn together, the women are seated very near to each other. In order to remedy this trouble, chairs for each person have been asked for. Similarly, regular control and efficient working of the system for the extraction of dust is demanded, since it may become operative for want of supervision. The floors should not be littered with waste and should be kept in a good condition of cleanliness. There should be protection for machine workers against the throwing off of bits and various waste. Closed receptacles, supplied with an automatic system of discharge, should be used for cements, the solvent of which gives off injurious fumes. It is advisable to supervise closely workshops where the less heavy work is carried on, or any work done by tuberculous convalescents still incapable of doing their ordinary work, this is in order to avoid their accepting badly paid work which may compromise their chances of recovery.

The State Board of Health of Massachusetts has obtained good results by frequent exhibitions of photographs, of specimens of harmless solvents, and of general measures of hygiene.

Legislation

As regards legislation, Quebec excludes boys of less than sixteen years and girls of less than eighteen years from polishing and mechanical abrasion with glass paper in boot factories. A resolution relating to safety in the boot industry was passed by the Finnish Government on 17 May 1927.

Brass

Brass is an alloy of copper with a base metal, usually zinc, but sometimes tin; it contains also varying quantities of other metals. Fine brass or red brass consists of two parts copper and one of zinc. However, as these two metals combine in practically all proportions, many alloys are possible. "Cheap yellow brass" is very rich in zinc.

The making of brass was known to the Phoenicians before Solomon's time. Pliny describes brass fumes. The copper of the Bible was probably brass.

To facilitate work on a lathe or file, lead is added (0.5-10 per cent.) to brass alloys.

Bronze is an alloy consisting of copper nine parts to tin one part. In the industry, however, red brass is very often styled "brass", although zinc is the other component instead of tin. Many metals and metalloids are added to brass and bronze to convey certain physical properties. Aluminium, copper, and German silver castings are other products.

Usually, in foundry work, scrap metal, consisting of all sorts and compositions of (non-ferrous) metals, makes up one-third or more of the alloy; then copper, zinc, or lead ingots are added, to arrive at an approximate composition. Consequently it will be seen that the brass manufacturing industry, or more properly the non-ferruginous metal-working trade, is engaged in the handling of large amounts of copper, zinc, and tin, while it must not be overlooked that lead, antimony, nickel, aluminium, cadmium, manganese, iron, phosphorus, arsenic, and sulphur may enter the brass crucible. In subsequent processes of cleansing, plating, and finishing, dangerous acids and cyanide solutions are used.

The possibility of continuously varying the percentage composition in these alloys suggests an analogy between an alloy and a solution, and A. Matthiessen (1860) applied the term "solidified solutions" to alloys, but modern work has shown that although alloys sometimes contain solid solutions, the solid alloy as a whole is often far more like a conglomerate rock than a uniform solution. If, however, after polishing a plane face on a bit or file, the new surface is examined with a microscope, the structure will be found to be a conglomerate of grains, each of which is an alloy of the complex nature of the solid solution.
a lens or a microscope, a complex pattern of at least two materials is found. The act of etching the surface has darkened the parts richest in copper, while the parts richest in tin remained white. The two ingredients revealed by this process are not pure copper and pure tin, but each material contains both metals. Higher magnification will show that each such portion is in itself a complex. The majority of alloys, when examined thus, prove to be complexes of two or more materials, and the patterns showing the distribution of these materials throughout the alloy are of a most varied character. The Latin word aes signifies either pure copper or bronze, not brass, but the Romans comprehended a brass compound of copper and zinc under the term aurichalcum, into which Pliny states that copper was converted by the aid of cadmia (a mineral of zinc).

There is every reason for believing that brass and zinc were already manufactured in Great Britain at the end of the sixteenth century.

When a small percentage of zinc is present, the colour of brass is reddish, as in tombac or red brass, which contains about 10 per cent. With about 20 per cent. the colour becomes more yellow, and a series of metals is obtained which simulate gold more or less closely; such are Dutch metal, Mannheim gold, similor, and Pinchbeck, the last deriving its name from a London clockmaker, Christopher Pinchbeck, who invented it in 1732. Ordinary brass contains about 30 per cent. of zinc, and when 40 per cent. is present, as in muntz — yellow or patent metal, invented by G. F. Muntz in 1832 — the colour becomes a full yellow. When the proportion of zinc is largely increased the colour becomes silver-white and finally grey. The limit of elasticity increases with the percentage of zinc, as also does the amount of elongation before fracture, the maximum occurring with 50 per cent. The tenacity increases with the proportion of zinc up to a maximum with 45 per cent.; then it decreases rapidly, and with 50 per cent. the metals are fragile. By varying the proportion between 30 and 43 per cent. a series of alloys may be prepared presenting very varied properties. The most malleable of the series has an elongation of about 60 per cent., with a tensile strength of 17.5 tons per square inch. Increase in the proportion of zinc gives higher tensile strength, accompanied, however, by a smaller percentage of elongation and a materially increased tendency to produce unsound castings. The quality of copper-zinc alloys is improved by the addition of a small quantity of iron, a fact of which advantage is taken in the production of Aich's metal and delta metal. Of the latter there are several varieties, modified in composition to suit different purposes. Some of them possess high tensile strength and ductility. They are remarkably resistant to corrosion by seawater, and are well suited for screw propellers as well as for pump-plungers, pistons, and glands. Heated to a dull red, delta metal becomes malleable and can be worked under the hammer, press, or stamps. By such treatment an ultimate tensile strength of 30 tons per square inch may be obtained, with an elongation of 32 per cent. in 2 inches and a contraction of area of 30 per cent.

In the arts brass is a most important and very used alloy. As compared with copper its superior hardness makes it wear better, while being more fusible it can be cast with greater facility. It is readily drawn into fine wire, and formed into rolled sheets and rods which are machined into a huge number of useful and ornamental articles. It is susceptible of a fine polish, but tarnishes with exposure to the air; the brilliancy of the surface can, however, be preserved if the metal is thoroughly cleaned by "dipping" in nitric acid and "lacquered" with a coating of varnish consisting of seed-lac dissolved in spirit.

**Industrial Operations**

The foundry workers receive the iron moulds containing zinc and fragments of copper generally in the proportion of two to three or one to three, as well as pieces of recoverable brass. The copper thus prepared is placed in crucibles, which are lowered into furnaces having a temperature of over 900°C. These furnaces are heated with coke. At present attempts are being made to introduce other types of furnaces less objectionable from a health point of view.

The crucibles are kept from fifty to sixty minutes in the furnace. When fusion is complete they are withdrawn from the furnace by using large tongs and the liquid brass is poured into the moulds or casts. Towards the end of the fusion, when the crucible is ready to be removed from the furnace, some zinc, almost pure, is added and in certain cases lead.

All the operations liberate metallic fumes, and in the absence of provisions for confining or removing them they fill the atmosphere and are inhaled by all those in the vicinity.

After casting, the foundrymen are relieved by other workers whose task it is to attend to the second firing required to render malleable the unduly thick brass plates, and thereafter to engage in rolling, finishing, and polishing.

Rough finishing is accomplished in several ways. One method is by chip-ting the rough castings with pneumatic chisels (an extremely noisy process), or by means of "sand blasting". In some of the factories the smaller castings are cleaned by hand with steel wire brushes.
on the final burnishing of brass is done sand an.d all rough surfaces. Other and the scrap iron removes the pieces of scrap iron and then rotated in brushes, or by being mixed with small or mechanical revolving wire brushes. The constant friction of the castings upon each other and the scrap iron removes the sand and all rough surfaces.

Polishing is usually accomplished by the employment of emery wheels, and the final burnishing of brass is done on "buffing wheels" covered with leather or circular pieces of cotton cloth. All the processes referred to are extremely dusty and expose the operatives to the inhalation of a conglomerate of dust with injuries to the eyes and respiratory mucous membrane.

Many castings are further subjected to plating, for which a cleansing dip in acid solutions is preparatory. Acid fumes arise when the castings are dipped into mixed mineral acids for cleansing them. A hood and vent pipe connected to a window or stack should be provided above the vats. Hot potash solutions stand usually in large vats. Breathing over them causes a dryness of the throat and an irritating cough. A low-hung hood with connection to proper stack should be suspended over such vats. Potassium cyanide is the compound used in these solutions, which are hot and stand in open vats. These should be provided with hoods and vent pipes if solutions are strong enough to emit the characteristic hydrocyanic odour. Also dipping the hands and arms in such solutions causes the intractable cyanide ulcers. Poison signs should be conspicuously displayed.

Final protection and gloss is given to castings, tubings, etc., by varnishing method. The vapours from the solvents used (wood alcohol, amyl acetate, benzine, etc.) cause irritation to the eyes, the respiratory tract, and occasionally the chronic forms of sickness usually ascribed to these poisons. If the hands are kept free of the solutions, the brushing and dipping processes are less harmful, but all spraying and atomising processes are deadly and demand cabinets with exhaust fans. The use of Japan mixed with wood alcohol and of Zapon lacquer (amy! acetate) as a final finish to chandeliers, art goods, etc., is injurious to the health and calls for special protection in the way of exhaust ventilation and steam-heated drying chambers.

**Sources of Risk**

The causes of injury are chiefly dust and fumes. It is well known that the fumes given off by the metal during melting, stirring and casting are the cause of "brassfounders' fever".

Other causes of injury are lead and antimony utilised in special processes; smoke liberated by oils, which causes nausea and vomiting; the high temperature, which causes abundant sweating and so exposes the workers to dangerous variations in temperature (opening of furnaces, stirring of metal, etc.), to rheumatism, fatigue, exhaustion and strain, lumbago; the gases escaping from the furnace (at the moment of opening the doors, to stir the casting): carbon monoxide, sulphur dioxide, etc.; the coal gas given off at the beginning of the process before the metal is molten; carbon monoxide, and carbon dioxide; thereafter the zinc commences to melt and carbon dioxide and zinc oxide fumes are given off. At the end of the operation of melting, when zinc in an almost pure state is poured into the crucible, a very perceptible liberation of oxide of zinc occurs in the form of tiny flakes, which rise in the air to fall again like a shower of snow. At the moment of casting oxide of zinc fumes are given off and when the crucible cools and when the crucible cools there is seen in it a white deposit, which is zinc oxide.

Besides injuries from the above causes account must likewise be taken of other products utilised in this industry: benzine, phosphorus, carbon disulphide, etc.

**Statistics**

In France the enquiry carried out by F. Heim de Balsac, Agasse-Lafont and Feil (1926) in a brassfoundry led to the collection of very interesting data in regard to brassfounders' fever.

Of 18 workers in the factory visited 13 had had fever. After leaving work, without experiencing discomfort the worker becomes stiff and prostrated; he suffers from trembling of the limbs, shivering, sometimes nausea, dyspnoea, headache. After going to bed he still shivers, his temperature varies round 38-40°C. After three or four hours the end of the attack is marked by abundant sweating. The following day, though a little stiff, the worker is usually able to follow his occupation.

Among the symptoms noted but not typical of these attacks may be mentioned cough, dyspnoea, asthmatic symptoms (due to irritation by zinc fumes), digestive derangements (nausea, vomiting). There has also been noted a sweetish taste in the mouth, which may however give place to a metallic taste.

Examination of the blood has shown that the red corpuscles are normal, a tendency to mononucleosis and usually a normal number of eosinophiles. This question receives more thorough consid-
eration in relation to etiology and pathogenesis in the article "Zinc".

Legge states that in Great Britain the mortality figures found in the Decennial Supplement of the Registrar-General (see later) show that there is undue incidence of phthisis among those employed in brass work. The industry is an extensive one in Birmingham where there are approximately 860 casting shops.

An enquiry carried out during the years 1910-1912 reveals a mortality percentage by tuberculosis for brass and bronze foundry workers higher than that for workers in other occupations. These figures correspond approximately to that found for the industries rated as the most dangerous.

The workers engaged in "dipping" are exposed to inhalation of acid fumes as well as to danger from standing on a wet floor. The polishers work in an atmosphere loaded with metallic and mineral dust containing particles of chalk from the polishing buffers, and they suffer from chronic bronchitis, tuberculosis, and pulmonary silicosis.

7 out of 1,200 brassfounders only 1 lived to be over sixty, and 3 workers only among those insured with the Brass Workers' Association were found to have survived the age limit fixed at fifty-five.

During the year 1921 the Registrar's death returns for the City of Birmingham showed that there were 508 deaths from pulmonary tuberculosis amongst males of fifteen years and upwards, and of this number 9.2 per cent. occurred among brassworkers, and in 1922 51 out of 508 deaths were recorded for these workers. These numbers were the largest for pulmonary tuberculosis associated with any occupation during the period, notwithstanding the fact that brass work, although an important section of the city's industry, was not the one giving employment to the largest number of persons.

G. B. Dixon reports in 1927 for Birmingham that the mortality percentage rate for pulmonary tuberculosis in that city for scissors makers is 34.5; file makers, 27.4; boot, shoe and slipper makers, 34.2; and brass and bronze workers, 27.3. The per capita mortality rate for pulmonary tuberculosis of males between the ages of twenty-five to sixty-five in England and Wales, for the period 1910-1912, was 17.8.

The comparative mortality figure for brassfounders (all causes) as given in the Registrar-General's Decennial Supplement (1921-1923 : England and Wales) is 1,530 and is exceeded by only fourteen other occupations. At the ages of sixteen to twenty their mortality is three times the average and it attains its maximum, 202 per cent., at the ages of thirty-five to forty-five. Mortality after sixty-five is not high, probably as a result of instability of occupation. The following are the mortality figures for various diseases, as given in the Supplement, for brass furnace men: influenza, 4 per cent. bronchitis (only exceeding grinders); phthisis, 164; cerebral haemorrhage, 168; myocardial disease, 156; bronchitis, 151; pneumonia, 178 (the highest figure for the 178 occupational groups dealt with); digestive diseases, 152. Mortality from accidents, 205.2 per cent., is above the average, and that from influenza, phthisis, pneumonia, respiratory disease in general, cerebral haemorrhage, and emaciation is more than double the average.

Guellman (1925) found among the Russian brassfounders that, in addition to well-known symptoms, the patients sometimes suffered from mydriasis, conjunctivitis, and a more or less marked irritation of the throat and of the face. He found sugar in the urine, also porphyrine and increased urobiline and indican.

In the United States the percentage mortality from tuberculosis among brass workers is twice that of iron and steel workers. Of 201 brass workers, 31.3 per cent. died of pulmonary tuberculosis, 9.4 per cent. of pneumonia, 8.4 per cent. of cancer, 8.0 per cent. of accidents. Hoffman's figures for 1897 to 1914 show 633 deaths, the consumption rate being 36.7 per cent. He says: "The proportionate mortality from pulmonary tuberculosis is decidedly excessive at all ages under sixty-five", and most so at fifteen to twenty-four, when out of every 100 deaths from all causes 58.2 per cent. are from consumption, against a normal expected proportion of 27 per cent. Insurance premiums on brassfounders, moulders, and casters are considerably above the usual rates. Those in finishing processes, including grinders and polishers, have more privileges or are not super-rated at all.

In Chicago the fact that 85 per cent. of 1,761 foundry workers were under forty years of age, and only 1 per cent. over fifty years was explained by employers as due to "slowing up", or incipient degeneration, and by workmen as gradual incapacitation from the inhalation of brass fumes and the strain of the work. The constant intake and elimination of unusual amounts of zinc and copper from the system, along with the repetition of brass chills or the constantly forced immobility to the same, are enough to cause degenerative diseases in themselves, even though the immediate affilictions above mentioned are overlooked. Chronic bronchitis or "asthma", emphysema, and pulmonary tuberculosis are very common. Observations invariably come under dyspepsia, "biliousness", and they are often icteroid. Pyorrhea alveolaris, carious teeth, gastro-enteritis, sallow complexion and anaemia, ill-nourishment, emaciation, and alcoholism, Bright's disease, nervous and heart diseases are all above the average.

In 1926 the enquiry conducted by A. Turner and R. Thompson into conditions in 22 brassfoundries employing 340 workers revealed that 33 to 64 per cent. had suffered from brassfounders' fever. An analysis of the air in workrooms showed that the air was contaminated by (a) fogging from manganese, iron and antimony lead, and naturally large quantities of zinc oxide.
Of the 212 workers medically examined, 102 exposed to inhalation of fumes of zinc oxide had had the fever; 68 likewise exposed had never had it; 42 had never been exposed to the fumes. In the first group, 26 per cent. had had one attack of fever per week; 11 per cent. two attacks per week, and 2 per cent. three attacks per week. On an average the sick workers had had from one attack per month to one or two attacks per annum.

These attacks occurred chiefly during the cold season or when the weather was heavy. It should be stated that 18 per cent. had grown acclimatised to the action of zinc oxide, and that the workers who had never suffered from the effects worked in well-ventilated workrooms.

**Pathology**

Wounds due to brass objects and similar alloys are of traumatic and infectious significance only. Brass dust (grinders, polishers, and buffers) does not produce brassfounders' ague, and has only the harmful effects of metallic dusts in general. The lead in the alloy-dust may produce its symptoms in very susceptible persons. Brass in any condition, short of the recent vaporous state of its components, produces no intoxication peculiar to itself, Ravogli has, however, reported a case of dermatitis with irritation, redness and oedema of the skin, affecting a brass polisher.

The essential health-hazard from brass is the inhalation of the metallic fumes. Analyses of brass fumes show:

Insignificant traces of arsenic, nickel, and manganese may be present, and Sigel found the chills where copper was absent in the fumes. Symptoms traceable to phosphorus in phosphor-bronze and manganese in manganese-bronze have rarely been reported. Antimony poisoning occurs, however, among type-metal refiners and molers, and dermatitis and "bbling nasotracheitis attacks the mouth. It distinguishes itself from "brass itch" and "zinc asthma" respectively. Braziers and hard-solder workers, especially where electric welding or the modern blow pipes (oxy-acetylene, oxy-hydrogen) are used, may suffer greatly from metal chills due to volatilisation of the alloys worked upon.

Brassfounders' ague is the only condition which can be recognised under this heading, and this is described under zinc, where it properly belongs. The condition was first mentioned by Thackrah in 1832, who considered it periodic because seasonal; the zinc factor was recognised by Blandet in 1845 and reaffirmed by Greenhow in 1862, Boudet, Sigel, etc. The earliest American cases were cited by Oppenheim in 1894, while later references are Moyer and Lavin, also Pietrowiecz (Chicago, 1904), Sicard (New York, 1905), Hayhurst (Illinois, 1910 and 1912), and Reisman and Bolis (1917), etc.

Brassfounders' ague, also called brass fever or brass chill, has many synonyms, while the workmen use cruder terms, such as "the shakes", "smelters' shakes", and "zinc chills". Brassfounders' ague is an acute, malaria-like sickness, which comes on in the foundrymen or any who are exposed to the vapours which arise from the metals. Practically all recent investigators regard it as an expression of acute zinc poisoning. Certain authorities, however, hold that the part played by zinc is only a secondary one, or even that it does not exist (Guérard, Lehmann, Laborde, Courtois-Suffit, Marcel Finard, etc.). These experts blame other factors such as excessive heat from the furnace, fatigue, dust (repeated poisonings, etc.).

Lehmann (1910) was the first to produce typical attacks of the "ague" with pure zinc fumes and prove the characteristic symptoms to be due to zinc fumes. He also recovered zinc in the urine (see article "Zinc"). The same or similar symptoms are now known to be caused by the breathing of the fumes of various metals, particularly copper, nickel, iron, cobalt, and cadmium.

Drinker and his collaborators point out that the metal fume fever reported in literature was generally caused by the inhalation of freshly formed zinc oxide fumes. It has long been thought that it did not exist until handled zinc oxide powder, but Hayhurst, and before him Bassett (1912), found same to occur in the bagrooms where zinc oxide was manufactured.

Koelsch, in July 1923, reported that attacks had been observed in cases in which inhalation of ordinary fumes caused in very finely divided powdered form had produced the characteristic symp-
toms, similar to those produced by
vapourisation. Drinker confirmed this
by experiencing, with a colleague, attacks of fever on inhaling finely
ground zinc oxide powder called "Kadox", particles of which were of
the order of 0.4 microns in size. The "Kadox" had been dried overnight at
110°C. and while still hot was blown into the cabinet where the experimentors
were located. Koelsch likewise reported
cases of the characteristic ague (metal
fume fever) from the inhalation of
finely divided copper oxide. Likewise,
inhalation of sprays of silver, copper,
zinc, mercury, iron, cobalt, and anti-
mony compounds may, according to
Koelsch, bring about a rise in tempera-
ture. Drinker mentions several in-
stances of similar symptoms from,
breathing fumes from burnt cadmium.
From this it may be seen that the
long-known brassfounders' ague is not
specifically due to this alloy, but is the
commonest of the metal fume fevers due
to the extensive use of zinc in an alloy
whose melting point is above the boil-
ing point of zinc.

HYGIENE

Strict provision is required in the
brass foundry, since much remains to be
done as regards the introduction of
measures of hygiene with a view to
eliminating risk of injury.

A well-arranged foundry is a roomy,
one-story building or top floor, with
impervious flooring, ceiling vents, large
windows, and unhampered by high
surrounding eminences. It is divided
into: furnace room, or at least partial
partitions providing adequate up-and-
down ventilation in the furnace area;
casting room, or an area covered by
broad spreading exhaust hoods beneath
which pouring is done; moulding shop,
where moulds are made (an entirely
cold process); core room, which has the
core-baking ovens well apart; chipping,
grinding and sand-blasting rooms,
equipped with exhaust ventilation,
where rough castings are smoothed
down; washing facilities consisting of a
sanitary trough, or small places, with
hot and cold water and an open outlet,
and, for larger places, a change house
or quarters provided with lockers on
one side for street clothes, shower baths
in the centre, and lockers or, better
still, ceiling hangers for work clothes
on the other side; sanitary drinking
water devices, preferably angle-stream
bubbling fountains; and luncheon quar-
ters.

Furthermore, prophylaxis consists in
selecting workmen through physical
examinations, regulating their habits
and work, then limiting, confining, or
removing the fumes. The adoption of
the electric furnace promises much in
this respect. Aerial dilution of the
fumes is insufficient. All furnace
areas and pouring areas should be pro-
vided with hoods and stacks to draw
off vapours. The Germans use flexible
exhaust ducts which are locally applied
during pouring. In addition, the found-
ry rooms need air-agitators (fans),
and arrangements for vertical (floor-
celling) ventilation which is most apt
to be efficient irrespective of weather
and wind conditions. The wearing of
respirators, although a help, will not
prevent the inhaling of gas or fumes.
The more zinc oxide in the air the
more imperatively are regulations and
improvements needed. Illumination is
often most inadequate in foundries due
to insufficient lighting units, absence of
reflectors, dirty windows and lamp
bulbs, and obstructions in general.

Certain precautions are necessary to
remove dangerous acid fumes (not-
ably nitrous fumes) which are evolved
in metal pickling, especially of brass,
articles for the purpose of giving them
a shiny or a dull surface. Severe and
even fatal poisoning has occurred in
this operation. An acid-proof earthen-
ware fan or an injector is necessary to
promote mechanical ventilation. The
fumes are caught in an absorption
tower filled with cone-shaped packing
material, through which water trickles
from a vessel placed at the top. The
fumes thus pass into solution in the
water which is changed when it
becomes unduly charged with acid.

LEGISLATION

In practically all progressive countries
there has been some legislation respecting
the brass industry. In Great Britain,
for the casting of brass, occupiers must pro-
vide proficient exhaust draught by means
either of (i) a tube attached to the pot,
or (ii) a fixed or movable hood over the
point where the casting takes place, or
(iii) which may be provided with a fan
in the upper part of the casting shop to
stimulate ventilation, or (iv) some other
effectual contrivance for the prompt re-
moval of the fumes from the casting shop
and preventing their diffusion therein.
A lavatory under cover, with sufficient
supply of clean towels, renewed daily,
and of soap and nail brushes, must be
provided, with wash troughs to allow
at least two feet for every five persons,
or a lavatory basin for every five persons.
No female is allowed to work in any
process whatever in any casting shop.
Employees are requested not to leave the
premises or to partake of food without
carefully washing the hands, and the em-
ployed person must use the apparatus provided for the removal of fumes. Injuries due to brass are subject to compulsory notification in parts of the United States (Connecticut, Massachusetts, Missouri, New Hampshire); in Pennsylvania, brassfounders' ague only; while compensation is compulsory in the States of Illinois, New York, and Ohio (see article "Zinc").

Breathing Apparatus, Respirators, Gas Masks

French: Appareils respiratoires (Appareils protecteurs des voies respiratoires, Masques).

German: Atmungsapparate, Gasschutzmasken, Respiratoren.

Italian: Maschere o Apparecchi contro i gas, le polvere.

Spanish: Mascaras respiratorias.

By the formula "apparatus for the protection of the respiratory tract" is to be understood apparatus designed to protect the individual either against every kind of poisoning or against every attack on the respiratory tract itself, such poisoning or attack originating in the physical-chemical composition of the inhaled air.

The determining causes of these risks are especially dust, smoke, fumes, and offensive or toxic gases.

The means taken to combat them are to place the respiratory tract out of their reach either by physical or chemical filtration of the air inhaled, or by complete isolation from the surrounding air, pure air being supplied through piping or from oxygen carried in a compressed or liquid form.

At the present time a large number of types of protecting apparatus are on the market: some of them are supposed to offer protection against all the risks together, others only against one or more of them; some are effective for an indefinite length of time, others only for a limited space of time.

Basing classification on the way in which they act (on which necessarily the efficacy of each one depends), the following categories can be distinguished:

1. Respirators acting by physical purification (filtration) of the inhaled air.
2. Anti-gas masks acting by chemical purification (to this category belong the army masks).
3. Masks with a flexible tube bringing pure air from a source situated outside the dangerous zone.
4. Self-contained breathing apparatus completely independent of the surroundings and themselves producing the air necessary for respiration.

GENERAL CHARACTERISTICS COMMON TO ALL APPARATUS

To be reliable for use, in spite of all unfavourable circumstances which can present themselves in industrial premises, all these forms of apparatus ought to conform to the following general conditions:

1. They should be strong, simple in construction and in application, and made of durable materials. They are intended to be used by men little accustomed to handle delicate articles; some of them have to be stored for a long time before they are required for use as occasion presents itself.

Despite that, they must be kept in a state of constant readiness, as otherwise they would afford a sense of false security and become a danger rather than a protection.

On the other hand they are frequently used for rescue work, notably in mines and under peculiarly difficult circumstances; the vital parts, therefore, must be protected against shock and external rubbing.

2. They should be sure to function, even in the hands of untrained or excitable persons.

3. They should be perfectly airtight in every part. Conditions 1 and 3 make it necessary to reduce to a
minimum the number of parts constructed of rubber and screw or other joints.

(4) They should have no part of the breathing circuit under a constant negative pressure which would give admission to poisonous gas or dust if the airtightness was not absolute.

(5) They should be easily worn: should not interfere with movements, nor cause any irritation of the skin at points of contact or fixation; leave the chest and arms free if possible; not make the wearer look ridiculous, because fear of ridicule accounts for so much of the opposition of workpeople towards wearing the protective appliances.

(6) They should allow of normal work without any effort or respiratory distress.

The wearer ought to be able to breathe quite freely; he ought not to feel that the air is insufficient, because then, unless particularly well trained in regard to this sensation, he will get agitated and so excited as to be led almost irrevocably to remove the apparatus.

(7) They should eliminate the requisite amount of the carbon dioxide in the expired air, thus presenting as small a dead space as possible.

The “dead space” is the volume inside the apparatus extending from the mouth of the wearer to the first valve and the contents of which, exhaled at each respiration, is filled again at the following inspiration. It ought not to be more than 250 cubic centimetres.

(8) They should be easy to maintain and inspect as well as being readily disinfected.

(9) Every apparatus equipped with a mouth-piece ought to be provided with a saliva trap and a nose clip. The saliva trap should be impossible to turn upside down, that is to say, it should not allow the external air to gain re-entry.

DIFFERENT TYPES AND THEIR CHARACTERISTICS

Respirators

Respirators are essentially mechanical filters, use of which is indicated in dusty processes.

As they are useless against fumes and poisonous gases, they can never take the place of anti-gas masks nor of breathing apparatus.

When the air contains poisonous dust in a very fine state of subdivision the respirator is insufficient as a protection, because a part of the dust can be drawn in by the air as if passes through the filtering medium. According to Winslow, this type of respirator cannot be regarded as a type that is both efficient and comfortable to wear.

In addition to the general principles laid down, a good respirator should fulfil the following conditions: it should be light and supple; permit the wearing of goggles; if possible allow the wearer to talk; present as wide a filtering surface as possible; with too small a surface for the air to pass through too rapidly and aspiration draw an excessive quantity of dust into the respirator.

In the choice of the filtering media it should be borne in mind that, even with equal porosity, all substances do not have the same property of retaining dust; some which resist the passage of air markedly allow dust to pass through readily, while others which allow the air to pass through freely stop dust well.

A simple and very effective respirator can be made of a strip of muslin about 35 cm. long and 12 to 13 cm. wide (33 x 5 ins.), using absorbent cotton wool as the filtering medium.

Respirators of this kind advantageously replace handkerchiefs, often dirty, so frequently used by workpeople who have not, or will not use, the special kind provided. They are easy and cheap to make in large quantities, and the cotton, when it becomes moist so as to interfere with breathing, can be readily replaced.

Further, and it is a remarkable fact, workpeople show the least repugnance to these improvised means.

The respirators on the market are generally composed of a mask covering the nose, mouth and chin, attached to the neck and top of the head with elastic bands in which is inserted, in front of the mouth, the filtering medium. Some masks cover the face of the wearer and include goggles. Some are provided with one or two valves. They all look when worn rather like a snout and this is one of the reasons why they are regarded with disfavour by the workpeople. Other objections are that they do not always adapt themselves to the face, are not quite airtight, increase perspiration which they do not absorb and so are inclined to set up irritation of the skin; they
hinder chewing, talking and spitting, and are not always supplied in sufficient number to provide each worker with an individual mask for his sole use.

The durability of a respirator is limited to that of the filter. When this is covered with dust so as to occlude most of the pores, it becomes unusable and must be replaced. The wearer knows when this occurs by the difficulty of breathing, taste, and the smell of the air inhaled. As this does not take place all at once, there is time enough to change it without inconvenience.

**Anti-Gas Masks**

These are filters acting at the same time both mechanically and chemically, or sometimes only mechanically. In this latter capacity they belong to the category of respirators. Certain gases when mixed with air have the property of being retained like fine dust (without the intervention of any chemical action) by filtering materials which allow the air to pass. This fact can be explained by the vibratory movements of the gaseous molecules in suspension in the air, movements so rapid that they allow of the contact of molecules with the walls of the pores during the very short time the air is passing through the filters. If a filtering material of very spongy surface be chosen, a veritable aspiration and fixation of the gaseous molecules takes place. The prototype of this material is wood charcoal usually employed in apparatus protecting against organic vapours. In the case of gases very readily acted on addition is made of chemical substances to the filters which convert the gases into harmless compounds.

Finally, use of appropriate catalysers causes oxidation at ordinary temperatures of certain gases as, e.g. carbon monoxide which otherwise only oxidises at a high temperature. When oxidised these gases become, if not harmless, at any rate less toxic or rendered capable of neutralisation subsequently by chemical reaction.

In the case of some vapours the time taken in passing through a filter, when compared with that of a breath, is insufficient to fix the molecules. It is possible in such cases to use filters the amount of air contained in which

**Conditions of efficiency**

- The canister should keep back at least 95 per cent. of the tobacco smoke at the end of the fifth minute.
- The canister should keep back at least 50 per cent. of the tobacco smoke at the end of the fifth minute.
- The men should feel no irritation in the respiratory passages or eyes.

**Tests similar to the above modified as required.**

- AB, AC, etc. (combinations of gases).
- Must satisfy separately the tests for each one of the gases in the combination.

**H. Universal canister.**

- The canisters are tested under the same conditions as the types A, B, C, D, and E and should last the same time as each of these types separately.
is equivalent to an average inspiratory effort and the mask is equipped with automatic valves. The expired air does not pass through the filter, but is emitted directly to the outside. The air to be inspired remains in the filter during expiration; the time thus gained may suffice to precipitate the toxic molecules.

Anti-gas masks can only be used on the express condition that the surrounding air contains, after passing through the filter, sufficient oxygen (at least 16 per cent.), a condition also necessary for respirators.

This can be put to the proof by means of a lighted safety lamp. The life of an anti-gas mask is limited by that of the filter.

If this is purely mechanical the life depends on the capacity for absorption of the wood charcoal or other filtration material; if it is chemical it depends on the amount of the quantity of the reagent used. If it is a question of catalytic action the life, theoretically unlimited, is limited by the fact that the catalysers, all of which are hygroscopic, become inactive when they are saturated with moisture.

In every case, however, the exhaustion of the filters is gradual, thus allowing the wearer of the mask to become aware of the fact in time by the taste or smell of the air breathed. For gases without taste or smell such as carbon monoxide a method of indicating when exhaustion is approaching is necessary.

Anti-gas masks essentially consist of:

(a) the mask properly so-called, analogous to that of respirators sold on the market with protection for the eyes;
(b) the filtering medium fixed directly to the mask or separated from it;
(c) possibly a flexible tube connecting the filter to the mask;
(d) valves.

These masks, as is well known, can be equipped with filtering material active against one or several gases, and even against all of them. With an equal volume the filter will obviously not last so long in the latter case. When the atmosphere necessitating the use of masks is constantly vitiated by the same gas or the same series of gases, it is preferable to get the kind of filter specially designed for the particular gases or gases, omitting the others. If, in certain industries, more than one kind of canister filter has to be kept in readiness, every precaution must be taken to make a mistake impossible in choosing the right one for a given purpose. The simplest way of securing this is to paint the different canisters in different colours. If this plan were adopted an international standardisation of all colours to be used would be necessary. To protect against carbon monoxide by means of a canister filter use is made in the United States of a catalyser ("Hopcalite") which is a mixture of copper oxide, manganese dioxide, and sometimes of silver and cobalt. On contact with the oxide the carbon monoxide in the air is oxidised with carbon dioxide. A type of mask, styled "Universal", for protection against all kinds of gases and fumes present in the air is the "All-Service Mask" tested by the Mine Safety Appliances Company of Pittsburg, Pa., and approved (No. 1403) by the Bureau of Mines in July 1924. The gases and fumes pass through successively the following series of substances: activated wood charcoal impregnated with copper sulphate; wood charcoal activated but not impregnated; cotton wool contained in a metal frame: anhydrous calcium chloride; "Hopcalite" (a mixture specially prepared of copper oxide and manganese dioxide); anhydrous calcium chloride: cotton wool in a metallic frame.

This type of mask would offer protection against the following toxic gases:

(a) Acid gases (such as chlorine, formic acid, hydrocyanic acid, sulphur dioxide), by chemical reaction with the caustic soda.

(b) Organic vapours (such as acetone, aniline, benzene, chloroform, formaldehyde, petrol, etc.), by absorption in the impregnated layer of wood charcoal and by the same unimpregnated material.

(c) Ammonia, by absorption in the layer of charcoal, and reaction with the copper sulphate.

(d) Carbon monoxide, by oxidation with the oxygen of the air which is converted into carbon dioxide as a result of the catalytic effect of the "Hopcalite".

(e) Smoke, mists, dusts, etc., by the filtering action of cotton wool.

Chloride of calcium is inserted to eliminate the water vapour present in the air due to the catalytic action of the hopcalite.
In France the G. C. canister utilizes not a catalyst but a reagent, a mixture of iodic anhydride and sulphuric acid disposed superficially on a granular support. The reaction liberates iodine; at the end of the first reaction oxolith gives a hint when exhaustion is near.

The life of the two types of canister is limited, and neither taste nor smell is formed, which fixes the iodine and carbon dioxide and furnishes at the same time oxygen to prevent the vitiation of air in the canister.

It is desirable, therefore, failing a certain indicator, to adopt a given time for its use below at least 50 per cent. of the theoretic life of each canister.
Further, even this precaution only confers absolute safety in the case of new canisters or those kept in storage under vigilant supervision, away from moisture which is greatly to be feared if it reaches even a moderate degree both catalyst and reagent are rendered inert.

Thus it is seen that the use of anti-gas masks against carbon monoxide, in their present state of manufacture, have to conform to very severe restrictions not always capable of being complied with under the local conditions where they are most needed (mines and blast furnaces, etc.). Table I enumerates the various gases and the corresponding canisters to be used as protection against them. The combination of various filtering media may enable polyvalent masks to be employed suitable under the most varied circumstances.

Anti-gas masks are efficacious, simple, light, convenient, and are not much in the way. Their storage and preservation is generally easy, provided some elementary precautions are observed. They do not contain any delicate parts and their use only requires brief instructions and training of the personnel.

These canisters, however, just as in the case of respirators, cannot be used in an atmosphere saturated with toxic gases.

Their life is practically limited by the life of the filtering medium since replacing one that has become exhausted can hardly ever be effected except in fresh air.

When gases are present having neither taste nor smell, exhaustion of the canister, which is not readily appreciated constitutes a danger. Experiments with canister respirators of German and English make have also been conducted in the Netherlands (see the Inspectors of Factories Report for 1924, page 287).

**Masks with Flexible Piping (Hose Pipe) Extending to Fresh Air Outside**

This form of apparatus isolates the wearer completely from the surrounding air and connects him, by means of a flexible tube, with a source of pure air some distance away.

They are usually worked with a mechanical bellows or blower arrangement so as to overcome internal resistance in the piping which would be difficult to overcome by mere aspiration from the lungs. To pump air in is really not necessary, provided the length of the piping is not more than 30 metres, with an internal diameter of at least two centimetres.

The apparatus consists essentially of a mask with goggles and valves, a flexible pipe connected at one end with the mask, and at the other with the air intake or bellows. The length of the piping may reach 100 metres.

When several pieces of piping are joined up end to end, special care must be taken to avoid any chance disconnection.

This apparatus enables the wearer to penetrate into any atmosphere, however poor it may be in oxygen. The life is unlimited, they are simple to maintain, and easy to look after; there are very few delicate parts and they can be used with very slight previous instruction.

Their good working can be guaranteed without the need for entry into the vitiated atmosphere.

Work people like them better than any other kind of breathing apparatus.

Their range of action, however, is limited by the length of the piping which, if more than 10 metres, becomes cumbersome and hinders the workman at his job.

**Self-Contained Oxygen Breathing Apparatus**

The necessity of penetrating vitiated atmospheres, where neither anti-gas masks nor flexible piping apparatus would suffice, has led to the invention of apparatus which will completely isolate the wearer from the surrounding atmosphere and themselves provide the means of respiration.

Of such apparatus there are several types, but they all depend on the same principle; to provide a respiratory circuit independent of the external air, placing in series the lungs and a purifier or regenerator which removes the carbonic acid gas expired. This circuit is connected at the one end with a breathing bag, and at the other with a bottle of compressed oxygen which provides the expired air deprived of its carbon dioxide content with the necessary amount of oxygen.

Apart from details of construction the difference between the various types of apparatus consists essentially in the manner in which the oxygen feed is arranged.

Thus distinction is made between:

1. apparatus in which the feed is automatically and solely regulated by the call made by the lungs;
(2) apparatus with a constant feed with or without additional supply directly under the control of the wearer;

(3) apparatus where the two kinds of feed are combined.

The first method which would appear to be the most logical requires the use of very pure oxygen (99 per cent.) under pain of exposing the wearer of the apparatus to the danger of excess of nitrogen because this gas is not absorbed either by the lungs or the purifier. If it is present in the oxygen it must remain in the circuit of the apparatus and finally accumulates to such an extent as to occupy the whole of the space, thus rendering the air irrespirable. As it is impossible to find commercial oxygen sufficiently pure, it is necessary to flush out con-

---

Fig. 20 - "McCaa" Breathing Apparatus (Bureau of Mines, Department of Commerce, U.S.A.).
BREATHING APPARATUS

9

The second procedure does not seem so apt, providing as it actually does a constant supply of oxygen for the requirements of breathing which are essentially variable. Thus it comes about that if the consumption of the wearer is less than the supply a certain amount must be lost irretrievably, and if the amount is more than he has an insufficient supply of oxygen and finds his breathing immediately embarrassed and himself obliged to renounce his effort. This might result in very serious consequences if, for example, mine rescue work was in question. This defect is got over by doubling the fixed quota by means placed under the control of the wearer. He must thus intervene himself to increase the supply of oxygen as soon as he feels he wants it, which is a tiresome matter for him to do just at the moment, perhaps, when, without any resistance, the slightest hindrance, he should be devoting all his energy and his two hands to the work before him.

Some apparatus carry an "injector" or nozzle with an orifice of capillary size through which oxygen from the bottle is discharged into the circuit. The suction produced by this escape of oxygen makes a narrow orifice increases the circulation of air in the apparatus, assists in overcoming internal resistance, and reduces the work thrown on the lungs. But the device is not to be recommended because it offers two grave objections: it creates a permanent negative pressure in a part of the circuit and it gets choked up easily.

In apparatus of the third kind the feed, regulated by the requirements of the lungs, only comes into play when the fixed quota becomes insufficient.

Apart from the aforementioned considerations the self-contained breathing apparatus ought to conform to the following particular requirements:

(1) The quantity of oxygen furnished ought always to correspond with the needs of the wearer, and the total quantity necessary ought always to be at his disposal. The reducing valve in connection with the cylinders for a constant supply ought to be regulated for a minimum supply of two litres a minute.

Apparatus supplying oxygen at a fixed rate ought to be provided with relief valve allowing an additional supply at the wish of the wearer. Such a by-pass is necessary on all apparatus.

In apparatus supplying automatically the quantity the lungs require, the supply ought to adapt itself immediately to the wearer's needs.

(2) The purifying substance should absorb the carbon dioxide from the expired air so completely that the air inhaled should never contain more than 2 per cent. The average percentage during a two hours' employment should not exceed one per cent.

(3) The respiratory surface should have nothing in it to interfere with free breathing; the whole internal resistance should not exceed 50 mm. of water.

(4) The temperature of the inhaled air should not exceed by 20° C. that of the temperature outside.

(5) The minimum life, without recharging, should be two hours.

(6) The weight of the complete apparatus when ready to be worn should not exceed 20 kg. It should be as light around and durable construction will permit.

(7) Apparatus with automatic supply to suit the respiratory demands ought to be provided with a relief device to prevent excess of nitrogen in the air breathed.

(8) Every apparatus ought to be provided with a manometer showing all the time the pressure of oxygen and the time it will last. The valve controlling the supply of oxygen to the pressure gauge ought to be readily under the control of the wearer and independent of the respiratory circuit.

(9) The main valve of the oxygen cylinders ought to be able to be fixed in an open position so that the wearer cannot shut it off entirely and in such a way that it cannot become accidently closed.

(10) The oxygen should be present to the extent of 96 per cent., contain no hydrogen, not more than 2 per cent. nitrogen, and with traces only of argon.

(11) The total minimum capacity of the breathing bags should be 5 litres when in one compartment and 8 litres when in two.

For apparatus intended to be used in the presence of petrol vapours or fumes from a gas generator, the following supplementary condition applies: the rubberised lining of the breathing bag is permeable to such fumes, and the protection afforded will not last for two hours unless the thickness of the layer of rubber is at least one-sixteenth of an inch (about 1.5 mm.). This minimum
should therefore be observed strictly. Apparatus which does not fulfil this condition ought not to be used for more than ten minutes, and the breathing bag afterwards aerated for a day — an operation to be affected after every occasion on which the apparatus has been used for no matter how long or short a period.

A self-contained oxygen breathing apparatus enables any atmosphere to be entered irrespective of how poor in oxygen it may be. Such appliances have a wide range of action; they enable a man to remain away from a respirable atmosphere for a period of three hours at a maximum, the distance being limited only by the life of the apparatus. But their construction is complicated and sometimes delicate, so that in spite of every care in manufacture their action is somewhat fortuitous. They require careful upkeep and selected and well-trained personnel. As they are almost exclusively used for rescue work in mines, objections to their use can be overcome by centralising all the material equipment and personnel in centralised rescue stations for mining districts. At these stations selection and training of the rescue parties can be suitably conducted, and maintenance and verification of the apparatus properly supervised.

Apparatus Supplied by Liquid Oxygen

In Great Britain use of two or three kinds of liquid-air apparatus provided with purifying material has been approved by the Mines Department. The advantages claimed for this type over those acting by compressed oxygen are the freshness of the air and the lightness of the apparatus. But they necessitate stations for the liquefaction of the air either at the mine itself or at the rescue station. Their use therefore is justified where liquid air is used for other purposes.

Such apparatus ought to allow of increase or diminution of the rapidity of evaporation, fixation of the oxygen by an absorbent to avoid waste when the receptacle is reversed, warming to a sufficient temperature the air produced by evaporation, prevention of excess of pressure in the breathing bag and elimination of impurities from the oxygen. Table II shows the characteristics of some of these forms of apparatus actually in use in different countries.

Choice of Apparatus

The following principles should be observed in choosing protective appliances:
(1) Secure separately protection against each risk anticipated, and do not attempt to combine in one and the same apparatus protection against several different risks, unless all of them should be present simultaneously in the same working area.

(2) Efficiency and safety being equal give the preference to the apparatus the least complicated in construction and the easiest to maintain in good condition.

The advantages and disadvantages described in the case of different makes will readily suggest the right type to choose.

RECEPTION AND CONTROL

When any apparatus is received it should undergo detailed testing to see if it conforms to the general and particular conditions enumerated above and if it provides complete protection under the circumstances in which it is to be used.

The best way to test an apparatus is to put it on and then to carry out methodically work of varied intensity during the period of time for which it has been guaranteed by the maker. In this way good indication can be obtained of the fitting, internal resistance, ease of respiration, freedom of movement and (for self-contained oxygen apparatus) of the oxygen supply and neutralisation of the carbonic acid gas. This test, general enough in the case of respirators, does not suffice for the other kinds of apparatus. Here examination of the diagram supplied and theoretical study of the respiratory circuit will reveal whether the general and particular conditions described above have been realised, and then detailed examination of the apparatus and all its constituent parts will show on subsequent tests whether all the other conditions have been fulfilled.

This examination will be directed spe-
comfort in wearing the apparatus (how the pieces fit to the face, ease in breathing, freedom of movement).

To test under pressure close all the openings except the breathing tubes, connect the expiratory tube to a water pressure gauge and aspirate until a negative pressure of 20 to 25 cm. of water is recorded; close this tube by a clip. Airtightness may be regarded as good if the negative pressure does not go down by more than two cm. of water in half an hour.

For apparatus of the last three types airtightness can also be verified in a gas chamber containing an atmosphere of 1 per cent. sulphur dioxide in which two men practise wearing the apparatus.

Resistance to breathing can be measured by a water pressure gauge with branch to the breathing circuit.

For a circulation of air of 85 litres per minute the total resistance in canister respirators and respirators with flexible tubing ought not to exceed 150 mm.; the resistance of the filtering medium alone should not exceed 100 mm.

In self-contained oxygen breathing apparatus the total internal resistance should not exceed 50 mm.

**Test of the Filtering Material**

This test requires to be done under exact laboratory conditions.

For respirators and anti-gas masks it will suffice, after having put the mask on carefully, to close the orifice for entry of air, with the palm of the hand, and aspirate deeply; the vacuum created in the apparatus makes the mask stick to the face of the wearer. If it is quite airtight it should keep so for at least fifteen seconds.

In the case of respirators with flexible tubing depending on pure air supply outside the vitiated atmosphere, the test for airtightness is less important if use is made of a bellows or blower fan.

For self-contained oxygen breathing apparatus the test should be carried out under pressure or under a negative pressure, but the thing to test for is airtightness against negative pressure. To test under pressure close the free ends of the breathing tubes and close the safety valve of the bag, allow oxygen to flow in, let the breathing bag fill, then close the inlet for oxygen, put pressure on the bag with the hand and if this resists and does not empty airtightness is good.

**Fig. 2a. — Diagram of a self-contained oxygen breathing apparatus:**

- E = Mouthpiece.
- O = Oxygen bottle.
- R = Regenerator.
- S = Breathing bag.

**Test for Airtightness**

The different filtering materials may be classified in eight categories:

**Type A.** Acid gases, such as: carbon dioxide, chlorine, phosgene, sulphur dioxide, etc.

**Type B.** Organic vapours, such as: acetone, alcohol, benzine, carbon bisulphide, carbon tetra-chloride, etc.
Type C. — Ammonia.
Type D. — Carbon monoxide.
Type E. — Dusts, fumes, and smoke.
Type F. — Other special gases taken individually.
Type AB, AC, etc. — Combinations of two or more of the preceding types.
Type H or Universal. — Combination of all the preceding types.

The conditions of the efficiency test differ according to the type of the filtering medium. Table III gives the standard conditions laid down by the United States Bureau of Mines, which can be taken as a guide.

To verify the chemical stability two of the canisters are subjected to each of the following tests:

(a) Pass through the filter, at the rate of 64 litres a minute for six hours at room temperature, air free of carbon dioxide, and with 25 per cent. relative humidity. Let the canisters be then submitted to the efficiency test, which ought to give a life of at least 10 minutes.

(b) Carry out the same test with air containing 85 per cent. relative humidity. It is a good plan to subject the canister to a severe test at maximum concentration; the passage through it a current of air containing 1 per cent. of the gas at the rate of 64 litres a minute, the other conditions of the test being for humidity: 50 per cent.; gas used: for type A, phosgene; for type B, carbon tetrachloride; for types C, D, E, the special gas in question; for the polyvalent canisters, several of the above gases.

Concentration: 1 per cent. in volume; number of canisters tested: 2 for each gas.

The life of the canister ought to be five minutes at least for every gas except carbon monoxide, which should be at least 15 minutes.

Test of the Supply of Air or Oxygen

For apparatus with flexible tubing test is made as to whether the bellows or blower fan can supply at least 60 to 70 litres a minute. The wearer of the mask ought to be able to breathe without trouble through the bellows at rest.

To test the supply available in self-contained oxygen breathing apparatus, it is sufficient if the feed is fixed at a definite rate, and the capacity of the breathing bag is known, to determine by means of a stop-watch the time it takes to get filled; what is actually found should correspond to the claim made by the maker.

If the feed is worked automatically, then the relief valve for the automatic release of oxygen is inspected to see if it is performing its work properly when the breathing bag reaches the limit stated by the maker. The working of the safety supply and relief must next be tested.

The supply of oxygen ought to allow an average consumption of 2 litres per minute.

To last two hours the cylinder ought to contain at least 1.6 litres under 150 atmospheres or 2 litres under 120 atmospheres.

Testing the Purifying Substance

Verification is best made in the first instance by weighing, and if necessary by chemical test of the power of absorption of the regenerating material, bearing in mind that it ought to last 50 per cent. longer than the cylinder of oxygen.

The mean respiratory quotient should be taken as equal to 1, that is to say, the average relation of the quantity of oxygen inhaled to the quantity of carbonic acid gas exhaled. For a total consumption of 240 litres of oxygen as much as 240 plus 50 per cent., that is, 360 litres of carbon dioxide should be taken or 16.2 molecules of this gas.

But the fixation of the molecule necessitates:

47 grm. of lime (Ca(OH)$_2$) or 80 grms. of soda (Na$_2$OH) or 112 grm. of potash ($KOH$).

The mass, therefore, necessary is then about 1,200, 1,300, or 1,800 grms., according as whether lime, soda, or potash is used.

Regeneration, however, becomes insufficient as soon as the carbonation reaches 70 per cent. in the case of the solid absorbent and 100 per cent. in that of the liquid. Supposing that the absorbent solutions are in a concentration of 50 per cent. that is to say, equal weights of the water and the base, the weight of the regenerating substance should be about:

1,700 grms. in the case of lime.
1,800 grms. solid soda.
9,500 grms. of soda.
9,600 grms. solution of soda.
3,600 grms. solution of potash.

These weights are pretty high; they can be reduced proportionately as the margin of safety, put at 50 per cent. in relation to the oxygen supply is exceeded.

Obviously verification by weight ought to be made, in the case of liquid absorbents, pari passu with verification of the concentration. The chemical test can be made in the same way as an ordinary analysis of carbon dioxide. Either the total quantity of carbon dioxide absorbed can be determined or the time during which the absorbent material remains effective. 75 litres per minute of air, containing 4 per cent. carbon dioxide being made to pass through in a continuous stream.

The total quantity absorbed ought to be at least 240 litres and the duration of effectiveness at least two hours. The tests may be considered to be ended as soon as the air leaving the regenerator contains 2.5 per cent. of carbon dioxide. The average concentration for the whole duration:
of the test ought not to be more than 1 per cent.

All these tests may be usefully completed, except in the case of simple respirators, by a very complete practical test, either inside, or outside, the gas chamber — a test, therefore, giving information as to the fitting qualities, the ease of breathing, and freedom of movement. It would confirm other tests notably those as to air tightness, efficiency and life.

Storage and Maintenance of the Apparatus

Storage

A place out of the sun, free from dust, acid vapours (especially sulphurous gases), high or low temperatures, and damp should be selected.

All rubber parts ought to be kept in a dark, damp room. A good place to keep them is in a double-walled zinc cupboard where a cup containing petrol, or a ball of cotton-wool soaked in petrol, is kept. If risk of fire is feared, water may take the place of petrol. This procedure is especially applicable in the case of spare parts. It is not to be thought of in connection with apparatus that ought always to be in perfect condition ready for immediate use. These are best dealt with by smearing vaseline on all the rubber parts.

Anti-gas masks ought to be stored in the cases supplied by the makers, and the canisters ought to be protected by means of tampons and corks against every possible penetration of air. The same is the case with the purifying material for self-contained oxygen apparatus.

In replacing the apparatus in their cases or boxes every care ought to be taken to avoid all kinking of the masks or flexible tubing.

Maintenance — Periodical Examination

If the measures for storage are well arranged, their maintenance will reduce itself to a monthly inspection of each apparatus in detail by someone of experience (made responsible for the work) and the replacing of any parts that may have deteriorated or got worn out.

After Use

Care should be taken to replace immediately all parts that have been used up — filtering, canister, re-generating material, oxygen cylinders, and all defective pieces.

The masks should be cleaned with a moist linen cloth and left to dry before placing them back in their cases.

The mouthpiece and connecting pipe should be disinfected using a disinfectant which does not attack any part of the apparatus: e.g. a solution of perchloride of mercury 1 in 4,000, or 2 per cent. Lysol apparatus: e.g. a solution of perchloride which does not attack any part of the should he disinfected using a disinfectant placing them back in their cases.

Moist linen cloth and left immediately all parts that have been used up: the measures for storage are well arranged, their maintenance will reduce itself to a monthly inspection of each apparatus in detail by someone of experience (made responsible for the work) and the replacing of any parts that may have deteriorated or got worn out.

For apparatus which includes a breathing bag, disinfection of the bag is done by exposure to formalin vapour for an hour, or by immersion in one of the solutions named. If the latter is done, the bag should be dried slowly and carefully for from 12 to 15 hours.

It is advisable to seal the cases and boxes containing the protective appliances.

Use of the Apparatus

Use of the protective appliances calls for certain precautions under pain of unpleasant, sometimes fatal, experiences.

Defective, badly fitting, or wrongly used appliances are much the more dangerous in that the wearing of them induces a false sense of security. Thus it should be a sine qua non when they are about to be worn to examine them most carefully and have them rapidly tested. The personnel called on to use them should be methodically trained to fit them perfectly and to use them rationally under the most difficult circumstances imaginable.

The examination of respirators should extend to their state of cleanliness and the way in which the filtering medium is fixed, how the mask fits the face, and the way the valves, where such exist, work (see above).

For canister anti-gas masks the examination should include: the state of the seal on the case; the nature and state of the canister (care especially should be taken to see if the corks have been properly inserted); the way the mask fits the face and the airtightness as in the case of the respirators; the valves and connections between the canister and the face-piece should be submitted to strict inspection.

Anti-gas masks require a little training by the persons likely to use them. Masks with flexible tubing require to have the face-piece examined (as above) and also the tubing, the connections, and the bellows or blower fan. The wearer should try breathing through the apparatus without setting the latter in motion. The test for airtightness is made as in the case of anti-gas masks, but by closing the orifice for the air entry into the bellows.

For self-contained oxygen breathing apparatus, rapid testing must be done on the external parts (pipes, bands, breathing bag, face-piece, or buccal attachment and its connections), and the airtightness must also be tested. It is necessary to close all the openings and blow down the expiratory pipe; when the whole apparatus is full of
air a further blowing up should be impossible.

To test if it is under negative pressure: negative pressure should be brought about by aspiration until the walls of the bag are quite close together: they ought to remain in this condition for five minutes after aspiration has ceased. The oxygen supply should be verified in the same way as when such apparatus is received; the amount of oxygen should be determined by simple reading of the manometer, and the regenerating substance tested as when received omitting the chemical test.

Use of self-contained oxygen breathing apparatus requires a highly trained personnel. The United States Bureau of Mines has published an excellent code of directions on this subject based on the experience gained at rescue stations.

In the case of all safety apparatus the wearer, completely equipped, should practise a few exercises for about five minutes before entering the poisonous atmosphere.

**Legislation**

Generally respirators are required by law to be supplied to all workmen exposed to the risk of inhalation of poisonous gases, vapours and dusts. These masks, supplied by the employer, must be maintained, washed and cleaned daily, and renewed when necessary.

When poisonous substances are in question the filtering material must be washed, cleaned or renewed once a week. Respirators must not be left in the workroom; a responsible person should be in charge of them.

In regard to breathing apparatus, especially that intended for mine rescue work, tunnels, chemical industries, etc., the regulations laid down are more stringent. They cannot be reproduced here in detail (see the *Legislative Series* published by the International Labour Office).

Generally speaking the Regulations require the apparatus (breathing and oxygen apparatus) to be examined once a month by a competent person familiar with their use, and the results of the examination to be entered in a register kept for the purpose, and to be shown to the inspector on demand.

The Chemical Section of the National Safety Council of the United States has proposed the adoption of a series of colours to distinguish the canisters with special filtering material against different gases. The standard list is as follows:

<table>
<thead>
<tr>
<th>Colour</th>
<th>Filtering material</th>

Breweries

The production of beer — a fermented drink prepared with malt or germinated barley and flavoured with hops — was formerly carried on in a great number of small factories. Nowadays, the tendency is, at any rate partially, to concentrate manufacture more and more in large establishments in which very modern equipment permits of a larger production as well as a notable improvement in the hygienic conditions of the persons employed.

Initial Substances

Initial substances include barley that has begun to germinate, or malt and hops, yeast, ice and water. Other initial substances are sometimes employed instead of barley. In some countries use is made of other cereals or, as substitutes, glucose and treacle. For hops other bitter products have been substituted and these substitutes are the result of local custom or of fraud on the proper character of the beer. They may exercise an influence on the health of the consumer and at times on that of the workmen, as when use is made of glucose obtained from acids not arsenic free.

Industrial Operations

The manufacture of beer comprises the following processes:

(a) Preparation of the malt (Mälzerei);
(b) Preparation of the hops (bleaching with sulphur);
(c) Preparation of the wort or mash;
(d) Decoction and addition of the hops;
(e) Cooling of the wort;
(f) Fermentation of the wort;
(g) Racking and filling of casks and complementary fermentation;
(h) Bottling;
(i) Maintenance of the barrels.

(a) Preparation of the malt, or malting. Malting or malt manufacture on a large scale (French: malterie. — German: Mälzerei or Maltfabrik. — Italian: fabbrica di malto. — Spanish: fabrica de malto) is quite separate from the brewery, constituting sometimes a special industry.

The preparation consists in placing the barley under conditions favourable for its germination and interrupting this at the moment when the malt contains the maximum of substances capable of entering into the composition of the wort.

The first process is the sorting and cleaning of the barley, then follows steeping which is carried out in tanks called cisterns and lasts for from 48 to 108 hours according to the nature and age of the grain. In the process of steeping the grain absorbs 40 to 50 per cent. of water, but loses about 2 per cent. of substances which are dissolved out of it. Carbon dioxide is given off in the operation, and the water, which is at first coloured brown, has to be renewed.

The steeping makes germination possible, and during its course the maximum transformation of the nitrogenous material into diastase is achieved.

The germination, or malting, takes place in the malthouse in semi-darkness. The wet barley is spread out on the floor of the malthouse in layers 12 to 15 cm. in thickness. It is turned over
at first every 6 hours, then every 8 hours, until it appears dry. When germination becomes general the area of the floor covered is reduced to one half, so that the layers become of a thickness of 25 to 30 cm. The temperature rises. Much water vapour condenses on the upper layers (sweating). Much carbon dioxide is given off and also certain ethers emitting a special odour. The layers are turned, their thickness is reduced so as to lower the temperature when germination is sufficiently advanced, that is, when the radicles exceed by about a quarter the length of the grain and the felting of the grain is normal.

The duration of germination varies according to season and climate. The barley loses about 7 per cent. of its weight. To avoid hand labour during germination, pneumatic malting has been substituted with the special object of trying to eliminate the carbon dioxide which is prejudicial to germination and to hinder and prevent overheating the grain. There are many systems of this pneumatic malting.

The grain coming from the malthouse (green malt) is carried to the kiln, and placed on the floor in a thick layer of 3 to 5 cm. It is turned 6 or 7 times a day. When dry the radicles are removed, some separating from the grain themselves, others are removed by machine. Complete separation is effected by a winnowing machine.

For the manufacture of certain beers, this air-dried malt suffices; but in the great majority of cases it is submitted to a kind of roasting more or less pronounced in an apparatus known as a malt-kiln.

The malt-kiln consists of two parts: that on which the grain is spread out, and that where the heat is produced for curing and roasting. Malt-kilns are of two kinds: smoke-kilns and hot-air kilns. In the former curing is done with the aid of the mixed gases and air coming directly from the combustion of the fire. In the hot-air malt-kiln, the curing is done by means of air and does not contain any of the fire gases. The grain is stirred from time to time by the aid of tools introduced through lateral openings. Malt-kilns are also constructed in which the grain is stirred mechanically.

Drying is done at first at a temperature of from 90 to 90° C. then at 50° up to 70° C. The degree of curing varies according as the desire is to produce a pale or high dried malt.

The malt-kiln only accentuates and completes the transformation commenced by germination. In order to colour certain beers, the malt is roasted over a naked flame in sheet metal cylinders like coffee.

Good malt ought to yield on extraction at least 70 per cent. of its dry weight.

(b) Preparation of the hops. — The hops used for the manufacture of beer consist of the female flower of the plant (Humulus lupulus). This flower which is in the form of strobiles or cones contains different substances having an action universally recognised and appreciated. It gives to the beer a special aroma; it retards the alcoholic fermentation and hinders considerably other fermentations in the wort.

The quality of the hops exercises a considerable influence on the delicacy of the flavour of the beer and on its stability. They must be gathered in favourable weather and must be dried properly so as to avoid their becoming mouldy.

Drying is effected either on screens in the open air or in the oast-house. Frequently, in order still further to preserve them, the hops are sulphured, that is, exposed to sulphur vapour. One to 2 kg. of sulphur are needed for 100 kg. of hops.

Sulphuring the hops, followed by exposure in the oast-house to a moderate temperature, or slight impregnation with a small quantity of alcohol, compression and preservation in a place hermetically closed, are the means adopted to preserve them.

The hops dried at a temperature of about 40° C. are subjected to strong pressure and are despatched done up in watertight pockets or bags. The world's production of hops is about 95,000 tons.

(c) Preparation of the wort. — Under the name of wort or mash is understood the liquor containing the solution of the products of the malt with the addition of what this liquid has been able to extract from the hops with which it has been in contact. The fermented wort becomes beer.

The preparation comprises: the crushing of the malt, mashing, decoction and addition of hops, and cooling.

The crushing, which must not be pushed too far, is intended to facilitate the solvent action of water. The mashing enables the maltose and dextrine to be extracted from the malt and increases the amount of this maltose and dextrine by the action of the diastase on the starch in presence of water. Similarly, it allows of the
production of peptone and para-peptone as a result of the action of peptone on the proteid substances. Washing is preceded by preliminary soaking to prevent unduly strong action of the hot water on the malt.

The mash is then carried to a suitable temperature to ensure saccharification. This is done either by infusion or decoction.

The first method is known as top fermentation and is employed in a great part of Northern Germany, in France, the United States, Canada, Great Britain, Belgium, and in some places in Central Europe. The second is known as bottom fermentation and is customary in a great number of breweries of Europe and especially in breweries yielding Bavarian, Viennese or Pilsener beers.

Whether done by infusion or boiling the work is carried on in special rooms which is the brewery so called (Sudhaus in German) with an equipment consisting of mash tuns, large copper in which either the infusion or decoction of the malt is effected with variations depending on the taste of the consumer.

The temperature of the liquid during the mash is from 45 to 70°C.

The residue after the malt is exhausted is called grains.

In certain countries glucose is added to the wort thus obtained in order to increase its richness. Glucose made with diastase should be used rather than glucose made with sulphuric acid which might contain traces of arsenic. Treacle is sometimes added.

(d) Boiling and addition of hops. — Boiling has for its object the concentration of the wort, solution of the ingredients of the hops, and coagulation of a part of the proteid matters, and precipitation by the tannin in the hops of the starch which has so far not been transformed. Boiling clarifies the wort and frees it of the substances which would hinder the preservation of the beer. The action of the temperature is reinforced by the addition of the hops, the effect of which is not only to give the beer a special flavour, but also to introduce into the wort substances aiding in its clarification, in the progress more or less rapid of fermentation, and in the preservation of the manufactured beer.

The hops are added after boiling has brought about coagulation of certain substances which must be extracted from the wort.

(e) Cooling the wort. — Cooling the wort must be carried out as quickly as possible to avoid the production of lactic acid between 25° and 30° C.

Cooling takes place either in the open air in huge vessels called coolers, or in making the wort circulate over refrigerating pipes, or by a combination of the two methods.

The temperature to which the wort is reduced depends on that of the locality where the fermentation is carried out and on the nature of the latter.

(f) Fermentation of the wort. — After having been cooled, the wort is ready to undergo alcoholic fermentation.

Depending on the temperature to which the wort has been brought or that prevailing in the fermenting room, on the quantity and kind of yeast, on the time, more or less long, taken, on the quantity and quality of the hops added, fermentation is carried out in two ways: bottom fermentation, and top fermentation. Lager beers are prepared by bottom fermentation.

In this kind of fermentation the wort is placed in large vessels (gyle vats) placed in cellars where the temperature in from 4° to 5° C. The yeast having been put in, the temperature of the wort has a tendency to rise during the principal fermentation (2,500 calories per 100 litre of beer containing 3° to 5° of alcohol). The liquid in the vat is cooled by means of floats containing ice or by a coil of pipes through which a solution of chloride of calcium at 2° to 3° C. circulates.

The principal fermentation lasts nine to ten days for lager beers and from 7 to 8 days for beers intended for immediate consumption.

The fermented wort is given the name of green beer and is placed in barrels which have been specially prepared to undergo a complementary fermentation. The temperature of the cellar must not exceed 1° or 2° C. in order that the secondary fermentation may be effected slowly.

The ice consumed in cooling the wort and for keeping down the temperature in the cellars amounts to 20 to 50 kg. per hectolitre of beer. The barrels, before they are placed on the market, are filled quite full for some days in order to increase the quantity of carbonic acid in solution.

Top fermentation is practised in Belgium, England, Northern France, Alsace, Bohemia, etc. The beers so produced do not keep so long as beers of bottom fermentation, but they are lighter and produce more of a head.

The fermenting vats are of large diameter and the addition of the yeast
is done at 12-15°C. — sometimes more (white Berlin beer). The principal fermentation lasts between three and four days. The secondary fermentation is carried out in casks, as in the case of beers of bottom fermentation, or in bottles.

Cooperage. — The cooperage constitutes an important part of the whole brewery. To prevent the beer penetrating into the wood with the consequent inconvenient result of setting up fermentations other than alcoholic, when the casks are empty (and also to avoid leakage) the inside of the barrels are coated with pitch or an alcoholic varnish. This coating of pitch or varnish has to be frequently renewed after the removal of the old one. In the cooperage also an important number of repairs are carried out on the casks and barrels.

The coating of the casks by means of pitch is done either directly or by hot air or steam. The operation is dangerous because of the risk of fire or explosion, the vapour given off from the pitch forming an explosive mixture with air.

Dangers

In small breweries the same workmen may carry out all the necessary processes, but in the large breweries the various operations are entrusted to different groups. The workmen, therefore, in small factories are more exposed to brusque changes of temperature than in the large, and consequently more liable to be affected by chills.

Electricity is coming more and more into use, permitting as it does of the substitution for hand labour, always arduous, of mechanical means for carrying out the different operations of raking of "the goods", mashing, washing the filters, tarring and washing the barrels, manipulating the blocks of ice, bottle washing, and labelling, etc., and especially of conveyance of sacks and barrels.

Without stressing too much the heavy work in the store-rooms of the malt-house or brewery, reference should be made as regards the first class to the injurious effect of the atmosphere charged with dust and carbon dioxide and especially to the high degree of humidity. The men are obliged to work with little clothing; they are continually mopping away sweat which is at the same time saturating the little clothing they wear. All this favours chills. Work in the kilns exposes to the action of a humid atmosphere as far as the second and third stages and to one extremely hot towards the end of the operation (62-99°C.), temperatures which excite great thirst. The same arduous labour is met with during the removal of the rootlets from the malt (at 40 to 45°C.) unless this is done mechanically.

Manipulation of the barley before germination gives off a considerable quantity of dust which is not easy to eliminate; the same unpleasantness is met with on the second (lower) platform of the oast-house when the grain is turned (shovelling) unless this is affected mechanically.

In brewing the workmen are exposed to the same dangers as those in the malt house — hot, humid, and cold air (fermenting chambers artificially chilled to 3-4°C. and to an atmosphere rich in carbon dioxide according to the type of plant (kilns with direct firing).

So far as the chronic effect of prolonged inhalation of high proportions of carbon dioxide (see that article) is concerned it must be admitted that it has not yet been accurately determined. Lehmann and his pupils, Brickel and Herrlighoffer, have shown that proportions of 0.5 to 2.0 per cent. by volume in the air cause no specially marked symptoms in the persons working in the fermenting rooms. Though the contrary may have been observed in the past, it is to-day exceptional.

Danger of asphyxia has been reported among workers, especially in the cleaning of the fermenting vessels; thus, for example, in Great Britain, in 1913, three such cases were reported in breweries; in 1914, 1 (fatal); in 1918, 1 (fatal); in 1919, 1 (fatal); in 1921, 2 (both fatal); in 1923, 3 non-fatal cases. The sulphuring of the hops, whether done directly or by burning the sulphur, involves risk of gassing by sulphur dioxide, as also will escape of this gas from the coils of the (sulphur dioxide) refrigerating apparatus. The same danger is present near an ammonia freezing apparatus when pipes break or joints are imperfect, etc.

Use of disinfectants and preservatives, such as, e.g., hydrofluosilicic acid (H₂SiF₆), called in Germany "Montanin", often impure from silieic acid, oxide of iron and zinc, etc., can also set up poisoning. In Prussia (1919) use of "Antiformin" for cleaning caused cases of poisoning (it consisted of a resin dissolved in a mixture of pyridine, acetone, etc.).

In the Netherlands cleaning the hop back with a solution of nitric acid
caused three cases of poisoning in 1919 (escape of nitrous fumes).

Use of methyl alcohol (see this article) as a solvent for painting the barrels and vats has caused in America (New York, Buffalo, Chicago, etc.) severe cases of poisoning (blindness). In the same country (Ohio) attention has been drawn to the possibility of lead poisoning from putting the capsules on the bottles, and in Austria (1914) from use of colours with a basis of red lead to mark the barrels. In Great Britain in 1914 a fatality was caused by the use of a paint containing trichlorethyrene.

The tarring of the barrels, especially when done by hand, exposes to the fumes given off from the melted pitch. (See article Tar.) When done on a large scale use is made of special apparatus with steam jet and absorption of the fumes, but all such apparatus are not free from imperfections. Finally sulphuretted hydrogen is given off from the decomposition of the residual waters (as in all industries employing organic substances).

STATISTICS

The statistics of sickness insurance societies, especially in Germany, show that the morbidity among brewery or malt house workers reaches that of the most unhealthy industries. Westergaard has even expressed the opinion that such morbidity is only attained in industries where a special danger exists, such as lead poisoning or inhalation of dust.

It must in fairness be said, however, that brewery workers and maltsters run considerable risk of accident, and it is not always easy from these statistics (Germany) to distinguish between incapacity from illness and that from accident.

Nevertheless, the following are the figures furnished by the sickness insurance societies of the brewers and maltsters of Berlin, Dresden, Kottbus, Mannheim, Schoeneberg-Berlin, Strassburg, Stuttgart, and Leipzig. The data of Sommerfeld are taken from the reports of the sickness insurance societies of the brewers and maltsters of Berlin only, and those of Backert from the Society of Brewers of Berlin, covering 25,000 cases of sickness, and of Dortmund where 1,450 were registered.

These different statistics show that diseases of the locomotor system and rheumatism are those that affect this class of worker most (about 20 cases per 100 members; 16.5 per cent. of the cases of sickness). Next come diseases of the respiratory tract (about 15 cases per 100 members; from 6-12 per cent. of cases of sickness). Gastric troubles and infectious diseases show also high morbidity rates from 7 to 10 cases per 100 members; from 7 to 9 per cent. of the cases of illness); very frequently accidents show a percentage of 16 to 20.

According to the statistics of the local sickness insurance society of Leipzig, the group (maltsters and brewers) had 25 days of sickness per 100 insured and only 15 days per 100 insured at the group aged 25 to 34 years, which would permit the deduction to be made that the unhealthy-ness of the trade is felt in later years. Though according to this experience tuberculosis and respiratory diseases show an average below that for other trades, and diseases of the digestive tract are about the same, diseases of the locomotor system are, on the other hand, very numerous as well as lesions (accidents) affecting it.

The general morbidity rate was 45 per 100 workmen in this group as compared with 40 per 100 in all the groups. Thus the relative value was as 1.16 to 0.77 per 100 workmen. Occupational poisoning is unknown. As regards rheumatism and diseases of the locomotor system, when compared with other industries, brewers show very high figures of morbidity: for Stuttgart, for instance, a percentage (per 100 members) of 21.69 as compared with 16.49 for other occupations, 20.09 for Berlin as compared with 14.54; and 13.17 for Leipzig as against 7.8 was revealed.

Villaret has described a peculiar lesion of the nails due to the action of the yeast. (As regards alcoholism, see later.)

An enquiry conducted in the State of Ohio in 1914-1915 by Hayhurst and extending to 11 malthouses employing 1,055 men did not yield information of special interest. He recalls, however, that the American Brewers' Trade Union had had notified to them in 1913, 732 deaths among its 42,218 members, that is, a mortality of nearly 17.34 per 1,000 caused mainly by tuberculosis (22.81 per cent.), respiratory diseases (11.88), heart diseases (10 per cent.), diseases of the kidneys and liver, etc. (4.78 per cent.). Fatal accidents showed a percentage of 13.16 and suicides 4.10 per cent. Grouped according to age the relative figures per 100 deaths were as follows:

<table>
<thead>
<tr>
<th>Age Group</th>
<th>Mortality</th>
</tr>
</thead>
<tbody>
<tr>
<td>Less than 20 years</td>
<td>0.96</td>
</tr>
<tr>
<td>From 21-30 years</td>
<td>10.79</td>
</tr>
<tr>
<td>From 31-40</td>
<td>19.26</td>
</tr>
<tr>
<td>From 41-50</td>
<td>33.30</td>
</tr>
<tr>
<td>From 51-60</td>
<td>69.00</td>
</tr>
</tbody>
</table>

According to Backert the mortality among the Austrian union of brewery workers was as follows:

<table>
<thead>
<tr>
<th>Year</th>
<th>Death Rate</th>
</tr>
</thead>
<tbody>
<tr>
<td>1910</td>
<td>1911</td>
</tr>
<tr>
<td>201</td>
<td>208</td>
</tr>
</tbody>
</table>

Number of deaths of members From deaths of members 301 298 332 345 Per 100 deaths From tuberculosis 38.3 29.8 22.2 30.7 respiratory diseases 8.0 11.4 12.6 digestive diseases 11.4 5.6 6.6 3.1 circulatory diseases 3.0 18.4 16.5 17.3 accidents 6.0 10.0 12.3 11.0

Westergaard (1901) has quoted Tatham's figures concerning English brewery workers and has reproduced the following table:
For every 1,000 persons at the following ages there died annually:

<table>
<thead>
<tr>
<th>Age-Groups</th>
<th>Brewers</th>
<th>All-occupied males</th>
<th>General population</th>
</tr>
</thead>
<tbody>

<td>13.01</td>
<td>21.37</td>
</tr>
</tbody>
</table>

For every 1,000 persons of all who died in the general male population 1,427 brewery workers died from the following causes:

- **Diseases of the liver**
- **Diseases of respiratory system**
- **Diseases of nervous system**
- **Alcoholism**
- **Phthisis**

The comparative mortality figure represents that maltsters and brewers run particular risk from changes in temperature and alcoholism. As regards temperature, the occupation upon a sample of the general male population enumerated at the Census of 1901, which showed 1,000 deaths.

Pathology

The above figures show that maltsters and brewers run particular risk from changes in temperature and alcoholism. As regards temperature, the description of the processes has shown that work in the malt-kiln is done in 70-80° C., that in the mash room it mostly varies from 15-20° C. and is sometimes even higher, and that, in the fermenting room, the temperature varies from 1-5° C.; in these workrooms the humidity rate is very high. For as the workmen employed ordinarily outside the brewery — draymen, carriers, etc. — they are exposed to the weather.

A very general custom in breweries is to allow the workmen free consumption of beer. In North Germany this reaches about 5 litres per day per worker; in South Germany 8 litres.

In a Lyons brewery the management had fixed 5 litres per day as the quantity to be distributed to the workmen. It was given up because of the pilfering resulting from this limitation which would react by favouring the frequency of diseases of the digestive organs brought on by ingestion of large quantities of cold liquor.

In some countries the draymen are frequently given drinks in the course of their rounds, not of beer, which they consume like their mates at the brewery, but of alcohol, glasses of which are taken at the counter at the moment of delivery.

In bottling breakages are pretty frequent and entail accidents to the fingers, face, eyes, etc. — a frequency especially prevalent among the persons employed in the store department and cooperage (transport of barrels, unless this is done mechanically).

Hygiene and Prophylaxis

Floors should be of flagstones or asphalt; use should be made of enclosed apparatus, ventilated or provided with efficient exhaust hoods especially over the boilers. There should be sufficient ventilation in the boiling and fermenting houses to reduce the humidity. Hand labour should be replaced wherever possible by mechanical devices as this much improves the health conditions in certain departments for the preparation of malt and beer.

In regard to temperature it is evident that work in the malt-kiln is unpleasant; nevertheless the workmen have to go in there in order to turn over the malt and to watch the effect of the heat. Almost universally hand
labour in malthouse work has now been replaced by machinery, and for recording the temperature of the malt in the apparatus devices exist by means of which this can be done from the outside.

The moist heat in the malthouse and in the brewery proper is very unpleasant from the health point of view, but it can be largely mitigated by efficient ventilation. Lack of movement in the presence of warm, moist air makes it all the more trying (see article "Warm and Moist Air").

The above remarks apply also to the oat-house and when sulphuring is practised; work should be so arranged that no one should enter the apparatus before it has been sufficiently cooled nor until the air has been sufficiently freed of sulphur dioxide by adequate ventilation.

It is most important to take measures to render asphyxiation impossible in the rooms and in connection with apparatus giving off carbon dioxide; malthouse, fermenting vats and cellars. Not a year passes without record of some such case in factory inspectors' reports. When carbon dioxide is produced with its tendency to collect low down, mechanical ventilation must be instituted. Entering fermenting vats and apparatus should be prohibited whether it be for cleaning them or for any reason whatever, until they have first been adequately ventilated.

To guard against escape of ammonia the pipes and joints must be closely watched, and masks or, better still, breathing apparatus constantly available. Precautions should be taken when sulphur or sulphur dioxide is used. Sulphur should be burned in metallic boxes and precautions taken to avoid dispersion of the fumes as well as to avoid gassing or premature entry into the sulphuring chamber. Useful purpose is served by exposing moist litmus paper which should not become pink. If fans are installed it should be remembered that iron is attacked by the acid gas and rapidly destroyed. They should be of earthenware. Ozone or electrified air assists normal fermentation of the wort and hinders parasitic action. The process is widely applied at the present time.

Ozone also serves to disinfect the filtering material, the chips, the apparatus, the piping (except india-rubber) and also for ventilation, particularly of the refrigerating plant (instead of filtering the air through cotton wool), the vats, cellars, bottles, etc. This system rationally applied in all stages of the manufacture permits of obtaining a product which renders pasteurisation unnecessary. Combustibles giving rise to black, thick, prolonged smoke should be avoided; the residues and waste in the precincts and workrooms should not be allowed to accumulate for more than a day; everything should be kept as clean as possible.

It must be admitted that purification of the residuary water rich in putrefactive organic substances, which can readily become acid by biological means, offers certain difficulty. Their mixture with some of the residuary waters of dwelling houses helps in maintaining a slight alkaline reaction. Preliminary decantation of the detritus and insoluble material must be secured before biological purification which should be followed by the addition of sufficient milk of lime to prevent fermentation of the organic matters. The process has not, however, been perfected so far.

To prevent alcoholism among the workmen the practice of allowing them to consume beer ad libitum should be discontinued. The danger from dust is less to be feared from the point of view of its action on the respiratory tract than from that of accident. Several explosions have been reported due to the fact that accidentally the dust produced in the grinding of the malt becomes overheated. Substitution of an alcohol varnish for that of pitch is scarcely to be recommended on the score of health; the alcohol used being almost always either methyl alcohol or wood spirit of which the injurious action on the sight is well known; this action is the more to be feared because the alcohol vapour, before dissipating in the workroom, escapes in large volume from the casks by the sole means of issue — the bunghole near to which the workman is obliged to keep his face in order to observe what is going on inside.

**LEGISLATION**

There is no special legislation relative to the manufacture of beer.

**BIBLIOGRAPHY**

At the present time the sulphuric acid is almost always replaced by hydrochloric acid and the manganese dioxide by the hypochlorite or chlorate of magnesium. This modification of the process permits of the recovery of magnesium chloride, which is a valuable by-product.

The extraction is very often carried out by means of chlorine gas. The mother-liquor trickles through a tower filled with stone, or through a tower with trays, traversed by an ascending current of chlorine. The vapour of bromine which comes off is collected in a cooled worm, the non-condensable vapours being retained by iron fillings, with which they form chloride of iron.

Before the war the industrial production of bromine was confined to Germany, where it represented a secondary industry connected with the salt industry. During the war, France organised the extraction of bromine from the mother-liquor of the salt marshes of Zarzis in Tunis. Recently the ever-increasing demand for bromine for the manufacture of tetra-ethyl lead and chiefly of ethylene dibromide, with which the tetra is used in commerce, has driven technical experts to seek out other sources and to have recourse to direct extraction of bromine from sea water. Bromine is then set at liberty by chlorine; the small quantities of free bromine are combined with aniline, and tribromaniline so obtained is collected on filter presses.

Moreschi has recently (1926) extracted bromine from the mother-liquor of a salt marsh by the use of chlorine. But he withdraws the bromine in a continuous manner by the use of a solvent — the tetrachloride of carbon — and then makes powdered hydrate of calcium act upon the solution obtained. He thus obtains a special bromide of lime which yields all its bromine in a free state by the simple action of dilute acids.

Crude bromine, which contains from 2 to 5 per cent. of chlorine, should be purified by distillation in glass retorts either alone or in the presence of bromides of potassium, of iron, or of calcium. Refined bromine still contains about 0.3 per cent. of chlorine, whilst chemically pure bromine contains traces of organic combinations of bromine.

Uses

Bromine is conveyed in the liquid state in glass bottles, or in the form of "solid bromine", which consists of
"Kieselguhr" (the remains of extinct diatomaceous) in the form of flour, after it has absorbed about 75 per cent. of bromine and has been moulded into the form of small sticks.

Bromine is used, either in the liquid state or in the form of gas, as a disinfectant: in laboratories as an oxidiser, often in the state of bromine water, an aqueous solution of which is preferred to chlorine on account of being easier to use; in gold and platinum metallurgy for extraction and purification; in medicine; in photography; in the production of artificial colouring matter, such as eosine, indigo bromide, of wood alcohol, and of asphyxiating and lachrymatory gases, such as bromide of benzyle, xylene, mono- and dibromacetone, bromo-methyl-acetone, bromopiricine, and bromocyanogen; in the preparation of Prussian blue and permanganate of potash.

Bromine is generally packed in large, blue glass bottles, carefully closed with ground stoppers and sealed. The bottles are placed in wooden or metal boxes filled with ashes or sand or "Kieselguhr".

**Sources of Dangers**

Every escape of gas or dust containing bromine represents a danger risk to the mucous membranes and skin. Accidents are quite common, although not as a rule, serious, in laboratories and factories where bromine is used. The manipulation of compounds of bromine used for asphyxiating gas is very dangerous. The risk of explosion at normal temperatures or at a slight heat when bromine comes in contact with phosphorus must be provided for. Danger from asphyxia by certain compounds of bromine must also be borne in mind, for example, in the manufacture of indigo when using bromide of xylene.

**Toxic Action**

Lehmann in 1887 by experiments on animals demonstrated the actual toxicity of this metalloid, the action of which is similar to that of iodine. This authority noticed that bromine vapour set up, among animals, a strong, irritating action on the respiratory and digestive passages, giving rise to numerous severe haemorrhages, from the surface of the gastric mucous membrane, for example, which are not caused by chlorine; and also that it exerted a solvent action on the hair of the body and head, which it turns yellow. A given volume of bromide gas acts in the same way as the same volume of chlorine gas, but by weight bromine is two and a half times less toxic than chlorine. According to Lehmann, however, experiments made upon men with very small doses have proved that the absorption of bromine is complete.

Bromine gas on the skin causes a feeling of heat, a yellowish staining, and some more or less pronounced congestion. If the action is of short duration, vesicles and pustules are reported to appear; if of long duration, ulcers appear which are painful, deep, and difficult to heal.

When inhaled the gas causes dyspnoea with a feeling of suffocation; these effects are extremely painful even with minute quantities.

This irritant and caustic action on the respiratory passages favours the development of such diseases as bronchitis and broncho-pneumonia.

Marino in 1919 studied experimentally the action of bromine gas on the blood. He found that it diminishes both the number of blood cells and the quantity of haemoglobin, and that this diminution is more marked in proportion as the quantity of vapour is increased; but it is not increased consequent upon repeated inhalations. On the contrary, some immunity is established so that the doses have to be increased if it is desired to get the same results as before. With small continued doses, bromine causes haemolysis and pronounced leucocytosis (about four times the normal) acting chiefly on the lymphocytes, and also, strange to say, on the neutrophile leucocytes when the gas acts in large doses and over a long period.

Pellegrini has found in animals that died in consequence of inhaling bromine vapour intense pulmonary oedema and serious lesions of the bronchi. If death occurs at the end of some days, foci of broncho-pneumonia are found. The alveoli are filled with oedematous fluid, rich in halogen combinations, rather than being affected by the direct action of the poisonous gas. Moreover, the respiratory apparatus is the path by which halogen compounds are eliminated when thrown off by other organs, and it suffers from circulatory troubles caused by asphyxiation.

No facts are available relating to chronic poisoning; nor to acquired immunity to bromine. It seems, however, that workmen are not affected by chronic forms.

Some experts, on the contrary, speak of an anaemic state which appears to be due to the chronic action of bromine.
The poisonous doses are not well known. Lehmann found that a dose of 5.5 c.c. per litre of air is quickly fatal or very dangerous to cats; that a dose of 0.22 to 0.33 acting during thirty to sixty minutes is dangerous, but not fatal; that a dose of 0.022 per litre during a similar period does not cause serious symptoms, and, finally, that a dose of 0.007 to 0.014 for six hours does not cause serious symptoms. However, according to some experts bromine does not give rise to methaemoglobinuria. Bromine introduced into the system is eliminated in the form of alkaline bromides by the urine or in other organic secretions.

**Symptoms**

In addition to local lesions on the skin and mucous membranes considered above, and troubles caused by the inhalation of the vapour, bromine generally causes acne, which was observed by Oppenheimer in 1915 among workmen who made asphyxiating gas bombs. The faces of these workmen were slightly oedematous, especially the eyelids, which were also the seat of discharging pustules and became rapidly covered with crusts. The acne also covered the cheeks and forehead, but rarely the neck.

Like the other halogens, bromine makes the teeth turn yellowish, causes conjunctivitis and even keratitis, as well as rhinitis and more or less severe stomatitis. In serious cases, bromine may cause troubles of sensation, with diminution or even an absence of conjunctival reflex, as well as troubles of vision.

A case of idiosyncrasy has also been noted in a student of Professor Bunge who had worked in the laboratory with bromine water under an exhaust hood. He showed violent irritation of the conjunctiva which did not affect his fellow-workers.

It should be said, however, that cases of poisoning of occupational origin by bromine are comparatively rare, when its frequent use is taken into account.

Among the compounds of bromine must be mentioned ethyl bromide (C₂H₅Br) obtained by the reaction of bromide and phosphorus on alcohol, or of neutral sulphate of ethyl on a boiling aqueous solution of potassium bromide. This compound causes, by its vapour, cough, headache, vertigo, and even loss of consciousness. Fortunately, in consequence of its rapid elimination from the system, it only gives rise to transitory symptoms.

For methyl bromide, see that article. The other compounds, used as explosives or as asphyxiating gas, are naturally violent irritants of the mucous membranes.

**Detection**

Free bromine is easily recognised by its smell. It can be isolated by distillation with sulphuric acid and manganese dioxide or potassium bichromate. In the urine, bromine can be detected, after having added an excess of potash, by evaporation, calcination, and shaking the residue so obtained with ether, chloroform, or carbon bisulphide. The bromine, which is isolated, can be recognised by its smell, by the colour of the solution, and by decoloration of indigo. Bromine can also be transformed into bromides or to the state of bromide of silver (see text books on toxicology).

**Hygiene**

As for all poisonous gases.

**Legislation**

As for poisonous gases. The injuries caused by bromine and bromide of ethyl are compulsorily notifiable in France and compensated as accidents in Switzerland. Cases of acute poisoning are generally grouped under the heading of industrial accidents.

### Bronzing and Bronze Manufacture

**Technology**

Bronze and brass (see article "Brass") are the most important alloys of copper. Under the name of bronze is understood generally a series of alloys characterised by their hardness, tenacity and resistance, in which copper and tin are the chief constituents. Ordinary bronzes often contain zinc or lead in small quantities, while special bronzes may contain reducing substances such as, for example, phosphorus, manganese, silicon, nickel, etc.

The copper is first melted. Bronze clippings are then added and, at the end of the operation only, some tin. The colour of the bronzes vary, chiefly according to the quantity of tin which they contain.

Industrial bronzes are of very varied composition according to the object for
which they are intended. The quantity
of copper may be said to vary between
70 and 81 per cent., and that of tin
between 4 and 11 per cent., that of lead
between 8 and 15 per cent., that of zinc
70 and 81 per cent., and that of tin
of copper may be said
which they are intended. The quantity
present very widely applied.

Ordinary kinds of bronze are utilised
in the manufacture of bells, cannons,
machines, and their numerous acces-
sory parts. They are also used for
making art bronzes (bronze for statues,
for instance, for which lead and zinc is
added, giving a softer alloy easier to
manipulate). Japanese and Chinese
bronze (very rich in lead), bronze for
making coins, medals, piping, etc.
Aluminium bronze is harder and more
resistant than copper bronze and is at
present very widely applied. It is used
for the manufacture of imitation gold
alloys, in the manufacture of jewellery,
table and kitchen ware, etc.

Bronze colours. — These are of much
greater importance from the point of
view of industrial hygiene. They are also
known under the name of "metallic
colours" or bronze powders. (French:
Bronze-couleurs; German: Bronzefarben,
Bronzepulver, Metallfarben; Italian:
Colori metallici, Bronzine; Spanish:
Colores por broncear.)

These colours are prepared from
waste from the metal industry and from
alloys reduced to very fine dust, even
microscopic flakes. In order to obtain brown shades,
the metals forming the alloy. Thus,
for example, orange bronze is got from
an alloy consisting of 89 per cent.
of copper and 1 per cent. of zinc, while
the latter two substances
are also in part due to the varying propor-
tions of copper, zinc, traces of lead,
arsenic, tin, iron, etc. — in short, of
the metals forming the alloy. Thus,
for example, orange bronze is got from
an alloy consisting of 99 per cent.
of copper and 1 per cent. of zinc, while
copper-red bronze is made of pure
copper. Silver bronze contains tin, zinc,
and aluminium in varying proportions,
while aluminium bronze consists almost
entirely of aluminium with traces of
zinc. Other coloured metallic powders,
such as rose, red, dark copper, pale
green, olive green, violet blue, are also
used for bronzing. The manufacture
of gilded or silvered bronze involves
liberation of a considerable quantity
of fine dust, even when the operations
of grinding, pulverising and drying are
affected in closed apparatus.

Gold leaf is in general an alloy of
copper and zinc rolled into thin sheets,
then hammered into still thinner sheets
and wrapped in parchment. Hammer-
ing, a noisy and tiresome operation,
is now almost universally done by
machinery. Metal leaf is used for
mouldings, frames, gilding and silver-
ing of furniture and ornaments, etc.
The gilding is applied by means of a
gum containing benzene, or benzol,
acetone, pyroxyline, wood alcohol,
amyl acetate, and ammonia (see these
articles).

Bronzing powders are used in
the lithographic and the printing indus-
tries, in mechanical printing of wall-
papers and other mural decorations,
for bronzing metallic powders, such as lamps, trays, cash boxes,
bicycles, and the stamping of pencils
and paint brushes and trade marks,
etc. They are used in leaf form in the
same way as gold by applying them by
means of special glaze or in powdered
form with thin glaze (bronze glaze).
The term "bronzing" comprises all
processes in which use is made of
metallic powder in a dry or wet state
for coating with gold, silver or bronze
a surface composed of paper, wood,
metal, leather, glass, canvas, etc.
This term is equally applicable to
other electrolytic processes used in
bronzing watch cases and other metal
articles.

Polygraphic industry (see article
"Printing Trades" for bronzing in the
lithographic industry).
Hand bronzing is still employed where the work is irregular or of slight importance. This operation is necessary in the printing of proofs which are too small in size to be put into machines, for certain types of paper (American paper), for fancy papers (thick and thin), cards and boxes, and for all work, in fact, for which the demand is too slight to justify the use of machinery.

The bronze is applied with a pad of cotton wool or of felt, or with a hare-foot brush dipped in the powder. This operation liberates much dust, especially where the workers are careless or inexperienced. The bronzed sheets are cleaned with a duster or clean pad.

**Letterpress printing.** — The printing processes are identical with those in lithographic printing, but as the sheets are usually smaller (sheets for fancy stationery) there is less machine bronzing. Bronze inks have been successfully introduced in letterpress printing, but are not suitable for rough parchment papers or for colour printing.

**Colour printing.** — This process does not involve liberation of dust and offers no risk.

**Wallpaper manufacture.** — Liquid bronze has now practically replaced dry bronze for this purpose. Hand bronzing is done in the smaller factories where block printed papers are manufactured. The powder is rubbed on with a soft brush and the paper finally dusted with a leather pad to remove the surplus bronze. For machine-printed wallpapers a more brilliant effect is said to be obtained by means of dry bronze, but in fact the difference is hardly perceptible. In dry bronzing the paper passes in course of the different processes through various closed apparatus. A little dust escapes from the grooves of the machine, but it is drawn off by exhaust ventilation. The use of liquid bronze (mixture of size and bronze powder) represents an economy by avoiding loss from use of superfluous powder.

**Metal lacquer.** — Sheets of paper and cardboard are often bronzed over the whole surface either with dry powders in bronzing machines or with liquid bronze in separating machines. If coloured metallic effects are required, hand bronzing is reverted to. Silvering and gilding are also done by hand where small fancy articles in tin, wood, leather, canvas, and glass are concerned.

**Bronzing of metal articles.** — Japanned articles and metal articles (tea trays, cycles, cash boxes, stove castings) are often decorated by means of bronze powder. Metal lamps after being covered with the bronzing powder are heated in an enamelling stove in order to set the bronze, and when cold are varnished.

Generally the workers size a certain number of articles before bronzing them. Little dust is raised, the covering of boxes with gold powder or varnish being done wet and hence not generating dust. There is likewise little production of dust in decorating japanned trays with gold leaf or gold paint which is applied with a leather rubber to the sized surface. For castings, lamps, and stoves, bronze powder mixed with spirit and copal varnish is applied either by aerograph, by a brush, or by hand where necessary. Little dust is liberated during this process.

**Bronzing of metal sheets.** — Black iron sheets are coated with aluminium by means of an ordinary cylinder bronzing machine as in printing. After bronzing, the sheets are passed through a dusting-off machine with enclosed machinery provided with well-fitting covers. There should be little escape of dust.

**Stamping on wood** (pencils, paint brushes, etc.). — Bronze powders (chiefly aluminium) are very widely used for stamping of wood by means of small automatic machines. The type is heated in a gas jet or by electricity and dusting off is effected either by machine or by hand. Little dust is produced in the process, the powder being heavier and more greasy than ordinary aluminium bronze powder.

The same process is used for the ends of paint brushes. This work, however, as well as the dusting off, is sometimes done by hand. Very small quantities of powder are used and the workers therefore do not suffer inconvenience.

**Bronzing of textile fabrics and leather.** — Liquid bronze is used for printing cotton cloth, velveteen and leather. For velveteen the dry powder mixed with starch is applied by bronzing machines. During manufacture of gold brocade materials fine metallic dust is liberated, which causes irritation of the mucous membrane of the conjunctivae.

Finally, attention should be drawn to the risk of explosion due to bronze dust.

**Pathology**

Pathology of bronze-founders is identical with that of copper- or brass-founders (see those articles). Only one case of poisoning by phosphorus is
known (due to phosphoretted bronze: reported by Kaup in an Austrian cannon factory). In this article only the pathology of workers engaged in bronzing, that is to say, workers using metallic colour, will be dealt with. The occupational risk in this category of workers is chiefly connected with inhalation over long periods of metallic particles, the injurious effects of which have been studied by Arlidge, Oliver, etc. Bronze dust is composed of angular particles similar in form to those of road metal, but which would not appear to possess such an irritant effect as the metallic dust generated in grinding metals. So far no specific damage of the respiratory tract due to this cause has been met with. It must, however, be admitted that as a rule the workers do not long remain in this industry and the work is largely intermittent, and the occurrence of more or less serious affections of the nose, upper respiratory tract (nasal catarrh, dryness of the throat, cough), referred to by Roepke and Poljak as affecting workers manufacturing and using the metallic colours, is certainly points to diminished resistance to tuberculosis.

As regards the toxic effects of these colouring agents in which copper is present to the extent of 70 to 90 per cent., it must be admitted that the danger is chiefly due to the impurities which they contain or to other substances used for bronzing (bichromates, solvents such as benzols, benzene, acetone, etc.). It is true that copper dust when it gains access to the digestive tract may set up symptoms (see article "Copper"). Zinc, which forms 30 per cent. of the powders usually employed and 77 per cent. of the silver powder, does not possess specially toxic properties (see article "Zinc"). Aluminium, which is present in these colours in small quantities, has no toxic effect.

The presence of traces of lead (according to Sternberg, 0.1, 0.2 and even 0.55 per cent.) has certainly been the cause of poisoning among workers engaged in bronzing (especially of women). The presence of traces of arsenic might also be responsible for more or less marked affections. However that may be, the dust generated during the preparation and use of these metallic colours is said, according to an authority, to have been the cause of the following symptoms: dyspnoea, vomiting, diarrhoea or constipation with colic, headaches and discomfort in the respiratory tract. A greenish line between the crown of the teeth and the gum, and often a greenish coloration of the teeth and hair and perspiration, and even nervous disorders where the worker has long been exposed to the action of the dust in question. Other authorities are, however, quite opposed to the theory which attributes these symptoms to copper or bronze. In a bronze colour factory, where the workers were coated with powder, Merkel states that no case of copper poisoning had ever occurred. He admits, however, that bronze dust is dangerous to the health, although this opinion is contrary to that expressed by the German factory inspectors when reporting upon conditions in the factories of Fürth and Nuremberg.

An English Government enquiry made by the Dangerous Trades Committee, when reporting in 1910 on bronzing in the lithographic industry, stated that the workers suffer fairly serious affections of the skin. Apart from bronzing that is to say, workers using metallic colour, will be dealt with. In hand bronzing (without provision for dust removal), when work was regular, 53 per cent. of the workers complained, and when irregular with less prolonged exposure 50 per cent. — facts which prove well the direct relation between more or less prolonged exposure to dust and the inconvenience experienced. Two groups of symptoms were noted in the enquiry: (1) nasal catarrh, dry throat, cough, slight irritation of the eyes due to dust, and (2) coppery taste in the mouth, epistaxis, nausea, sickness, headache, lassitude, anorexia, constipation or diarrhoea, with colic, and irritation of the skin due to the special nature of the dust, and liable to disappear when the worker changed his occupation. Dentists have noted swelling of the gums and pyorrhoea as well as slight stomatitis. There has also been reported a type of eczema due to the bronze powder used in chromolithography (use of bi-chromates?) and troubles caused by solvents.

In the German book-binding workshops, it was noticed in 1921 that the workers suffered from fits of coughing and very disagreeable metallic taste in the mouth due to the inhalation of bronze powder. Simon and Knuyt have, among others, drawn attention
to the risk of lead poisoning due to the use of bronzing powder containing 7 per cent. of lead, but the cases notified have been rare. The bronze powder is often present in suspension in benzene, acetone, pyroxyline, wood alcohol, amyl acetate, etc., and presents all the dangers connected with these substances (see these articles). Cases of muscular atrophy and of gastro-enteritis among workers handling bronze colours have been noted by Popoff and attributed by Casamajor to zinc, but the likelihood of this has been contested by several authors, for, as has been stated, it is generally accepted that the symptoms attributed to copper are, indeed, rather due to impurities present in the bronzing powder. The workers engaged in the manufacture of gold leaf in Vienna showed high morbidity and mortality rates from bronchitis, chronic emphysema, and tuberculosis. The morbidity rate for Austria was, according to Jehle, 42.5 as against 27.5 for workers in other industries. According to Hirt, these workers were particularly susceptible to respiratory diseases, and especially to tuberculosis.

The workers in question also incur risk of injury due to the explosion of bronze powder. Burns are in many cases localised on the hands and more especially on the interdigital space of the left hand (Ullmann).

Hygiene

Where it is impossible to ensure the installation of an effective exhaust system for dust removal, the employment of children and young persons should be prohibited on all bronzing processes. The liberation of dust during bronzing and cleaning of bronzed articles should be as far as possible prevented by the use of closed machinery provided with good exhaust apparatus. The enveloping of the joints of the cover of the machine in strips of lambs' wool is to be recommended.

The use of ventilation hoods without closed machinery, as well as that of closed machinery without an exhaust system for dust removal, gives negative results. Elimination of dust by downward suction is preferable. In chromolithographic printing good results have been obtained by a machine provided with a vacuum. The excess of the bronze powder falls through a perforated grid into a recipient placed under the machine and is drawn off by a draught into a “cyclone” separator, whence it is brought automatically to the pipe which provides the machine with bronze. When bronzing is done by hand it should be carried out on tables provided with a perforated grid and an exhaust system, or inside a box the upper part of which is covered with a flap having a space in front to allow of the worker inserting his hands and arms.

Another method is to use perforated tables with a metal grid on top and furnished with drawers in which the surplus dust escaping from the machine is collected. Dusting-off machines when separate should be provided with localised and adequate exhaust ventilation. Bronzing machines used in textile and leather factories should always be closed, provided with localised exhaust ventilation and installed in a separate workroom. The flooring of the bronzing shops should be uniform and impermeable. It should be frequently swept wet and maintained in good condition.

Wherever possible, the bronzing shop should be separate from other workshops, and should never be situated beside machinery (for instance, lithographic machines in the polygraphic industry). Workers engaged on bronzing should be suspended from work or given different work as soon as they complain of symptoms possibly due to dust inhalation. Measures of personal hygiene applicable to unhealthy trades should be enforced. In factories where bronzing is carried out on a large scale, douche baths should be installed for the use of the workers. A certain amount of time should be granted for compulsory washing before meals and prior to quitting the establishment.

In American factories respiratory masks are sometimes used (see article "Breathing Apparatus, etc."). These are in reality not very practical, are viewed with dislike by the workers, and are generally useless except in the rare event of impossibility of dust removal by means of ventilation in factories of wet processes. Working clothes and headgear, changed and washed weekly, should be placed at the disposal of the workers, who should also be provided with cloakroom accommodation.

For hygiene in bronze foundries, see articles "Copper" and "Brass".

Legislation

In Austria, the regulations of 1923 for the polygraphic industry ensure special measures in regard to bronze (see article "Printing Trades"). In France the Decree of 13 May 1893 forbids the employment of young persons under 16 years of age in bronzing factories. In Germany, special regulations dealing with bronz-
ing have been drawn up by the town of Berlin. In Great Britain, the regulations of 11 April 1912 deal with bronzing by metallic powder in the polygraphic industry and in the covering of metal leaf. In Holland the law relating to the work of women and children prohibits the employment of women and young persons in bronzing operations (Cat. B. 1), especially in the typographic and lithographic industries and the manufacture of frames (Cat. G. 10). Bronzing in the printing industry, or other occupations even where toxic bronzes are not used unless special measures are applied relating to the cubic space allowed, the height of the workrooms, etc. (section 57, 1, etc.). In Norway a Decree, dated 1920, comprises measures in regard to installation of bronzing factories in the lithographic industry. Measures drawn up in regard to brass and copper foundries are also applicable in the case of bronze foundries (see these articles).

**BROOMS**

**(Broom Corn, Sorghum)**

Broom corn is an annual grass plant which attains a height of two to four metres, the most commonly utilised species of which is _Sorghum vulgare_ with long spikes, dark brown seeds, oval in form, and ending in a sharp point enclosed in a sheath equally pointed. Sorghum, largely used in the manufacture of brooms, represents a danger for the workers who handle it, as already observed by Ramazzini.

Sorghum is chiefly cultivated in North America, Africa, and northern Italy. The manufacture of brooms from this plant is very widely developed in Italy (north) as a domestic industry. Whole families are employed in the work, buying raw material and the tools, and selling the product of their labour to wholesalers. Factory workers engaged on this type of work are, however, also numerous, and recently factory production of this kind has made rapid strides. The preliminary operations are effected by peasants, who cut and harvest the sorghum plant at the end of summer, remove the seeds by beating each stalk or several stalks at a time above a receptacle or by passing a wooden lever over the stalks laid on the ground. These operations cause the liberation of much dust. The dried seeds are used for animal fodder. The stalks are exposed to the sun for a few days, then tied in bunches and sold to broom makers.

The _manufacture of brooms_ is carried out either as a domestic industry or in factories. In the first case, the work is effected in the peasants’ homes, almost always on a mud floor without any protection against damp. In winter the work may be carried on in stables or byres. The workroom is in general overcrowded and crammed with material. Lighting is of course very defective. The operations are similar to those effected in the factories, where in general conditions are less unhealthy than in the domestic industry, though lighting is also not infrequently defective even in the factories, which may be also overfilled with material and very dusty. Factory regulations are certainly applied, but the working day is long and the wages low. In certain districts the worker has a contract by which he is guaranteed work throughout the year.

The stalks are at first bleached during twenty-four hours in chlorine or sulphur dioxide fumes in small hermetically sealed places, then exposed to the air during a fairly long period to allow of elimination of the fumes. It most frequently happens, however, that the stalks are manipulated before this elimination has been completed. A certain number of stalks are then firmly attached to the handle of a broom by means of a metallic wire or several twisted of a thin flexible branch. This operation, effected by men, calls into play all the muscles of the body, and the effort required is considerable. A certain dexterity is also necessary. The posture required for this work is bad.

The subsequent processes, mostly effected by women, consist in binding the stalks together with a large broom wire and a firm binding medium. Women and children then fix the head of the broom on to a block and cut the ends to uniform length with a hatchet. Children chiefly are employed in sorting and dividing the stalks of sorghum, flattening them and arranging them in different sizes. They also carry stalks from one workroom to another as the processes proceed. Each of these operations raises a large quantity of dust, partly composed of the debris from the sheaths which contained the seeds. Even with the naked eye it is possible to distinguish the dust from the seeds in two points. These contain fragments of the seeds completely dried so that the dust raised is almost entirely composed of such pointed debris. With a microscope it is possible to see that the film-like substance which encloses the seeds is covered with transparent and faintly coloured spikes. Application of a few drops of sulphuric acid is followed by rapid ero-
sion and the bursting of the envelope, laying bare spikes with a hard compact surface which resist erosion possibly by reason of their silicious nature. While laboratory experiments have been able to supply the explanation of the irritant mechanical action of the dust on the skin, other research effected with the extracts to ascertain whether there exists also a toxic chemical action has been without result.

It should be recalled that this grass plant is attacked by several parasites, among others by the Bacillus sorghi, Pass, the Pyrausta nubitalis Huba, etc., and certain authorities attribute the cutaneous lesions met with among workers in the industry in question to these.

**Pathology**

The fumes of chlorine or sulphur dioxide cause irritation of the mucous membranes (respiratory and conjunctival) with coughing and lachrymation. The fumes are bitter and irritant, but, short of producing symptoms of suffocation, they cannot be said to give rise to a specific poisoning and may almost be considered as without danger.

The particles of debris with which the dust is charged cause exorciations and morbid affections of the skin, the most frequent of which is erythema. If sorghum dust be applied experimentally to the face of a man for two periods of thirty seconds each, there is caused severe hyperaemia which, however, differs in character among different individuals and even for the same individual on different parts of the body, since resistance is greater where the epidermis is thick. Prolonged friction causes erythema with slight excoriation, which lasts several hours and then disappears completely until the next application.

The erythema is often complicated by more or less diffuse eczema, generally situated on the uncovered parts of the body: forearm, neck, feet (when bare). When, however, clothes are hung in the workroom, the dust may penetrate inside these and may later attack all parts of the body. The worker affected with severe itch scratches himself and thus produces a series of sores known under the name of "broom-makers' disease", which, however, disappears once the cause is removed.

Hoffer in 1918 studied twenty-five cases of erythema affecting seven American families who had been occupied in cutting brooms. He was not, however, able to satisfy himself whether symptoms were due to the sorghum itself or to parasites inhabiting it.

The operation of fixing the end of the broom with metal wire causes the formation of a callosity situated on the palmar surface of the left forefinger. Another callosity crossing the palm of the hand is due to the pressure of the metal wire and to a deposit of oxide of iron. Bad posture, particularly during this operation (trunk bent forward and chest contracted), leads to dyspepsia and epigastric pain (contraction of the abdominal organs), often obliging workers to quit their work and engage in agricultural labour, which leads to recovery. Binding the stalks of broom with metallic thread or a flexible branch causes among women furrows due to drawing through the large needle and situated on the palm of the right hand, which is, nevertheless, protected by a piece of leather. A callosity is also formed at the point in contact with the arm on pushing it in and drawing it out. All these workers have their hands covered with sores and scratches caused by the sharp points of the broom stalks, by the fibres of the sorghum, or by the metallic wire or cutting tools.

Lachrymation due to the acid fumes is transitory and very rarely gives rise to conjunctivitis which, when present, is probably due to other factors. A simple form of conjunctival catarrh, due to the dust, is very frequent and may often become chronic. No other derangements of sight have been met with, except those which might be ascribed to bad lighting. There has also been ascribed to dust and to acid fumes the outbreak of acute cases of pharyngitis, often accompanied by complications (tonsillitis, rhinitis, laryngitis, and tracheitis). In certain cases a temperature of 38.5° to 39.5° C. and other symptoms have been met with, the effect of individual reaction to inhalation of the dust. There is often coughing, catarrh of the pharynx and larynx, dryness of the throat, intense thirst, headache, loss of appetite, exhaustion, and sometimes photophobia. Fever generally lasts twenty-four hours and gives after rest and light diet. Chronic bronchitis is rare; anaemia and pallor are often due to bad hygienic conditions, and rheumatism to work on a damp floor or to draughts. Dysmenorrhoea is common amongst women.

No statistics are available in regard to the broom-making industry, which, up to the present, has been badly organised, comprising as it does very scattered workers. It is at the present time, however, in course of rapid organisation. Observations made by a certain number of medical men justify the statement that the incidence of tuberculosis does not exceed the rate reported for other country workers.
though there may exist a slight susceptibility to irritation of the respiratory passages, favoured by unhygienic conditions, sedentary life, fatigue, and malnutrition.

**Hygiene**

Breaking machines should be placed under a hood providing for elimination of the dust from the seeds and other foreign matter. All the dusty processes should, as far as possible, be carried out mechanically. Some establishments reduce dust production by the process of breaking in a wet state. The injurious effect of acid fumes can be avoided by exposing the stalls for a sufficient period to the sun and fresh air subsequent to bleaching and prior to further manipulation.

Workers should be provided with cloakrooms and lavatories and all necessary aids to personal cleanliness. Such installations should, of course, be separated from the workroom.

**Building Trade**

**General Observations**

This industry comprises quite a group of professions and trades involving various risks and calling for adequate precautionary measures. Without mentioning them all it will suffice to refer to the more important.

**Labourers** dig the foundations and prepare the soil by removing earth and stones or by filling up where necessary. **Masons** carry out the principal building work either in different materials (bricks, ashlaid stone, griststone, etc.) bound together with mortar, or constructed entirely of reinforced concrete. **Plasterers** carry out all the plaster work, facing and relacing the outside and inside walls, ceilings, cornices, and different decorative designs. Often (as in Paris, for example) the masons themselves do this work. **Tilers** and **slaters** cover the roofs of houses (with tiles, slates, zinc and lead sheeting, etc.). **Builders' carpenters** do the woodwork of large size — the construction and setting of such work as attics, floors, and staircases. On the other hand, it is the business of the joiners to carry out the smaller type of woodwork, either fixed (wainscotting, panelling, plinths, stairs, stair railings) or movable (frames of doors and windows). **Carriers** should be made also of *parquet floor layers* and *floor tilers*; **paper hangers**, who apply the papers to the walls with a brush, the printed papers being cut into suitable lengths and backed with paste; **decorators**, who carry out the painting work inside the houses; **plumbers**, who lay the water and gas pipes, and sometimes those for central heating; **electricians**, who do the wiring for electric lighting, and sometimes for power, etc.

**Sources of Danger**

All these operations are not attended with the same degree of risk to health.

The most important risks for masons arise mainly from work in the open air and from weather conditions, and are increased by the fact that modern technique allows of work being done in cold weather. Among other injurious factors the constant standing and the carrying of the loads must be mentioned. While means of transport and mechanical lifting are more and more used there still remains a certain number of unavoidable manipulations. Carriers of lime and stone, for example, have still sometimes to carry weights of 80-90 kg. up to the top of several stories.

The nature of the materials handled also plays an important rôle in the pathological effect produced: work in stone and cement notably gives off different dusts (see articles "Cement", "Lime", etc.).

Mention must be made of certain *special risks*: of lead poisoning among those covering the roof with lead, painters and decorators, etc.; risk of carbon monoxide poisoning among those watching over building operations when fires in open brasiers are kept going at night for speeding up the drying of the rooms (Leymann). Paper hangers are also exposed to special risks, especially when the hanging is preceded by the scraping off of old papers, which is a very dusty operation if care is not taken to wet the paper well beforehand. Sand-papering is also an extremely dusty operation. Men-
tion must be made, too, of the risk of poisoning by lead or arsenic when the papers contain these. Risk of accident, arising from work on scaffolding (fall of material, falls of workmen), must not be omitted. Severe accidents, it is true, have diminished since legislation has dealt with accident prevention, but the possibility of buildings collapsing remains, which mostly happens as the result of heavy rain on unfinished buildings; and particularly there is to be reckoned with the possibility of slight injuries, bruises and cuts, etc., giving rise to whitlows and inflammations.

**Statistics**

The statistics of the Leipzig Sickness Society give interesting information relating to the morbidity and mortality of certain groups of workers in the building industry:

**DAYS OF INCAPACITY FOR WORK FROM SICKNESS RATES RELATING TO 100 WORKMEN DURING ONE YEAR**

(All the Rates are for “All Ages” Relate to 100 Workmen; the Others to 100 Workmen from 25-34 Years of Age)

Ascher reports (1905) that, among 5,685 masons who were members of the Sickness Society of the Berlin Masons, 2,181, or 38.2 per cent., had recourse to sick pay on account of sickness or accident which could be classed as follows: external lesions, 18.3 (more than half of which, 55, were accidents from work); respiratory diseases, 20.7; rheumatism, 7.6; diseases of the blood, 2.6; diseases of the digestive tract, 7.6; nervous diseases, 5.08; diseases of the genito-urinary tract, 0.9; diseases of the skin, 57; acute infectious diseases, 6.

The old statistics of Hirt showed that of 1,038 masons 34 per cent., suffered from pulmonary diseases, of which 12.9 per cent. were tuberculous.

In another set of statistics Kober and Hayhurst give the following percentages of the different causes in 2,399 deaths of stonemasons and bricklayers:

- Tuberculosis, 13.9;
- Pneumonia, 8.2;
- Other respiratory diseases, 2.5;
- Diseases of the heart, 13.2;
- Diseases of the digestive tract, 2.3.

Hoffmann’s statistics relating to 1,467 deaths from all causes show a mortality rate of 31.1 per cent. for diseases of the respiratory tract, that of tuberculosis being 17.7 per cent. The death rate from diseases of the urinary tract is 13 per cent. and from heart disease, 10.1. Gher-
ardi published, in 1921, the results of a study, covering a period of twenty years, 1897-1916, relating to 111,920 deaths among masons, that is, an average of 5,596 annually, which gives a mortality rate for masons of 16.1 per 1,000 as against 21.1 for all professions (including infantile mortality) or 16.7 per 1,000 for males in all professions above fifteen years of age. It is seen that mortality from all causes is less than the general average and, according to this authority, it is the same also for acute diseases of the respiratory tract. He does not give figures of deaths from specific causes.

Hoffman gives a mortality rate for accidents of 9 per cent., that for journeymen being 3.8 and for apprentices 6. For the period 1897-1916 Gherardi shows for Italian masons the following mortality rate per 100,000:

<table>
<thead>
<tr>
<th>Accidents</th>
<th>Falls</th>
</tr>
</thead>
<tbody>
<tr>
<td>Males over 15 years ..........</td>
<td>42.8</td>
</tr>
<tr>
<td>Masons ..................</td>
<td>39.3</td>
</tr>
</tbody>
</table>

While deaths from falls constitute 38.4 per cent. of cases of death from accidents of all kinds for males above fifteen years, this figure for masons rises to 56, that is, nearly a half more.

Deaths from falls, however, increased in the second decennial period under review (1907-1916), because at Milan for the period 1896-1906 (eleven years) they numbered 59 deaths, that is, 5.4 per year, and for the period 1907-1912 (six years) there were 92 deaths or 9 per year.

The number of accidents from falls is still higher if the non-fatal cases be included.

Cases of poisoning by carbon monoxide have been reported in various German inspectors' reports (1900, 1908, 1913) as occurring among watchmen. Among paper-hangers Hoffmann has shown that of 319 deaths in this class 107 or 33.5 per cent. were due to tuberculosis, 11.1 to other lung diseases, which gives a total of 44.6 per cent, for diseases of the respiratory tract. The normal percentage to be expected should be 23.6 per cent.

**PATHOLOGY**

Exposure to inclement weather conditions brings on maladies due to cold; neuralgias, chronic articular and muscular rheumatism, lumbago, sciatica, etc., especially in old workers. Occurrence of respiratory diseases, bronchial catarrh, asthma, tuberculosis, is further favoured by the local action of dusts.

The dangers from heat stroke are much less frequent.

The continuous standing favours the development of varicose veins, phlebitis, etc. According to Descamp, tilers and slaters show, as a result of work done in the open air at a certain height and in a bent position on slippery surfaces, a certain numbness of the legs accom-

panied by loss of sensitiveness and muscular tremor. In young workers these symptoms disappear when they get to the ground, but in older workmen a kind of paralytic weakness affects the lower limbs and renders them incapable of climbing. According to information from the local sickness societies of Berlin, these workmen have to give up between forty-five and fifty years of age.

The position assumed may involve other lesions: synovitis, inflamed bursae, etc.

Lifting and carrying weights that are too heavy causes especially acute hernias due to strain. It does not appear, however, that these are more frequent among the masons than among others. It is not so though with the labourers, which is due to the fact that they have generally a less sound constitution. Mention should be made also of the development of bruises and ulcers on the shoulder, callosities, formation of rhabades, and, as the result of always carrying loads on one side, changes in the shoulder blade, the upper part of the neck and the thorax.

Working the stone, use of cement and lime, and the dust produced cause various kinds of lesions. Of these, dermatitis ranks first (cement workers' itch). While the predisposing causes are mainly of a physical nature (humidity, maceration of the horny layer, dusts, various traumatic agencies favouring abrasions and excoriations), the determining causes are essentially due to the alkaline earthy bases of the lime, the sulphuric acid, and the alumina in the cement. The lesions are situated on the hands, the interdigital spaces, the wrist, and, more rarely, the palm; the lesions sometimes may extend to the forearm and chest. They may start with isolated or confluent red plaques, showing an infiltration of the derma and papillary layer with oedematous itchy swelling. In the second stage small isolated vesicles, sometimes confluent, develop, changing into dry pustules, grey or yellow, and later followed by desquamation. The nails show transverse fissures owing to the detachment of the superficial layer from the bed. As complications lichenisation and purulent dermatitis have been found. This condition lasts for a long time, treatment is rather difficult — the more so as the disease proceeds by successive attacks (Artom).

Without giving figures, Martial (1906-1908) states with confidence that a third at least of the persons handling line and cement show cutaneous lesions, and Besnier (1907) insists on the
fact that dermatitis is much more widespread than is believed, as only a small proportion of those affected for medical treatment, the doctor rarely being called on to treat the lesions.

Conjunctivitis is observed as a result of particles of cement, lime, stone, iron, or wood getting into the eyes. The pulmonary troubles found are due to the dust setting up pneumoconiosis among dressers and polishers of stone. These anatomical changes are characterised by a chronic interstitial irritation, which leads to the formation of fibrous tissue, the lung being sown with numerous nodules the nature of which depends on the kind of dust involved. This is the reason why those who work with the chisel on fine sandstone are more predisposed to tuberculosis than those who work on granite, of which the dust is heavier.

It is not necessary to describe in more detail the morbid symptoms set up by the poisons.

In the development of the different morbid troubles account must be taken of individual predisposition. This explains why the morbidity and mortality among masons, despite the risks, does not reach the general average. Only strong young men take up the work, entering the trade young and developing and strengthening their physique (Gherardi). It is remarkable how different the conditions are in the case of the labourers, who are nevertheless subjected to the same influences. Teleky explains this by the seasonal nature and uncertainty of the work adopted by persons without professional instruction, of poor constitution, and low social level, who have not been able to find employment in other trades.

A factor aggravating the pathological findings may arise from the abuse of alcohol and tobacco. It is a regrettable fact that the number addicted to alcohol among the labourers is double or treble that of the average. Interesting research has been effected in relation to masons’ work, on the lines of scientific management with motion study; it will suffice to cite the classic work by Gilbreth and the recent studies (1927) of G. Lehmann and Baader, etc.

**HYGIENE**

Preventive measures are essentially of a general nature.

As means of protection against bad weather conditions, installation of wooden sheds, capable of being heated when necessary, is recommended. They can be used by the workmen for taking their meals, changing their clothes, and washing.

Protection against damage caused in carrying heavy loads can be best obtained, on the one hand, by using as far as possible mechanical means of lifting and carrying and, on the other, by placing a limitation on the weight to be carried by the workmen. The neck and shoulders should be protected by a cloth.

Damage from dust can be partly avoided by moist methods of working (sawing and polishing stone) or in working on the lee side of the wind. Further, wider and wider use of automatic apparatus for making cement and mortar will much reduce the risk caused by the dust of these substances.

Scraping down old painted wallpapers should also be carried out by wet methods and the usual precautions adopted in regard to the danger of poisoning by lead, arsenic, chrome compounds, etc.

To guard against poisoning from carbon monoxide the use of open braziers for drying new houses should be prohibited, or allowed only under certain conditions.

Means for cleanliness (wash basins, soap, etc.), medical supervision of the personnel, instruction of the workers as to the professional risks and dangers run (by issue of leaflets and warning notices), as is done by certain German associations, are specially suitable measures. All measures of safety against accidents (on scaffolds, etc.), must be taken.

**LEGISLATION**

In Czechoslovakia an Act was passed on 7 April 1927.

**France:** Limitation of the weight of the loads (Decree of 29 December 1909). A Decree of 9 August 1925, amended 10 March 1927, lays down the measures of health and safety for persons employed in building yards.

**Germany:** Employment of women is prohibited (Police Orders in various States); the use of open braziers is prohibited (Orders of 4 July and 10 December 1913); sanitary supervision of the yards by factory inspectors is demanded. Section 120 of the Labour Code contains regulations in regard to building sheds and yards. In 1925 a draft Order was issued for the protection of persons employed in building construction covering the following points: prevention of accidents, welfare, drinking water, first aid, etc.

**Great Britain:** The Building Regulations dated 21 June 1926 are in force.
In the Irish Free State an Order affecting the building trade was issued on 10 November 1926.

The Act of 18 August 1924 and the Grand Ducal Decree of the same date deal with measures of health and safety for persons employed in building in Luxembourg.

Notification of the following conditions and diseases is obligatory in the Netherlands: synovitis and bursitis of the knee in masons and slaters, diseases of the skin, dermatitis and eczema, inflammation of the joints, tendons and subcutaneous cellular tissue, ulcers of the cornea and conjunctiva.

On the subject of compensation for dermatitis, see article "Skin Diseases".

Compensation for miners' phthisis in South Africa was extended so as to cover masons working outside the mines in 1926.

***

Buttons (Manufacture of)

RAW MATERIALS

Buttons began to be generally employed as fastenings as early as the 15th century. They are made of metals (brass, iron, gold, and silver), jewels, filagree, ivory, horn, bone, mother of pearl and other nacreous products of shell fish, vegetable ivory, wood, glass, porcelain, paper, celluloid, and many other artificial compositions. Ivory buttons are amongst the oldest of all. Glass and porcelain buttons are chiefly made in Bohemia. Buttons of vegetable ivory, which now form one of the most important branches of the American button industry, were first made in 1859. The freshwater pearl button industry has developed greatly towards the end of the 19th century, especially in the region of the Mississippi, and these buttons, together with ocean pearl buttons, represent over 50 per cent. of all the buttons manufactured in the United States.

TECHNOLOGY

Buttons were first fashioned separately by skilled artisans, but later, to reduce the cost of production, they were stamped out in dies instead of being cut, engraved and ornamented by hand.

Vegetable ivory or African ivory or corozo nuts are the names given to the seed of the fruit of the ivory palm (Phytelephas macrocarpa) often known as the ivory nut. It resembles genuine ivory in texture and colour, and is about the size of a hen's egg. These nuts are first cleaned by being made to revolve in a cylindrical drum, which permits the dust and shells to drop down. This drum revolves in a closed envelope and is emptied from time to time. The shells are used as combustibles and the nuts pass to a circular saw, subsequently to lathes, and later to another revolving drum for pouncing. They are then polished with sawdust, and bleached with hydrogen peroxide. The dust and waste are sometimes utilised as manure. When used for making beads, the material is first dampened. Beads and buttons are cut out on lathes and often engine-turned.

For the manufacture of buttons, studs and ornaments from freshwater pearls, the shells of molluscs are used. These are cooked and freed from fleshy parts, sorted into sizes and soaked for several days to render them less brittle. While still wet they are sawn into blanks and subsequently cut into discs, bored, planed, faced, ground, polished, and domed.

Bones coming from America are very often boiled, prior to export, but nevertheless they still exhale a very characteristic odour. The work on these involves: cutting into strips of required thickness by means of circular saws, work on a lathe (cutting out), boring, polishing in a drum, sorting, arranging in sizes, and packing.

STATISTICS

Button makers are one of the occupational groups included in a study of workers exposed to different kinds of dust carried out by the Prudential Insurance Company of America amongst workers exposed to general organic dust.

Mortality statistics of button makers in the United States, based on 127 deaths from all causes, show 48 or 37.8 per cent. to have died from consumption as compared with 14.8 per cent. for males in the registration area, while there were in addition 14 deaths, or 11 per cent., from other diseases of the lungs. Of 390 deaths among button workers in Vienna, 1895-1905, 272, or 69.7 per cent., were due to tuberculosis, and an examination of 150 pearl button workers conducted by Teleky in 1907 revealed 93 only to have normal lungs. (See also article "Mother of Pearl").

SOURCES OF DANGER

Mortality statistics for respiratory diseases would appear to indicate that the trade under consideration involves a serious health hazard, but it must
be remembered that the very considerable labour turnover plays an important role in this industry. Inspection of a sawing department (pearl buttons) revealed the belts, machines, walls, ceiling, clothing, and even faces of the workers to be covered with fine white pearl dust, even with the existence of suction devices for dust removal.

An extremely fine dust (finer than that produced in sawing) is produced by the machines used for cutting out the buttons, and drilling holes in them, and also during the polishing; but here exhaust hoods effectively installed afford adequate protection. Engine-turning of vegetable ivory (beads) is done on lathes and gives rise to fine dust, which calls for the installation of a good exhaust hood. The inhalation of the fine dust thus produced predisposes to diseases of the respiratory organs. Ivory dust, like horn dust, is composed of sharp, angular particles, and therefore very harmful.

Amongst female workers and minors engaged on the production of pearl buttons, dyspeptic and catarrhal affections of the respiratory passages, with subsequent more serious developments, have been noticed and ascribed to dust inhalation. Further, vegetable ivory lending itself particularly well to application of colour, its manipulation offers additional risk from the use of toxic colouring matters, where these are used.

In 1907, De Marbaix noted amongst the workers engaged in a bone-button factory in Antwerp that a special disease ("bone-button makers' disease") affected all the workers without exception. All workers inevitably contracted one attack of this disease which appeared to confer certain immunity, and which consisted in benign inflammation [infection?] of the fingers, healing subsequent to invariable suppuration. The workers, especially those engaged on machine work, continually suffer from cuts, scratches and superficial sores on the fingers, caused either by the machine or, more frequently, by the numerous ragged fragments and fine edges of the bone. The workers have, besides, their hands and, in fact, their whole bodies powdered over with an impalpable bone dust, which constantly floats in the atmosphere of the factory. At a given moment one of the scratches in question becomes infected, giving rise to the affection known as "bone-button makers' disease".

The workers in question also run the risk of exposure to infectious diseases (especially anthrax) in the event of the raw material coming from an infected animal.

The work of scouring metal buttons involves exposure to the risks attending this operation.

Finally, an important factor in fatigue is provided by the following circumstances: in the last few years the manufacture of buttons has come to be almost entirely automatic. Nevertheless, workers skilled in rapid work are still required for making certain buttons (especially mother of pearl). It is here of interest to recall Frois' remarks regarding the movements of a woman worker engaged in making buttons on a small lathe. This worker made approximately 1,776 buttons per hour, or one button every two seconds.

The worker in question attained this speed by effecting a series of very rapid movements: one of the right foot from right to left, to bring forward the small wheel for smoothing the face of the button, and simultaneously a movement of the right hand for placing the button on the chuck; another of the left hand for bringing forward on the chuck a ring to hold the button in position. These three movements have a certain range and demand perfect dexterity. In one hour the worker effects 1,776 movements of the right foot and in the same time 1,776 movements of the right hand, and 1,776 movements of the left hand — totalling three simultaneous movements every two seconds. Reckoning also the return movements, this means that the worker effects three simple movements every second.

**HYGIENE**

The aspiration and removal of dust should be specially aimed at in this industry. It would be possible in certain instances to substitute wet processes for dry.

Some practical difficulties are encountered in connection with dust elimination as regards sawing operations, in course of which the workers are exposed to large quantities of sawdust which are with difficulty removed by suction, since with the best protective devices some dust escapes. It is advisable to disinfect bones especially those coming from countries where anthrax infection is rife, and where disinfection has not been effected prior to export.

Adequate precautions should be adopted during scouring of metal buttons.

The makers of metallic buttons use presses, punches and other tools which
stamp out the metal by blows or by successive pressure.

The bad effects of this work are chiefly connected with noise and shock. It is therefore advisable to set up such presses and punches on foundations free from the walls of the workroom, to limit the number of such apparatus, and to provide them with wooden or rubber shock absorbers or insulating devices calculated to deaden the shock.

The work should be so organised as to prevent undue fatigue of the women workers occupied at lathes. The working day should be so arranged that the very rapidly repeated movements demanded by the machine work may not give rise to chronic fatigue and overstrain.

LEGISLATION

Amongst the countries which have drawn up provisions offering protection to workers employed in the button industry may be mentioned the following:

Belgium: exclusion of young persons under 14 years of age from the manufacture of metal buttons (scouring departments).

France: exclusion of young persons under 18 years of age from work on machines for making of metal buttons as well as presses and punches with automatic working, when dust is disseminated freely throughout the workshop.

Italy: exclusion of boys under 15 years of age and girls under 21 from sorting of bone and horn for the manufacture of buttons, etc.

Spain: exclusion of boys under 16 and girls under 21 from the manufacture of buttons; etc.

Certain legislative provisions provide for the exclusion of young persons from the work in question by the inclusive formula: "from all operations involving dust production".

Prof. G. M. Kober
(Washington).
Cadmium

French: Cadmium. — German: Kadmium. — Italian and Spanish: Cadmio.

Cadmium (symbol Cd, atomic weight 112.4) is a white malleable and ductile metal with a density of 8.65. It melts at 320° C. and boils at 778° C.

Cadmium when heated in the presence of air burns and gives a yellowish-brown oxide. It dissolves with liberation of hydrogen in sulphuric hydrochloric and acetic acids, forming the corresponding salts. Salts of cadmium when dissolved give a yellow precipitate of sulphur of cadmium with hydrogen sulphur and the alkaline sulphurs.

Cadmium is found in the soil in the state of sulphur (greenockite); it is present with zinc in zinc ores (Silesia, Freiburg, Derbyshire, Cumberland), the ores in question containing also lead, iron, and sometimes arsenic.

**INDUSTRIAL OPERATIONS**

Cadmium distils first when zinc ores (see article "Zinc") are treated, and becomes condensed in the extensions of the retorts. The first dust (cadmia) deposited in these extensions is collected and dissolved in sulphuric acid. A current of sulphuretted hydrogen then precipitates the cadmium in the form of sulphur, but the precipitate contains a little copper and zinc; in order to eliminate this, the sulphur is dissolved in hydrochloric acid and treated with ammonium carbonate. It can also be got from ashes of zinc.

Metallic cadmium serves in the preparation of welding materials with a low melting point and in the manufacture of different derivatives, particularly sulphur derivatives. It is found in certain kind of brass.

Cadmium sulphur or cadmium yellow (CdS) is used in the painting industry for its beautiful colour. It has a high covering power and resists light and damp very well.

A solution of cadmium nitrate is prepared by dissolving in nitric acid cadmium quite free from lead. The solution is precipitated by carbonate of soda; then the carbonate of cadmium thus obtained is transformed into sulphur by means of a solution of sodium sulphide. For the latter operation there is also used, but less frequently, a current of sulphuretted hydrogen.

Different colours are obtained; straw, lemon, orange, red, etc., according to the temperature at which the precipitations and the concentration of the reagents are effected.

Cadmium yellow cannot be mixed with colours with a lead basis, for formation of lead sulphide produces blackening. Its high cost prevents it being used except in art painting.

**Cadmium iodide** is used in medicine and in photography. It is prepared by digesting iodine and cadmium with water.

Austria, Germany, and the United States occupy the first place as regards the production of cadmium:

**PATHOLOGY**

Marme quoted by Tracuski (Silesia) has already drawn attention to the fact that cadmium causes the following disorders: gastro-enteritis, emaciation, fatty degeneration of the heart and the kidneys.

Erben and Kober hold that the action of the salts of cadmium is analogous to that of zinc salts. Cadmium was considered by Sigel to be the cause of brassfounders' ague, but this theory has been abandoned, as likewise that of Gadamer, which attributed to cadmium the forms of irritation of zincfounders. The data provided by this author, as well as by Erben, were based on a report by Tracuski, according to which fumes from zinc factories were said to contain 3 per cent. of cadmium. In fact they contain up to 5 per cent.
According to Schwarz and Otto the sulphate, the carbonate, and the oxide of cadmium are said to give rise to the following symptoms among animals: marked emaciation sometimes followed by death, modification of the blood picture, diminution of the haemoglobin, of the number of red cells, of the polymorphonuclears, increase of the lymphocytes. Irritation of the conjunctivitis and the mucus of the respiratory passages has been noted.

An interesting case of poisoning by cadmium was reported in 1914, in Saxony, in a factory where cadmium plates for electric mines were made. One of the workers engaged at the press complained of weakness, lack of appetite, and nausea. This condition lasted for three weeks and was attributed to the presence of salts of cadmium oxide in the stomach, absorbed by dust inhalation or by absorbing with food. Dust samples were sent to Dresden for analysis. The analysis proved that the dust was not solely constituted of metallic cadmium, but also of traces of cadmium oxide and insoluble cadmium salts; but present to such a feeble extent, however, that they could not injure the worker's health.

Stephens (1920-1921) found cadmium in the liver of an old Welsh workman whose case had been diagnosed as lead poisoning, though the characteristic colic, peculiar to the latter poisoning, was lacking. The liver contained in fact 0.120 grm. of cadmium per kilo, and 0.05 grm. of zinc. The presence of lead was not discovered.

In Germany there were recently reported cases sometimes fatal in the course of the production of cadmium; these cases were due to arseniuretted hydrogen (Fischer).

A fatal case of poisoning by cadmium fumes was reported (Legge) in Great Britain in 1928. It affected an engineer in a colour factory, who had been in the habit of receiving the metallic cadmium in sticks the length of a pencil. A few months before the accident the cadmium arrived in ingots, which had to be melted in a crucible, heated by gas and not connected up to a ventilation pipe. Two workmen assisting him became seriously ill also, but recovered later. The symptoms complained of were the following: dryness of the throat, headache, rapid pulse, nausea, brown colour of the urine, shivering.

The autopsy showed signs of congestion of the larynx, the trachea and the bronchial tubes and acute inflammation of the stomach and intestines, fatty degeneration of the heart and liver, haemorrhagic inflammation of the spleen, and inflammation of the kidneys.

Kochmann recently (1925) studied the pharmacodynamic action of cadmium. which, according to his research, would appear to possess properties analogous to those of zinc and mercury; it is principally astringent, caustic in high concentration and inductive of hyperaemia.

Otto has continued his experimental research on cadmium oxide at the stage of production making cats inhale air containing 2 mg. of cadmium fumes per litre for from 2½ to 15 minutes and during 10-16 days.

The experiments have proved that the fumes of cadmium oxide when inhaled cause fatal pneumonia or broncho-pneumonia due to the local irritant action of cadmium. The latter resembles zinc very much, but while zinc fumes are, particularly in the brassfoundries or in the course of autogenous welding, notoriously the cause of brassfounders' ague, they do not exercise any serious local action. It is therefore to be recommended that health authorities should require effective local exhaust ventilation in all cases in which the liberation of cadmium fumes is to be feared. The question of whether certain respiratory troubles (catarrh, pains in the chest) met with amongst zincfounders should be attributed to cadmium is one which calls for further detailed study.

HYGIENE

Although cadmium only plays a secondary role in industry, the fumes and dust of this product ought to be removed wherever they occur as in all metal foundries.

BIBLIOGRAPHY

**Calcium**

French and German: *Calcium*. — Italian and Spanish: *Calcio*.

This metal (Ca) is very widely distributed in the state of carbonate (limestone, marble), sulphate (gypsum), fluoride, silicate, phosphate, etc.

It is slightly yellowish in colour, ductile and malleable, and oxidises easily on exposure to damp air. It is prepared by electrolysis from chloride of molten calcium. The chloride is decomposed in a carbon vat which serves as the anode; the cathode is represented by steel wires placed vertically along the axis of the vat, and it is to these wires which the metal droplets adhere firmly. By raising the cathode slowly there is obtained, by means of successive deposits, a large stick of calcium.

During the war, calcium hydride, or hydroth, was prepared and used in the manufacture of hydrogen for aircraft. In the metallurgical industry it serves for dioxidising and fixing nitrogen. It is used in the manufacture of certain alloys, etc.

Amongst these compounds the most important is oxide of caustic lime (see article "Lime"). Less important from a practical point of view is slaked lime (Ca(OH)) which, however, exerts a caustic action on the mucus membrane (especially the conjunctiva).Arsenate of calcium is at present widely used in the campaign against vegetable parasites. The chloride exerts a narcotic action on the mucous membranes. Nitrate is used in the manufacture of calcium cyanamid and artificial manures in general (see article "Fertilisers").

Another compound, calcium carbide, is produced by one of the oldest electrochemical processes, dating from 1894 (see article “Calcium Carbide”).

Calcium is not of itself of any importance industrially. On the other hand, its compounds are of importance (basic slag, see that article).

Three cases, one of which was fatal, due to sulphuretted hydrogen have been reported in a German tannery where a vat had been filled by lactic acid instead of sulphuretted compound of calcium.

---

**Calcium Carbide**

**TECHNICAL DATA**

Calcium carbide, a solid dark-grey substance, is prepared by heating in an electric furnace a mixture of lime and of coal (CaO-3C = CaC2-CO). Anthracite of good quality or coke from a gas or metallurgical factory is used. The lime must be very pure (97% of CaO) and the constituents must not possess more than a very slight phosphorus content.

The raw materials are, on their arrival at the factory, stored in silos. Before mixing they are submitted to mechanical crushing. Sixty parts of lime and forty of coal are mixed with the shovel or mechanically; for instance, by allowing the coke and lime to pour into a large pipe on issuing from the measuring hopper, a slight vacuum being maintained. Separation of dust is often effected by mechanical devices.

The furnaces are charged either by shovelling after the mixture has been placed on the charging hearth or by skips, or through chutes leading directly into the furnaces. The latter are always situated in large shops, very high and well-ventilated, for they give rise to great heat and liberate much carbon monoxide. Electric arc furnaces using alternating single, two and three phase current are in principle composed of a sheet-metal interior, lined with refractory material composed chiefly of magnesia. The lower electrodes of graphite are embedded in a cast-iron hearth and are level with the surface of the lining covering the bottom of the interior of the furnace. The upper electrodes, likewise of graphite, dip down into the interior of the furnace, being maintained there by a system of suspension, which allows of their height being regulated.

While the pressure on the furnaces varies between 75 and 95 volts, the current strength is on the contrary enormous — 30,000 to 80,000 amperes, and even over that — this explaining the great heat given off. Since the pressure must remain constant, and there is interfered with by the wearing down of the electrodes, it is necessary to provide for adjustment every minute. Every pair of furnaces must, therefore, be supervised by a workman, who, as soon as pressure falls, sets in motion a small motor to lower the electrodes. The worker in question works in the
Transformer shop and is not exposed to dust, but his task is exhausting on account of the high degree of attention demanded. Many factories have now installed an automatic adjustment device for the furnaces.

The majority of furnaces are open, but certain types (the Norwegian, for instance) are closed and provided with exhaust ducts for the carbon monoxide.

Production is continuous; the mixture of the lime and the coal is constantly fed into the furnace from the top, and periodically (eighteen times in the twenty-four hours on an average) the carbide is tapped issuing from the tap hole situated in the lower part of the furnace. At other times this hole is obstructed by solidified carbide. When tapping takes place, the worker approaches the hole with an iron bar led to earth by large conductors. A sparking discharge is set up between the iron bar and the furnace, and the plug of carbide is reduced to a liquid state in a few minutes.

The liquid carbide flows into a cast-iron mould as soon as hardening takes place, is cast in a shell and separated from the mould. Later, the shell is broken, and the carbide can be broken up with a pickaxe into large pieces, which are transported to crushing machines, generally of the revolving cone type.

The pieces of carbide are no longer done by hand, but by using two kinds of apparatus: the drum (a sheet-metal cylinder revolving round an inclined axis having holes of increasing diameter) or a kind of shock transporter with an apron, perforated in the same manner. Cast-iron ducts receive the pieces of carbide and convey them to metallic barrels, which are hermetically soldered as soon as filling is effected.

These operations raise great quantities of dust which should be removed by suction and cast outside.

Carbide of calcium is found on the market in three forms: unprepared, crushed and sorted, and granulated.

This product has only two industrial uses, but these are very important: preparation of acetylene (see that article) and manufacture of calcium cyanamide (see also that article). The market value of carbide depends on the volume of acetylene liberated per kilogram of the product in presence of water. Ordinary carbide is generally "at 300 litres". The volume of acetylene given off is carefully checked in the laboratories of carbide factories, as well as the phosphorus content, which must be very low to prevent formation in presence of water of phosphoretted hydrogen, which is poisonous and liable to spontaneous ignition.

Sources of Danger

Danger is mainly connected with impurities contained in this product: phosphoretted hydrogen (which according to Jokote is present in acetylene obtained from American carbide in a proportion of 0.04 per cent., and according to Lunge and Cedernkreutz may attain the value of 0.06 per cent.), ammonia, sulphuretted hydrogen, acetylene (in presence of moist air), silicon carbide, ferrosilicon, sulphur, and calcium phosphorus. During production, the workers attending the furnaces are exposed to the risk of carbon monoxide poisoning.

Apart from injury to the mucous membrane by the carbide (caustic) and to the skin (as a result of prolonged contact: skin eruptions, eczema, ulcerations), experts on the subject assert that the carbide industry when effected under good conditions is not now more dangerous than other industries.

Attention must, however, be drawn to the risk of explosion when soldered receptacles are opened, as these often contain acetylene under pressure which ignites at 480° C. The soldering medium melts at 180-230° C., however. It is therefore necessary to guard against using unduly hot tools or a naked flame. Egli and Rust quote the case of a worker whose face was burnt by an acetylene flame during soldering of a tin box containing carbide.

Pathology

Occupational dermatitis due to carbide was reported for the first time in 1913 by O. Sachs, of Vienna, affecting a worker in a carbide factory for the preparation of acetylene gas.

Carbide causes two kinds of skin lesions: dermatitis due chiefly to handling of hard and dry carbide and then lesions in the form of necrotic ulcers with clearly marked edges. When the hands come in contact with the liquid a well-known reaction follows, causing ulceration of the skin, analogous to that caused by caustic lime. The lesions are chiefly situated on the pads of the fingers, where there are frequently found scars of lesions already healed. The use of leather gloves is not advisable, for the carbide attacks them very rapidly and comes in contact with the skin.

Hygiene

Besides general measures of hygiene, it is advisable to install the tap hole, which gives off great heat, below the
level of the flooring of the workroom. Certainly the special conditions in this industry do not permit of the work being effected in perfectly healthy surroundings, yet individual precautions can effect remarkable improvement: prevention of the escape of dust and gas. The workers should wear smoked glasses. Adequate protection of the mouth and nose should be provided (a handkerchief damped with pure water, since the workers are averse to wearing masks). Good sanitary installation to permit of personal hygiene is necessary.

Workers engaged in handling carbide should protect their hands by application of perfectly anhydros pure American vaseline, which is applied to the hands before putting on gloves made of sailcloth. Leather gloves should be absolutely forbidden. Receptacles containing carbide should be stored in dry, well-ventilated places. Precautions against fire should be adopted.

**LEGISLATION**

See article "Acetylene".

In Switzerland injury caused by calcium carbide is compensated in the same manner as accidents.

***

**Calcium Cyanamide**

French: Cyanamide de calcium. — German: Kalkstechstoff or Kalziumcyanamid. — Italian: Calciocianamida. — Spanish: Calcio cyanamida.

**CHEMISTRY**

The commercial product known under the name of nitrolime is a lustrous greyish-black powder with an oily feeling to the touch — not dusty — partially soluble in water, which contains about 57 per cent. of calcium cyanamide (CN Na or Ca CN.) 21 per cent. of quicklimes, 14.18 per cent. of carbon; about 10 per cent. of various impurities of little importance, derived from chlorine (up to 6 per cent. of calcium chloride, added at the time of its manufacture), iron, salicylic and phosphoric acids, acetylene, phosphuretted hydrogen, and sulphuretted hydrogen, etc. The total content in nitrogen is from 17-20-24 per cent., in calcium from 40-42 per cent., corresponding to 56-57 per cent. of calcium oxide.

In a moist atmosphere the nitrolime gives off small quantities of ammonia; acted on by hot water it gives rise to dicyanamide (C, N4 H4) and other products. Under the action of steam under pressure all the nitrogen in the lime is converted into ammonia, and it is on this reaction that the industrial process for the manufacture of ammonia and its salts is based. Calcium cyanamide is a valuable manure, which in the soil is decomposed into ammonia and nitrates under the action of warmth, humidity, and the acids of the humus and bacteria.

**PRODUCTION**

When a current of nitrogen is made to pass over calcium carbide at high temperature the salt calcium cyanamide is formed. Industrially, carbide of calcium in powder form is introduced into a vertical furnace built of refractory materials and provided with a cover. The broken-up carbide is placed in a retort in the middle of an electric furnace and transformed, by means of heat generated by the resistance, under a current of pure dry nitrogen obtained by the rectification of the liquid air through pipes arranged in the lower part of the apparatus. The nitrogen can also be obtained by making the air pass over copper at red heat. The reaction being exothermic, it is sufficient to begin by heating to 700-1000° C. for some time. The cyanamide is dissociated above 1360° C. It comes out of the electric furnace in the form of a compact black mass which then requires to be crushed and pulverised in ball mills. Hydration follows with water (5-9 per cent.); it is then granulated or oiled (2-4 per cent. of heavy mineral oil) and bagged or packed in cans of corrugated sheet metal.

When the crude cyanamide is to be used as a manure, the operation of finishing is practised with the object of decomposing any traces of carbide remaining in it and converting it into an oily powder easy to handle. The dicyanamide (C, N4 H4) has the form of colourless inodorous crystals, almost insoluble in cold water, soluble in boiling water; melting point 16° C. It is employed in the manufacture of explosives, of colouring agents, cyanures, urea, salts of hydrazone, etc.

The cyanamide is used as a manure, for the manufacture of cyanures, urea, guanidine, etc., and as a constituent of the powder applied in the tempering of metals.

**TOXICITY**

Accidents from calcium cyanamide do not occur, except when the product is in the form of dust, whether in the course of manufacture, packing,
transport, or in its use in agriculture. Its effect is exerted at first on the skin and exposed mucous membranes. The fine dust can, however, like all fine dust, reach the respiratory tract, but only a small portion reaches the deeper recesses, as most of it gets deposited on the mucous membrane of the nose and large bronchi, whence it is coughed up. A very small quantity is swallowed and reaches the intestinal tract.

The action of cyanamide is due mainly to the action of two of its constituents, lime and cyanamide. The lime irritates the tissues, in consequence of a dehydrating action and power of coagulating the albuminous substances. The lime irritates the tissues, in consequence of a dehydrating action and power of coagulating the albuminous substances with concomitant heat production. The epidermis is raised and softened, and this process, favoured by a preliminary or concurrent moistening of the skin by humidity (rain, mist, sweat, mucous secretions), is rather severe when the epidermis has disappeared or in the presence of small wounds, cuts, and scratches. This action is, perhaps, due to ammonia liberated on the decomposition of the nitrolime by heat. When nitrolime is inhaled as dust, inflammation of the bronchi and bronchioles results.

The researches of Gergens and Baumann, Lange, Coester, Stritt, Koelsch, Hesse, and others have elucidated the toxicity of cyanamide by subcutaneous injections of doses of from 5 to 10 mg. per kilogram weight in the frog, of 0.1 to 0.3 grm. per kilogram weight in the rabbit. Respiratory distress accompanied by secondary cramps, salivation and diarrhoea ensue, which they consider to be specific. The fatal subcutaneous dose is 20 mg. per 50 grm. weight of the frog, and from 0.5 grm. per kilogram weight for the rabbit; a dose of 0.75 to 1 grm. when swallowed is fatal for the rabbit. In carnivora this dose is 5 or 6 times smaller. Chronic poisoning has never been observed. Accumulation does not seem to be produced.

Cyanamide, when it has been absorbed by man in the form of nitrolime, either by the respiratory or digestive tract, becomes converted into carbonate of calcium or reconverted into cyanamide (CN.NH₂), under the influence of the moisture, heat and carbonic acid gas present. It seems to act directly upon the respiratory centres—a phenomenon which has also been observed in animals (Koelsch).

In very marked cases the blood shows, on spectroscopic examination, a dark line in the yellow-green portion, as well as an appreciable darkening towards the extremity of the spectrum in the green blue, modifications recalling the spectrum of cyanmethaemoglobin (of cyanhaematin). Fatal poisoning is unknown— the minimal dose being too great ever to be reached in ordinary practice. It must certainly be from 40 to 50 grm. of nitrolime for an adult.

Langlois found (in 1912) during an enquiry in a cyanamide factory, where the workmen refused to continue working, that wine played a role in the genesis of the trouble. This fact was subsequently confirmed by Italian and German enquiries. Koelsch considers that alcohol renders the system susceptible to the action of cyanamide—an action similar to that which it exerts in respect of nitro and amido derivatives of benzene; or again of light on eosin, haematoporphyrin and similar fluorescent substances. On the other hand, Hesse is of opinion that cyanamide is capable of giving a potential action to a series of physiodynamic substances—both paralysing and exciting—due probably to the increase in the receptivity of the nervous system for certain substances (solubility of cyanamide in liquids). Alcohol, chloral, chloroform, vohimbine, codeine, papaverine, atropine, etc., have the same property.

More alcohol has been found in the brain of animals that have been treated with cyanamide previously than in the controls.

There is no doubt that the action of cyanamide-alcohol, which recalls that of nitrite of amyl, differs in several respects from ordinary alcoholic intoxication. Further, there are other specific central effects of cyanamide. The relative fugitiveness of the symptoms is due to the fact that cyanamide is rapidly decomposed, and that the quantity of dust which is absorbed into the system is minimal. The researches of Raida, however, have proved that cyanamide is distributed indiscriminately throughout the organs without preference for any special one, and that decomposition is already in progress during the first hour following absorption. 70 per cent. of the cyanamide is then changed into urea and excreted in the urine. The ingestion of alcohol effected simultaneously, though giving rise to typical combined action has no influence on the disappearance of cyanamide from the circulation and tissues.

Lo Monaco, who carried on the researches begun by Hesse, arrived at the conclusion that the action of cyanamide alcohol was the same in animals as in man, and attributed
the toxic action to the group CN, augmented by the group NH₂, while alcohol favours its reabsorption. Marzioli (quoted by Lo Monaco), in the belief that this toxic effect is mainly caused by the formation, in the intestinal tract, of ammonia from the calcium cyanamide, recommends acid drinks. Examination of the nasal cavity has not given positive results. The explanation put forward by Hesse of a combined action may, perhaps, be considered the more probable. Nevertheless, there are still specific effects not so far fully explained.

The toxicity of dicyanamide is one third of that of cyanamide. Absorbed by the digestive tract, it is slowly decomposed in the intestinal tract in such a way that only a relatively minimal quantity of cyanamide circulates in the system. Excretion is effected in the form of urea.

**STATISTICS**

Little statistical evidence exists as to the morbidity of workers on nitrolime. In a hospital where many such persons applied for treatment, Koesch noted 50 cases of dermatoses (5.42 per cent.) during the four years prior to the opening of the factory, and 102 cases (4.59 per cent.) during the four subsequent years. He counted 90 cases of inflammation of the respiratory organs among the 448 patients in four and a half years.

An enquiry of E. Fabri’s in 1913, in a cyanamide factory at Terni, dealt with some 300 workmen with 3 years’ duration of employment. The industry in question, which was considered by Fabri to be in a condition unfavourable to the health of the workers because of the dust given off, especially in grinding and bagging, quickly set its house in order and the health conditions soon improved. In the grinding department, 4-hour spells of work were introduced and in the bagging department piece work was instituted, but with a wage scale equivalent to an 8-hour spell. Oiling was only done twice a year on receipt of orders. The factory instituted strict medical examination on commencing work and periodically afterwards. Wearing of gloves, goggles, and respirators was made obligatory. The two first-named are without any doubt useful prophylactic measures in the majority of occupational maladies. Sickness rates for rheumatism and influenza were found to stand highest. The humidity of the district and the epidemic prevailing at the time, together with work at the furnace, were accountable for this circumstance. Gastric attacks were common, but Fabri could not attribute them to cyanamide dust. No case of tubercles was found. Inflammations of the nose, pharynx, tonsils, and larynx were numerous, due either to the dust or to rheumatic conditions.

Incidence of infectious diseases of the respiratory tract (especially pneumonia) was very high, and forms of neuritis and tachycardia, without other obvious cause than cyanamide and alcohol, were found. Dermatitis affected the majority of the workers with frequent subsequent attacks so that many workers had to leave. Cases of inflammation of the eyes were not characteristic of cyanamide poisoning. In France, Brissy collected, in his thesis of 1926, thirteen records of injuries due to calcic cyanamide.

**PATHOLOGY**

(a) Lesions of the skin and mucous membranes in practice show a marked polymorphism depending on the site of the lesion and the predisposition of each worker. They occur soon after work has been begun and are favoured by the fact that nitrolime coming into contact with sweat or other moisture present forms a paste mass which sticks to the skin. While slight cases show only erythema, and swelling, moderate ones become the seat of acute or subacute eczema, with blackish colouration of the skin, and the worst cases develop papules, vesicles, and bullae, followed by skin lesions presenting a weeping condition or crusts. Itching is sometimes very troublesome; scratching aggravates and leads to complications with mixed and septic infections. Sometimes the whole body is involved, but the seat of infection is not characteristic. The junctions of the skin and mucous membrane, however, are preferred (corners of the mouth, nostril), the interdigital spaces, the elbow bend and axillae. The ulcerative process, at first clearly defined and separate, assumes, in consequence of scratching and in the presence of moisture, wide extension, especially amongst agricultural labourers who scatter the manure, and gives rise to extensive necrotic patches, blackish in colour, which penetrate deeply, are painful, with heaped-up edges, and very slow in healing. The presence of a grain of cyanamide dust in a small scratch or cut may quickly cause it to assume a serious aspect from the phlegmonous inflammation or even supplicative periostitis induced.

Brissy has described a specific lesion due to calcium cyanamide, which takes the form of an atomic ulcer of the fingers and palm of the hand, in workers who manufacture this product. The ulcer is situated in the folds of the skin and follows a transversal direction in relation to the axis of the member. It is found also, according
to Favre of Bellegarde, on the lateral surfaces of the metacarpal phalanges of the three last fingers, where it takes a more or less circular form. It consists in general of a black hard friable and adherent crust containing debris of the epidermis and grains of cyanamide. When removed there appears underneath fairly deep and conical ulcerations painful at the root. The evolution is fairly long, but the condition heals easily if the ulcer is protected and treated from the outset. If left to itself, however, it may become infected and give rise to troublesome septic conditions.

The cyanamide causes small inflamed ulcers on the mucous membranes. Among labourers conjunctivitis, rhinitis, gingivitis, tonsillitis, laryngitis, and bronchitis are frequent. Koelsch has never seen in factory workers irritation of the eyes or its sequelae (such as ophthalmia, keratitis, or ulceration of the cornea), although they have been described in husbandmen as a result of the dust getting into the eyes or of rubbing them with soiled fingers.

(b) The headaches of which many of the workmen complain would alone seem to indicate general disturbance, slight in importance but manifesting itself particularly in a special localised congestion affecting the upper portion of the body. The skin of the face, neck and scapular region assumes a deep red or bluish colour (as when very heated or excited), most frequently with a bright red scarlatiniform-like rash on the arms and trunk extending in some cases below the collar bone as far as half way down the sternum, and on the back as far as the spine of the shoulder-blade. This redness (mal rouge) is typical of acute poisoning by calcium cyanamide, just as lead colic is typical of an acute crisis of lead poisoning. In some cases this colouration descends lower. The redness may be uniform with toothed edges, rarely with healthy zones of skin between, or may take the form of more or less large blotches. The scleroties are strongly injected; the lachrymal secretion appears increased; the mucous membranes and the membrane of the palate and the pharynx are very injected. No noticeable rise in temperature occurs corresponding with the erythematous portions of the skin; on the contrary, the hands very often seem to be cold and the whole body a prey to slight tremor (cold shivers). The respiration rate is a little increased, thoracic, and often broken by deep inspiratory efforts easily detectable by the ear, as well as a slight cough; the pulse is rapid (100 to 130 a minute). Sometimes acuity of hearing is diminished by reason of the strong pulsations in the ear; blood pressure is generally lowered. The differential count of the blood is normal. (For spectroscopic examination, see above.)

In severe cases there is slight vertigo, tremor and jactitation, probably of psychical origin and noticeable in susceptible persons (weaklings and women). In general cases are slight, but are more severe when large quantities of the dust in question have been absorbed (and this is equally so in the absence of alcohol). The symptoms on the contrary are very noticeable in practically every person who has taken alcohol in any form at the same time or shortly before or after the absorption of the dust. If there has been intermission from work for a day or two or longer, alcohol can be taken without risk of congestion, but if contact with cyanamide is continued the reaction appears again on taking alcohol. Acclimatisation apparently does not take place. Individual predisposition is undoubtedly necessary. Nevertheless, all the workers, almost without exception, are susceptible to some degree.

The duration of the attack varies and depends mostly on the amount of alcohol taken; generally it lasts one or two hours. Vomiting almost immediately improves the condition and lessens the redness. After the attack is over, there is slight collapse and shivering. So far, sequelae have not been observed, nor do the attacks get worse although duration of employment may have been long. No chronic effects even after many years' exposure are known.

Diagnosis rests on knowledge of the kind of work performed. The dermatitis and irritation of the mucous membranes are hardly specific; on the contrary, the greyish black crusts are distinctly characteristic. The general symptoms, however, are so definite as to be unmistakable. Strangely enough, the action of animal charcoal, combined with that of alcohol, causes the same congestions (Moench).

Demonstration

Shake urine vigorously with ether, add some drops of ammoniacal silver solution. Dissolve the yellow precipitate obtained (insoluble in ammonia) with nitric acid and titrate with a solution of sulfocyanate of ammonia.
HYGIENE

So far as treatment is concerned, the dust adhering to the skin and superficial mucous membrane should be removed by careful sponging with oil and petroleum benzine. Washing with soap should be avoided. The treatment for the itching and acute eczema, etc. is that appropriate for eczema generally.

Now that the workpeople know the causation and symptoms, medical interference is hardly ever called for. In severe cases rest for some hours is advisable, and the face, should be smeared with oil and vaseline. The German Association of Dealers in Nitrogenous Manures has prepared a cautionary notice on the subject of the scattering of nitroline. Goggles and means of protecting the nose are recommended, also stout shoes, protective overalls, with jackets and hoods capable of being fastened in such a way at the wrists and ankles as to cover the body completely. If no overall is worn the clothing needs to be closely buttoned up. The uncovered parts of the body, particularly the hands and the face, should be smeared with oil and vaseline. Scattering should be with and not against the wind. Persons with any cut or scratch should not handle the material, nor should those who are subject to respiratory affections. Hot water for washing should be available.

LEGISLATION

No special regulations for the manufacture of calcium cyanamide exist, the preventive measures prescribed against dust being sufficient. Should the use of calcium cyanamide become more widely practised in connection with the technical production of synthetic chemical products (urea and its derivatives), the want of legislative measures in relation thereto would have to be remedied. In fact where carbides, acetylene, particularly bad carbides containing compounds of lead, arsenic and sulphur, etc. are used in the chemical industry in question, the workers are in danger of exposure to phos- phurized hydrogen, arsenic, etc., as well as to that of explosions. So far as the work of women and children is concerned, see the measures laid down for chemical manure factories.

The lesions and effects set up by cyanamide are brought under the Workmen's Compensation Act in Switzerland.

FABI. E. "La morbilita degli odietti alla ind. della calciocyanamide." Il Cesalpino, No. 8, 1913.
Camphor (Synthetic)

French: Camphre artificiel ou synthétique; Camphène. — German: Camphilen; Künstlicher Kampfer. — Italian: Camfora artificiale o sintetica; Camfene. — Spanish: Alicantar artificial.

This product has the same chemical composition as ordinary camphor (C_{10}H_{16}O), but it is produced artificially. There are various methods of preparing it, but essence of turpentine is most generally employed as the basis of synthetic camphor, the essence being extracted by steam from the resins issuing from incisions made in pine trees. They are composed of terpene hydrocarbons: C_{10}H_{16}. The pinenes are a constituent of maritime pines. The transition from pinenes to borneoles and isoborneoles can occur by two different processes (by passing through the stage of camphenes). From the borneoles and isoborneoles, camphor is obtained. During this operation there is liberation of nitrous fumes which are recovered. Direct transition from camphene to camphor has also been effected industrially by greatly simplifying the process.

Synthetic camphor is in the form of a crystalline powder, which is sometimes compressed and which possesses the same properties as ordinary camphor, except that it has a less fragrant odour. It is manufactured in France, Germany, Great Britain, the United States, etc.

Medical literature records the death of a German worker whose duty it was to attend to the heating of containers in which synthetic camphor was dissolved. Trismus in such a pronounced form was present that efforts to unlock the jawbone after death, even with the aid of an instrument, failed.

Professor Lewin finally investigated the case, and found during personal inspection of the conditions that even short exposure to inhalation of the fumes escaping in small quantities from the cover of the container aroused in him a feeling of oppression in the chest, and after the lapse of two hours caused slight faintness, so that the product could not be characterised as perfectly harmless. Artificial camphor, when pressed into the blood stream in sufficient quantity from the stomach, rectum subcutaneous tissue, or lungs, can cause the same functional disturbances as the natural camphor. The hair of the worker in question smelt strongly of camphor three days after death, proving exposure to strong fumes. Poisoning probably occurred rapidly, the strong fumes evolved in presence of heat accelerating the invasion of the brain and spinal marrow by the camphor.
Candles (Manufacture of)

French: Bougies. — German: Kerzen. —
Italian: Candele. — Spanish: Buñas, Can-
delas, Velas.

Candles are cylinders of combustible materials provided with a little wick in the centre by which the candle is lit and burnt.

A good candle should burn without smoking and without smell, tranquilly and without flickering. When it is blown out the wick ought to become extinguished suddenly without smoking. A candle ought not to soften under ordinary conditions of temperature. When it burns, the matters of which it is made should form a liquid which can be drawn up easily by the wick, ought not to run, and, once the flame is extinguished, ought not to be filled with melted matter.

RAW MATERIALS

The wicks are made of threads of cotton plaited loosely. The body of the candle is made of the following substances:

Stearic acid, a fatty acid (formula, C₁₇H₃₅COOH) which melts at 70° C., and is the principal constituent of animal grease and fats. Formerly tallow was also used, but this is abandoned now as it burns with a smoky flame and gave off an unpleasant smell.

The hydrocarbons, used either alone, or mixed with fatty acids. These are: paraffin, a mixture of solid hydrocarbons, for which a basis is, white, translucent, chemically inert, without smell or taste, and insoluble in water. The superior hard qualities melt between 56° and 65° C.; the 50° inferior at from 30° C. Paraffin burns without smell and gives more light than stearic acid and beeswax.

Ceresine (ozokerite, mineral wax) is a solid residue from the evaporation of petrol, resembling beeswax, but is less crystalline than paraffin. It melts at 60°-70° C. and gives a smoky and scintillating flame.

* Montannine * is a white substance, prepared from bitumen as the starting point and extracted from lignite and is extracted from sperm oil. It consists mainly of cetyl palmitate (palmitate of cety); it melts at 44° C.

Beeswax, obtained by melting, purifying and moulding, and sometimes by pressure, is of a yellow colour; it whitens in the air and under the action of oxidising agents (nitric acid, chromic acid, oxygenated water). The yellow wax has a smell of honey; white wax is without colour or taste. It melts at about 63° C.

Spermaceti is a white wax; it is crystalline and is extracted from sperm oil. It consists mainly of cetin (palmitate of ceti); it melts at 44° C.

Carnauba wax is a vegetable wax which is collected from the leaves of a wax-palm of Brazil (corypha cerifera); it consists mainly of myricyl cerotate. It melts at 84° C.

The waxes such as beeswax, carnauba wax, and sperm wax are used to make candles de luxe; the other products are used for ordinary candles.

INDUSTRIAL PROCESSES

The type of manufacture described is the ordinary one of stearic acid.

Preparation of Stearic Acid and Fatty Acids

These bodies are extracted from animal fatty matter by saponification. But as most of this matter contains, besides solid fatty acids, liquid fatty acids (oleic acid), there is advantage in increasing the yield in solid acids by a preliminary hydrogenation of the fatty matters. In saponification by lime, the suet, heated in an autoclave provided with stirrers, is mixed with water and milk of lime or magnesia. The fats become hydrolysed into glycerine and fatty acids. When the process of saponification is finished (it is controlled by repeated analyses), the product is allowed to stand. The mixture separates into several layers, the uppermost consisting of liquid fatty acids and the next of glycerine, and the lower of insoluble calcareous soaps (stearates, oleates, and margaricates of lime) coming from the partial combination of the free fatty acids with the lime. Decantation follows. The glycerine is recovered separately; the liquid fatty acids are distilled with steam; the insoluble calcareous soap is treated while hot with sulphuric acid. Sulphate of lime is thus obtained while the melted fatty acids collect in the upper part. If they are too black they are redistilled by steam; if they are sufficiently white, they are washed with boiling water and are cooled in cakes.

After purification, the fatty acids are led into cast tin trays placed one on top of another in cooling chambers, maintained at a temperature such that crystallisation takes place slowly (10-12 hours). The crystals of stearic or palmitic acid are then of sufficiently large bulk and retain in their network the oleic acid.

When there is no oleic acid the stearic acid obtained can be used directly for the manufacture of candles. If there is oleic acid, this must be got rid of to obtain an acid with as high a melting point as possible. The mixture is then pressed cold (50 atm.), at a temperature of 50° to 60° C. The oleic acid flowing away still contains solid acids (stearic and palmitic) in solution. These acids are left to
crystallise out in well-cooled cellars; they are drained through woollen sacks, and mixed with crude acids. The residual oleic acid is used in the manufacture of soaps or of hydrostearic acid.

The fatty acids pressed into cake form are still slightly coloured at the edges. These portions are removed and used in another process. If small quantities of lime or oxide of iron soil them, these impurities are removed by treatment with sulphuric acid. The fatty acids melt and give up the iron, while the lime yields to the sulphuric acid. They are decanted and washed with hot water until every trace of acid has disappeared. A second melting takes place before they are used for the manufacture of candles.

Saponification by Sulphuric Acid

This is the process utilised for grease and fats of inferior quality (garbage, putrefying bones) or poor in fatty acids, as well as for the final treatment of the fatty acids obtained by the preceding process. In the Milly process the melted suet and sulphuric acid (at 66° B.) are first mixed, and the whole is brought to 30-35° B., while the whole is stirred. The fatty acids are freed; one part of the glycerine of the fatty matters is converted into sulfoglyceric acid, and at the same time sulfo-fatty acids are formed which are decomposed by boiling water. The sulphurous gases which come off are collected separately.

Distillation by superheated steam, formerly practised, is replaced to-day by distillation under a vacuum.

In the Droux process the fatty acids, after preliminary drying, are distilled under a partial pressure in a retort with the aid of superheated steam (260-360° C.). Stearic acid, mixed with margaric and palmitic acid, is collected, and, if there has not been preliminary hydrogenation, a fairly high proportion of oleic acid.

Preparation and Colouring of the Mixture

The stearic candles, made generally with a mixture of stearine and paraffin (50 per cent. of each), to which has been added a little ceresin or carnauba wax to lower the melting point, have a yellowish colour, which is first corrected by addition to the paste of blue colouring matter (methyl violet, Prussian blue). For coloured candles, organic dyes soluble in alcohol are used because these least affect the burning of the candle. For red, use is made of Sudan IV, flexin, Bengal rose, rhodamin; for yellow, chinolin yellow, auramin; for blue, indulin, Prussian blue, methyl violet, and even chromate of lead and white lead have been used. The mixture is melted at about 65° C., the colouring matters being added by stirring.

Preparation of the Wicks

These are made before moulding. Cotton threads are loosely plaited together and then dipped in an acid saline solution (boric acid and sulphuricchloride, ammonium sulphate or phosphate; chloride or nitrate of potassium). The plaiting brings about theshrivelling up of the wick when burnt so that the extremity burns without smoking. The chemical solution vitrifies the ash of the wick and the minute particles of glass leave the end of the wick free for the ascent of the wick when burnt. In the absence of this chemical treatment the wick burns short in the flame causing a persistent flickering.

Moulding

The machines for moulding the candles consist essentially in one or several batteries of moulds, kept in a metal box into which, at will, hot or cold water can be made to pass. Each mould is made of tin through which passes a piston which can be lowered or raised. The wicks rolled round bobbins at the lower part of the apparatus pass along the axis of the piston and the centre of the mould to end in the candles of the preceding batch, which are kept in place by special clamps.

After the hot water has been let into the box to warm the moulds, the candle material is passed in in quantity greater than that necessary to fill the moulds, in order to make up for the contractions due to cooling. The moulds are then cooled by introducing cold water, which solidifies the candles. The preceding lot of candles being held above by the special clamps, the wicks are cut through and the bundle is detached. The excess of candle material is removed by scraping with a special tool. The candles which have been made are ejected into the trough, placed above the moulds, which carries
CANDLES (MANUFACTURE OF) — 342 —

the wicks. The pistons which were pushed up for this ejection are pulled down and the cycle of operations recommences. Some moulding machines, of a relatively simple character, instead of delivering a finished candle, only make the cylinder with the mesh in the middle. In such a case, after the moulding, the candles in cylinders require to be cut of equal length and weight, and the base has to be modelled (in smooth or fluted conical form).

When the candles are finished, they are bleached by exposure to air, then polished by rolling between two plates of walnut wood, very smooth, and cleaned with woollen rags, next trimmed to remove mould marks, marked, and then packed.

Paraffin Candles

These are made as has been described, but with a paraffin of high melting point (50° C.). They are white and smoky, which distinguishes them from stearin candles. The flame is smoky, especially when they are prepared with paraffin of low melting point.

These candles are generally made of a mixture of paraffin and stearic acid (3 to 15 and even 33 per cent. of the latter), which raises the melting point. Minute quantities of carnauba wax or stearin, which raises the melting point, are sometimes added. The transparent candles made of 100 parts of paraffin and 2 parts of beta-naphthol, melt at 80-90° C., and yield a mixture which remains transparent after moulding. Other mixtures contain: paraffin, 70 or 90; stearin, 15 or 5; petroleum, 15 or 5 to 100 parts of the mixture.

Spermaceti Candles

These are made especially in Great Britain or North America with refined sperm whale oil, to which is added 5 or 10 per cent. of paraffin or white wax. They are white, semi-transparent like alabaster, and are luxury articles costing a high price.

Wax Candles

Wax candles are rarely made from pure beeswax, but often with a mixture of beeswax and a more or less important quantity of cere sine, paraffin, etc., or still more often, a mass made of these substances inside and coated on the outside with wax or a mixture of wax (60 per cent.) and paraffin (40 per cent.). These candles are made also by moulding or ladling by pouring the wax or melted mixture on to the wicks stretched on hoops turning above the copper containing the melted mixture. This operation is repeated until the wax has attained the desired thickness. This is in this way that church candles are made.

The method of immersing the wicks repeatedly into the wax or mixture is sometimes employed. The candles then are formed of concentric layers.

In the method with a perforated plate for moulding, the wick, of undetermined length, passes into a bath of the molten material, then successively through perforated plates of larger and larger diameter until the requisite size is reached.

PATHOLOGY

The question of whether the emanations given off in the manufacture of candles are injurious or not to health is still an open one. Some writers maintain that the olfactory organs alone are affected, and show statistically that the duration of life of workers in these factories is generally above the average, forgetting that the weakly avoid such occupations.

The causes of injury to health are to be found in the volatile fatty acids which are given off in the course of the melting of the fatty matters: acetic acid, butyric acid, cyanhydrates of ammonia, pyridine, picoline, etc., sulphurised hydrogen, etc.

Among the symptoms noticed in these factory workers are cata rhal or chronic laryngitis, due to the irritation from the fatty vapours and to the brusque changes of temperature; bronchitis due to the same causes; subacute and chronic affections of the digestive tract, catarhal jaundice, which are ascribed to the ingestion of alkaline vapours neutralising the gastric juice and thus hindering digestion. The vapours and fatty acids are even said to be the cause of injury to the stomach, which may go as far as pyloric ulceration.

Less doubtful and more frequent are the lesions set up by the fatty acids on the ocular conjunctiva and skin. Blepharitis, conjunctivitis, as well as eczemas of various kinds, have been described due to the irritating action of the alkalis and fatty bodies, acids, and etheric oils. One particular form of eczema (umbilical and abdominal) is attributed to the carrying of melted substances and fatty acids in trays supported on the stomach without intervening impermeable aprons.
HYGIENE

The workrooms should be constructed of impermeable materials, especially the walls and floors. The floor should be fluted and sprinkled with sawdust to absorb the fatty matters. Cleanliness must be strict; the floors and walls periodically washed. There should be good general ventilation with use of efficient closed apparatus. Precautions must be taken against the diffusion of smells and vapours, by means of hoods and chimneys. Precautions require to be taken against danger of fire. The vapours and gases given off in the manufacture should be destroyed by burning them (over hearths in special apparatus). Furnaces and boilers must be situated outside the workrooms. Inside the factory provision should be made for keeping fine sand to put out commencing flames. Steam should be used for heating the distilling apparatus. Use for firing of waste impregnated with fatty acids should not be allowed.

Tallow should always be melted over a water bath or by steam — never over a naked flame. Purified fats only should be used. The workrooms for storing the raw materials should be kept separate from those of the finished articles. Decaying refuse should not be allowed to accumulate, but be burnt. All residues likely to cause bad smells should be removed as frequently necessary, every day. The residual waters should be collected in a special reservoir. They ought not to be turned into the sewer before complete neutralisation. They can well be removed in hermetically sealed barrels.

While processes calling for the use of such antiseptic products as vinegar, alcohol, etc., are used less and less and are limited to special cases, modern methods make use of desiccation, salting, smoking, freezing, and, above all, of sterilisation.

TECHNICAL DATA

This article is confined to an examination of the preparation of food in cans; the reason being that, thanks to the perfecting of appliances and to the increasingly extended use of automatic machinery, this industry has assumed a great importance. It includes the preservation of fish, to which must be added in the case of some countries, e.g. United States, the preservation of oysters and shell fish, meat, vegetables, condiments, sauces, and pickles.

Preservation of Fish

This is carried out by several processes:

(a) Drying, applied especially to cod prepared in the fresh state on ships and sold on return. The fresh cod is washed and dried either in the sun, stretched on screens or hung by the tail to wooden brackets, or in stoves.

(b) Smoking is used for herrings and for salmon. The fish are put in barrels with brine, then taken out after a fortnight, washed, threaded on small sticks, hung in the fuming chambers, which are low ceiled rooms or galleries underground, where they remain exposed to the smoke. After smoking the herrings are oiled and put in barrels or small boxes.

(c) Salting, or preservation in brine, used for herrings, sardines, and anchovies. The fish have the fat removed and are scaled; next the head and tail are cut off. Then follow cleaning, gutting, removal of bones, putting in brine, draining, and putting in barrels. On reaching the works the salt fish should have the bath of saturated brine renewed daily.

(d) But the process of preservation most employed is canning fish, a process which is based on the well-known method of Appert — boiling in receptacles and then hermetically closing.

The sardine industry is the most extensive and flourishing; the season lasts from May to November.

The sardines reach the factory in boxes, each of which holds 250 sardines and are then subjected to a series of operations. The heads are removed by means of special scissors, which at the

Canning and Food Preserving Industries

The preservation of food to-day is no longer carried on according to ancient and empirical recipes, which, as a rule, robbed the products treated of their natural appearance and flavour, but rests on a scientific basis which enables skilled workers in this industry to protect vegetables and fruit, meat, and fish from microbial changes, and, at the same time, to preserve all their nutritive qualities.
same time remove the guts, thus cleaning or gutting. After passing through brine, the fish are washed and put on screens of tinned wire, tail upwards in cages of galvanised wire, in divisions and put to dry in the sun for three hours, or in chambers heated by steam (tired and cleaned). The meat, ragout, potted meat, or potted liver is put in a can, which is filled with a sauce or prepared gravy; the remaining operations are done as in the case of preserving fish.

For making meat extract, the meat is chopped, boiled with its weight of water, then drained and pressed. The liquid, after the fat has been removed, is evaporated over an open fire, then concentrated in vacuo and put into pots or jars, which are subsequently sealed down according to the usual technique.

**Preservation of Vegetables**

Dry vegetables such as beans, peas, and lentils, after picking over, sorting, and cleaning, are dried in a hot-air stove.

In the preparation of dried vegetables, these are washed, picked over, cut in shreds, and treated in an autoclave at 115° C., or are simply scalded by immersion in boiling water for a short time; then they are dried in a stove and put up in packets. In order to make compressed vegetables, they are cut into shreds, and then dried at a stove; next they are compressed with a press and then sawn into tablets.

**Salting** is used for some vegetables—for the making of sauerkraut in particular. The cabbages, divided into quarters, are cut up by machine or by hand; then they are put into casks in layers alternating with layers of salt. The casks are closed with double bottoms and tightened by a screw press.

The preparation of canned vegetables, i.e. vegetables "au naturel", is concerned chiefly with green peas, French beans, dwarf kidney beans, artichokes, asparagus, tomatoes, mushrooms, and truffles.

The manufacturing processes are as follows: first comes preparation of the vegetables; here green peas are shelled and sorted by hand or better still by machine; French beans are cut into strips and sorted; asparagus is peeled or scraped, cut to one length and sorted according to size; tomatoes are left whole or cut in two (tomatoes for stuffing), or crushed into puree, and after a little cooking passed through a sieve; mushrooms are skinned and washed; truffles are skinned and brushed.

For French beans machines have been invented which cut them into lozenge shape, lengthwise, or obliquely. Preserved spinach and sorrel is prepared by machine choppers and strainers, whilst potatoes, carrots, or onions are peeled with other machines.

In the same way, by means of special turning-boxes cabbages are perforated
and the bottoms are removed, and leaves are trimmed off artichokes.

Blanching is then carried out by light cooking in boilers for a short time (five to eight seconds). This operation requires careful watching and handling. Copper sulphate is added to green peas and French beans to preserve their green colour.

The baskets of vegetables when taken out from the boilers are put into vats to cool, which is effected with cold water. Then follows canning or bottling, depending on circumstances; juicing, which consists in pouring into the cans filled with vegetables juice from the cooking, or a juice prepared separately; and finally the sealing of the cans.

Fruit Preserving

Some fruits consumed as condiments are preserved in salt; for example olives are put into cans in alternate layers with salt. Others are preserved in vinegar: thus capers, gherkins, cucumbers, onions and various mixed pickles are prepared generally by vinegar makers and makers of mustard.

Sweet fruit is preserved in its natural state in juice or syrup. The fruit picked over, stoned, topped and tailed when necessary, is sorted and then scalded with hot water; canned or bottled; after juicing, with juice from the cooking, or a special syrup, the sealed cans or bottles are put into the autoclave at 110°-120° C. for half an hour.

For making fruit pulp the fruit, after being washed and cooked by steam, is crushed and reduced to pulp, which is cooked again, put into moulds and dried in a stove.

Fruit preserved in brandy is chiefly prepared by dealers in spirits or confectioners.

When the factories are not able to deal at the same time with the whole crop, say, of cherries, for instance, part of the fruit is passed on for sulphuring. The small cages full of fruit are stacked on their arrival in brick chambers in which sulphur is burnt; there they are left for about twenty-four hours. The decoloured fruit is then put into open vats filled with salt water, which covers them completely.

Sources of Danger

The hygiene of the industry in preserved foods has been improved in large towns; it is, however, still far from satisfactory in some rural preserving and wherever primitive methods are employed. Among the sources of danger the following must be mentioned: the strenuous nature of the work, with heavy loads to carry, up to 20 to 30 kg., long hours of work, especially as regards some seasonal preserved foods, such as fish, vegetables and fruit, with all their injurious consequences; overtime, night work, and absence of regular meal hours; exposure to moisture: in canning factories the steam is very dense in the workshops, especially in the blanching departments and the cooking, when it condenses on the clothing of the workers. One must bear in mind, in this connection, exposure to inclement weather when certain operations are done in the open air, such as smoking or drying fish or meat. In rural districts where fruit is preserved, the temporary camps put up for the seasonal workers are often the cause of injury to health on account of inadequate accommodation and sanitation.

There should also be mentioned, in some cases, dirty floors which cannot be properly cleaned by washing with water, and work in overcrowded rooms with insufficient available cubic air-space.

In addition to these sources of danger arising from general working conditions, others arise either from the raw materials used, whether meat, fish, vegetables, mushrooms, or fruit, or from certain substances used in canning. Thus, for example, soldering introduces a risk from lead poisoning and from acid fumes.

For some years past, especially in the United States, instead of solder, a solution of india-rubber, resin, and red colouring matter, in commercial benzene, called red clay, is used; this solution is projected into a groove stamped round the top of each can. An automatic machine ensures the evaporation of the benzene, which leaves a thin layer of india-rubber adhering to the bottom of the groove. It is during this operation that injuries to the health of the workmen arise, especially if there is not a good exhaust system for the removal of poisonous vapours.

Finally should be mentioned, danger from the fumes of sulphurous anhydride, as well as from various substances which may possibly be used, e.g. salt, mustard, and vinegar; they may poison and cause painful sores. Risk also exists of burns by hot mixtures and of falls on moist and slippery floors.
PATHOLOGY

The general pathology of the workers in the preserved food industry does not present anything definitely specific. In addition to fatigue due to long hours of work and exposure to moisture, which may cause catarrhal affections, rheumatism, and pulmonary disorders, lessened resistance to infectious diseases is observed and a decided frequency of tuberculosis.

A very detailed enquiry among the personnel of the preserved food industry is that of Harris and Dublin made in New York in 1917.

The most characteristic damage is that caused by handling the food materials. Thus, for example, handling meat may carry with it risk of infection by diseases transmissible from animals to man such as anthrax, bovine tuberculosis, glanders, and actinomycosis, or at any rate to a condition of septic sores and wounds. In the same way the handling of fish may similarly mean a risk of septic punctures. Some cases of erysipelas and erysipeloïd forms have been reported by Klauder, Richter, and Hartrins.

Recently (1927) there have been observed in Germany among 22 out of 48 women workers in a factory for preserving mushrooms, various troubles consisting chiefly of ocular affections, photophobia, mydriasis, defective sight, eyestrain with diminution of visual acuity, and lachrymation due to a superficial keratitis. These lesions were accompanied by disorders which were either general, e.g. fever, or confined to the respiratory apparatus with distressing cough, laryngitis, and bronchitis or to the digestive organs and liver with gastric symptoms, anorexia, vomiting, and jaundice. These conditions were due to helvellic acid, which becomes vaporised in the air in fine droplets when the heads of the mushrooms are washed in cold water.

The handling of vegetables and fruit may cause eczema and dermatitis (see article "Occupational Diseases: Skin"), due to the action of juice and liquid sap.

Thus, for example, in a preserving factory in the State of Brunswick there were reported during 1922, especially during the asparagus seasons, numerous cases of irritation of the skin. In the severe cases it was necessary to prohibit work entirely. In an Italian factory for preserving tomatoes, G. Foa, in 1927, observed several cases of eczema localised to the inner surfaces of the fingers and the interdigital spaces — which very closely resembled itch. Next the eczema extends to the palms of the hands in the form of deep and painful fissures.

Enquiry showed that the trouble was due to acid juice and particularly to citric and malic acids. This small epidemic ceased completely when the women employed in peeling the tomatoes were provided with basins containing a solution of 1 per cent. hydrate of soda for rinsing their hands and running water to wash away any trace of the alkali.

Similarly cases of dermatitis have been met with among workmen handling figs and dried prunes. The lesion was caused by living or dead insects, Carpoglyphus passularum, found on the fruit. (For further details, see article "Skin Diseases").

In the case of a few English workers in the food industry employed in sorting and packing provisions preserved by drying, Ch. Russ in 1923 observed a cutaneous eruption situated on the posterior surface of the forearm. It was due to a ceriopella resembling in appearance an asteroid trichophyton. It is supposed that it was connected with a mould on the sacks imported from the East.

Symptoms of poisoning with lead or benzene have been found among workmen employed in sealing cans.

HYGIENE

Workers employed in the preservation of food should be carefully examined, and all those who show symptoms of contagious or transmissible diseases should be eliminated.

Special care should be given to the construction and maintenance of preserved food factories. The floor of workplaces must be impermeable and constructed so as to ensure sufficient drainage and to prevent the accumulation of waste. Frequent washing down must ensure a thorough state of cleanliness. Gratings to stand on should be provided at particularly damp places. The walls must be smooth and impermeable up to any height liable to be soiled by the food handled. The establishment must be abundantly provided with water. A good system of artificial lighting is very important. Every means should be taken to ensure the most ample admission of daylight. Adequate ventilation is required, either natural or, if necessary, artificial, to remove smells so as not to incommode the workers or the neighbourhood.

Efficient local ventilation must be provided for removing steam, fumes, and various poisonous gases.
The smoking chambers must be made of non-combustible materials. Boilers and apparatus for heating and cooking must be arranged in such a way that the removal of the steam to the outside does not inconvenience the workers or the neighbourhood.

Debris must be placed in closed receptacles which are easy to clean. They must be emptied as often as required. The swarming of flies must be avoided.

Waste and fermentable remnants must be placed in silos or properly drained separate store places.

The supply of water and steam must be sufficient to ensure a sanitary state and head-dresses for women. Provision may be mentioned the wearing of work-vests for work, and for cleaning and washing down, must be pure and fit for use.

All apparatus for washing, boiling, and scalding must be supplied with water from a continuous and plentiful supply. They should be emptied and cleaned once a day or as often as necessary.

Mechanical transport should be employed to reduce fatigue caused by heavy loads.

The use of lead solder should be prohibited, as well as the use of cements or mastics containing benzene. The plan of closing cans by stamping or compression should be adopted; it eliminates any risk of poisoning.

The question of waste water is also important (see article "Industrial Waste Waters"). Water from washing and waste water should be conducted to a drain by underground channels, after having been cleared of solid debris. If such drainage is not possible and particularly when the water is intended for irrigation, it must be evacuated so that the outflow does not stagnate or cause nuisance to the neighbourhood or pollute streams. In some cases recourse may be had to biological purification. Some recent experiments made in the United States have shown the possibility of purifying waste water from factories for preserving fruit and vegetables by decanting and filtering, and so rendering them clear and non-putrescible.

Among personal measures of hygiene may be mentioned the wearing of working clothes, mackintosh aprons, shoes, and head-dresses for women. Provision should be made for the use of the personnel of neutralising solutions to counteract the effect of juices, liquid acids, or alkalis, and of drinking water and of baths.

In rural districts special attention must be given to the sanitary conditions of labour camps.

Medical examination of the personnel should be undertaken on commencing work and periodically.

**Legislation**

Young persons of less than sixteen years are prohibited from work in Belgium, at salting and smoking fish, and at salting and preparing meat; in certain States of the United States at soldering; and in France at soldering of cans; young persons of less than sixteen years and young girls of less than eighteen years in Canada at soldering cans; in Spain women of less than twenty-one years at soldering cans; in Italy, boys of less than fifteen years and women of less than twenty-one years at the sardine industry, and at the treatment of animal waste with the object of rendering its use inoffensive.

Compensation for dermatitis (see article "Skin Diseases"), septicemia, or anthrax, contracted from the handling of meat and food products, is provided in the States of Victoria and Queensland.

---

**Cantharides**

The cantharides (Lytila vesicatoria Fabricius) are coleoptera the vesicatory and aphrodisiac qualities of which have been known since antiquity. The majority of these insects are found in Hungary, Rumania, and Southern Russia (which furnishes most of those placed on the market). The harvest is
gathered by shaking the trees on which the cantharides live; they are put in closed receptacles in which they are killed by means of carbon disulphide, chloroform, or petrol fumes. They are then dried in the sun or artificially at a temperature of 40° C. The active principle contained by the coleoptera is cantharidin, which varies between 0.3 per cent. and 1 per cent. of the weight of the dried insect. The alkaloid, which is the anhydride of the cantharidinic acid, is extracted from the powder by means of chloroform and is in the form of colourless crystalline lamellae, insoluble in alcohol, carbon, disulphide, and water, slightly soluble in ether, but readily soluble in heavy oils and alkalis.

The pharmaceutical preparations with a basis of cantharides have caused numerous accidents. Accidents of occupational origin have been reported as occurring amongst druggists and chemists or workers in factories for the production of pharmaceutical products. These consisted chiefly of cases of conjunctivitis and keratitis due to contact with powdered cantharides handled without adequate precautions. Hilbert studied a case of blepharitis and conjunctivitis with slight veiling of the cornea and phlogistic condition of the iris affecting a chemist's assistant engaged in grinding the cantharides with a mortar. In the medical treatise by Zander and Geissler (Lesions of the Eyes, 1884), they refer to conjunctivitis met with among workers engaged in gathering cantharides. Two cases of occupational poisoning by cantharidin were recently reported (1922) by Steiner and Marton Prager, of Budapest.

---

**Carbanilide**

Carbanilide is used as an accelerator in the rubber industry and is prepared by making carbon disulphide act on aniline oil. During its preparation there is danger of poisoning by carbon disulphide, which may likewise occur during its utilisation. Serious cases reported, with rapid fatal termination, have all occurred during the manufacture only.

---

**Carbon Dioxide**

*(Carbonic Acid Gas)*

**Properties**

Carbon dioxide (CO₂) is a colourless and odourless gas which is present in small quantities (about 0.03 per 100 volumes of air) in outside air, but in very large quantities in certain gaseous emanations from volcanoes and in grottoes, etc. The gas has a specific gravity of 1.529 (when compared with air as unity), at a temperature of 0° C. and 760 mm. of pressure; it is liquefied at a pressure of 36-40 atmospheres at 0° C. It is soluble in water (1 volume of water dissolves 1 volume of CO₂ at 14° C. and ordinary pressure); it is found in nature either dissolved in water, or in mineral waters or in combination with metallic oxides (carbonates: marble, chalk, dolomites, etc.).

**Production and Uses**

Industry produces CO₂ in different ways: by decomposing the natural carbonates by means of sulphuric or hydrochloric acid; by calcining stone to lime, magnesite, etc.; by burning coke, charcoal or heavy hydrocarbons; and by fermentation of sugary organic liquids. In some places also carbon dioxide is used as it is given off from mineral springs. The liquefied acid appears as a colourless and odourless liquid which evaporating rapidly gives rise to a very low temperature and partial precipitation of the acid in the form of white flakes. Liquid carbonic acid may, with or without purification, be compressed by means of special apparatus.

Commercially, it is sold in steel cylinders, provided with a screw-cock, protected by an iron cover, which cannot be uncharged except by means of reduction valves or pressure regulators.

Solidified carbon dioxide is also known (obtained by rapid evaporation of the liquid acid) and appears as a white mass like snow. It melts at 56°7 C. at a pressure of 5 atmospheres and can be kept for some time.

Carbon dioxide is used: in the manufacture of alkaline salts, beer, effervescing drinks, sugar, white lead, and chemical manures; for sterilising worts and other organic liquors; as an extinguisher of fires; as a motive force (to force liquids from the cellar to the bar for instance, to fire torpedoes, etc.); to produce cold indus-
trially; to harden white metal; in metallurgy to send up great jets of steel without having recourse to blowing.

It is used also to combat asphyxia (e.g. among aviators and persons overcome by gas); it is then mixed with oxygen (5 per cent. of $CO_2$ to 95 per cent. of oxygen). It has also been used to preserve perishable products (milk, eggs, butter, raisins, etc.); in freezing machines concurrently with ammonia, etc.; to make freezing mixtures; in analytical and histological work; in different chemical industries; in the manipulations connected with oxydisable products (phosphorous organic compounds); in the preparation of salicylic acid, of pure carbonates, of synthetic urea; in the rubber industry to make an atmosphere of inert gas during vulcanisation, etc.

DANGERS

$CO_2$ is given off either in the course of its production or use, but also, in quantities more or less large, alone or mixed with other gases, in many industrial operations or particular kinds of work; in foundries (of brass and iron, etc.); in brickmaking, lime kilns, glass manufacture, potteries; in the manufacture of soda (Leblanc process), size, yeasts, starch, etc.; in redressing skins; in cellars during the preparation of fermented drinks; in confined spaces, such as silos, submarines, mines, underground railways, tunnels, gas-works, etc. Carbon dioxide is found very often mixed with more poisonous gases; in sewer gas, lighting gas, industrial gases, gases resulting from decomposition; products of combustion; explosives, soldering, acetylene gas, etc. Under these conditions it may be carbon monoxide, sulphuruted hydrogen, ammonia sulphide, etc., rather than carbon dioxide, which constitutes the main danger.

PHYSIO-PATHOLOGY — TOXICITY

Normal outside air contains 0.3-0.7 of carbon dioxide per 1,000 (in volume), but this proportion varies much and can be excessively raised in houses, factories, etc. Pettenkofer allowed for domestic premises a normal proportion of 1 part per 1,000, which in factories might reach from 1 to 4. These figures bear, however, strict relation to the cubic capacity, and above all, to ventilation, humidity of the air, etc. The permissible maximum is now regarded as 1 part (by volume) to 1,000 parts of air. (See article "Air of the Workroom").

Analyses made in the laboratory of Paris have shown strikingly that while the air in Montsouris Park is represented by 30 litres of carbon dioxide per hundred cubic metres of air, the air in the Metropolitan Railway showed 75 litres and in summer 63 litres, while the air in a printing works showed 44 litres and that in a dressmaking workshop 458.

Carbon dioxide normally excites the respiratory senses. The influence of venous blood on the movements of respiration has been known for a long time. An animal breathing a gaseous mixture poor in oxygen or rich in carbon dioxide immediately shows signs of distress (dyspnoea). The same signs can be evoked by making the animal breathe pure nitrogen or carbon monoxide, or a mixture of the two gases, with an insufficient quantity of oxygen, or an excess of carbon dioxide in a mixture containing the natural proportion of oxygen.

The importance of carbon dioxide as a normal exciter of respiration has also been known for a long time and it is certainly greater than that of oxygen deficiency. The organic oxidations take place in the cells themselves; in addition to the gaseous exchange taking place in the lungs there are gaseous exchanges taking place between the blood and the tissues. The experiment of Spallanzani is known, by which he shows the production of carbon dioxide by snails placed in an atmosphere deprived of oxygen. The production of $CO_2$ has been proved also in the various tissues; exchange is more active at optimum temperatures and varies with the state of repose or activity of the muscle, the activity of the organ, etc.

Account must be had, therefore, of the three following phases: tissue respiration, transport by the blood of the agents and gaseous products of the respiration of the tissues, and gaseous exchange of the blood in the pulmonary capillaries. The gaseous exchange effected by the blood can take place from every surface linked up with the respirable medium. It can take place, therefore, from the surface of the skin. According to Scharling, the carbon dioxide exhaled by a youth of 16 years of age weighing 67.7 kg. amounts every 24 hours to 4.34 grm. from the skin, 812.72 grm. from the lungs; by a man aged 28 years, weighing 82 kg., respectively 8.95 and 878.88 grm.

The proportion of carbon dioxide in the arterial blood of a man is about 40 c.c. and is always in excess of the
Carbon dioxide has become considerable. Without removing the carbon dioxide an animal shut up in a closed space will eventually suffer from lack of oxygen in the atmosphere which is not renewed takes on a new combination, and about 10 c.c. combined with the red blood corpuscles.

Expired air contains compared with that inspired less oxygen, and, on the other hand, a very appreciable quantity of carbon dioxide. In deep and rapid breathing, however, the better the aeration of the lungs the less the quantity of carbon dioxide (2.5 per cent. instead of 3 to 4).

While the partial tension of oxygen in the external exchange taking place in the lungs is 15 to 17 per cent. of air atmosphere, that of carbon dioxide in expired air is 3-4 per cent.; in alveolar air it is still higher. Alveolar air is noteworthy in that it contains more carbon dioxide than expired air because a part of the inspired air does not penetrate beyond the large bronchi and is expelled without being altered by expiration.

The mechanism of the pulmonary gaseous exchange is not yet completely understood; it appears, however, that the elimination of carbon dioxide is not due solely to a purely physical mechanism, but active participation of the pulmonary epithelium is involved, behaving thus in a manner like glandular epithelium.

Deprivation of oxygen or accumulation of carbon dioxide in the air breathed or in the blood causes asphyxia by reason of deficiency of respirable air. Under these circumstances hematoisis diminishes, and dyspnoea occurs as a compensatory mechanism to the diminished blood supply, but if this is insufficient asphyxia takes place.

The death of a living organism in an atmosphere which is not renewed takes place when the bulk of the oxygen has been exhausted, but the effect is due also to the accumulation of carbon dioxide. As a matter of fact if a sufficient supply of oxygen is given to an animal shut up in a closed space without removing the carbon dioxide produced during respiration, death supervenes when the proportion of carbon dioxide has become considerable.

Carbon dioxide is not in itself toxic, but its presence in excess in consequence of its excessive pressure in the surrounding tissues offers an obstacle to the elimination of carbon dioxide in the blood; at the same time the carbon dioxide formed by metabolism in the tissues does not enter the blood and tissue suffocation results. Several writers, however, maintain that carbon dioxide is really toxic.

Many experiments have shown that animals can live in atmospheres containing 20 per cent. of carbon dioxide. The gas should be considered as inert — its innocuousness being proved by the consumption of aerated waters, by its use without hurt under pressure (in laboratories), by its injection into the veins (which is said only to cause the death of an animal when the quantity is too great to be dissolved), etc. But account is not taken of the rapid elimination of the gas both through the lungs and the digestive tract (eructations after ingestion of waters aerated to excess).

A man plunged into a closed apparatus filled with carbonic acid gas, with his head outside breathing freely, experiences a sensation of prickling and warmth, followed rapidly by marked prostration necessitating an end to the experiment. P. Bert had observed that birds die rapidly under these conditions and more rapidly than when they are plunged into inert gases (hydrogen, nitrogen).

Carbonic acid does not seem to act on haemoglobin which can fix a certain quantity. This fixation is rather on the proteid matter than on the pigmentary nucleus of the haemoglobin. The new combination does not interfere with the oxygen fixation, but the absorption of this gas is said to be less than in the absence of the carbon dioxide. The combination gives to the blood a dull red colour and exhibits spectroscopically almost the same lines as haemoglobin; only absorption of the green and greenish blue rays is more marked. Hamburger and Botazzi are of opinion that carbon dioxide damages the red blood cells, making them lose important quantities of protein matter.

**Symptoms**

Carbon dioxide also exerts local action on the skin and mucous membrane, showing itself in diminution of the sensibility after transitory irritation. This action is sufficiently noteworthy to be utilised therapeutically (anaesthesia).
A proportion of one to three parts of CO₂ per cent. of air is considered as directly harmful without, however, proof that it is so; 0.5 to 2 per cent. in volume, common long ago in the fermenting vats in breweries (such amounts nowadays are exceptional), do not produce acute symptoms even among those experimenting with them (Lehmann, Bickel and Herrligkoffer). There is no doubt that when the content of the air in carbon dioxide exceeds 4, 5 or 6 per cent. acute symptoms are produced (Emmerich); difficult breathing, feeling of cold, headache, dilatation of the peripheral vessels, and loss of consciousness after a short time. According to Hill (1920) a proportion of 3 per cent. suffices to induce a pretty marked dyspnoea with slight headache; if the proportion is from 5 to 6 per cent. the dyspnoea is pronounced and accompanied by headache and sweating; a proportion of 10 per cent. for a minute only sets up headache, visual disturbances, tremor and loss of consciousness, etc.

Massive doses penetrating into the lungs cause a state of depression and anxiety, noises in the ears, syncopy, slowing of the respirations and cyanosis; the extremities become cold and death supervenes.

A proportion of 0.5 per cent. breathed for a long time causes real discomfort, which is more marked and rapid in an atmosphere containing a proportion of 1 per cent.; a proportion of 10 per cent. renders the air insupportable. According to P. Bert about 82 grm. of carbon dioxide are required to kill an adult weighing 60 kg.

There is no proof that small daily minimal doses acting several hours exert any chronic toxic action.

Murrer has proved that a proportion of 2 per cent. in the Silesian mines is without appreciable effect.

In an English coal mine 4.56 per cent. has been found at the ground level and 1.21 per cent. at the coal face; in submarines a proportion of 3 per cent. has frequently been registered and in caissons, where work is very trying, 1 per cent. or more. It must, however, be remembered that here it is the partial pressure which is of importance and not the percentage. Really 1 per cent. of carbon dioxide, for example, at a pressure of 3 atmospheres is equivalent to 3 per cent. at 1 atmosphere. At 2 atmospheres the ventilation in the diver's helmet ought to be double that at 1 atmosphere; at 3 atmospheres it ought to be three times as great, etc.

**Statistics**

For a long time past cases of death have been known where people have been packed together in too confined a space: of 146 prisoners shut up during the war in India in 1756, in a room where the air only entered through a narrow opening, 123 suffocated in less than 12 hours; the prisoners shut up in vats and baskets for terrace of the Tuileries in June 1848 died under analogous conditions, etc. In these cases the toxicity of the confined air was due mainly to the carbon dioxide, but, as may be seen in another article ("Air Control in Workrooms"), to other factors as well.

Although frequent cases are reported of malaise, slight poisoning and, more rarely, deaths from asphyxia in vats, wells, pits, graveyards, soils made up from organic matter (giving rise to the poisonous gases: Irregularly), mines, quarries, grain cargoes, silos, fermenting vats (wine, beer, cider and sugary liquids in general), incandescent mantle factories and generally wherever gas is burnt, etc., it is not always possible, however, to give statistics of cases of carbon dioxide poisoning. Such cases take on generally an acute form bringing about the death of the victim and sometimes that of the would-be rescuers.

As an indication of the number of cases of poisoning, the following figures for Great Britain may be cited: 1913, 12 cases (1 death); 1914, 3 cases (1 death); 1917-1919, 9 cases (6 deaths); 1920, no cases; 1921, 5 cases (4 deaths); 1922, 1 case; 1923, 10 cases (2 deaths); 1924, 5 cases (3 deaths).

**Demonstration**

As to methods for doing this, see the article "Air of the Workroom." Reference should be made here to the fact that generally a candle flame is used to judge of the poisonousness of confined air, or of air vitiating by carbon dioxide. This flame becomes extinguished in atmospheres where the proportion of carbon dioxide is insufficient to cause immediate danger of asphyxia; similarly, an animal in a cage (such as a bird or guinea pig) can be introduced into a supposed toxic atmosphere. American authorities allege that it is defect of oxygen in a mixture of injurious gases rather than increase in the carbon dioxide, which is the main factor in extinguishing a flame, as well as in affecting human beings.

The flame of a match or an oil lamp is extinguished when the proportion of oxygen falls to about 17 per cent.; that of an acetylene lamp at a proportion of 11-12 per cent.; Burrell and others, of the United States Bureau of Mines (1916), have shown that the flame of a oil lamp goes out when the proportion of oxygen is 16.3 per cent.; with carbon dioxide the same result is obtained with a proportion of 10 per cent. (which corresponds to 17.1 per cent. of oxygen).

Whatever the proof may be, the fact remains that if a flame goes out it means that the air is dangerous for man.
HYGIENE

The ideal from the hygienic point of view would be to ask for a maximum limit of one part per thousand of air (by volume); this quantity, however, should not be taken alone, but always in conjunction with the cubic content and ventilation of the room (see the articles "Air of the Workroom"; "Ventilation").

LEGISLATION

In Greece, employment of young persons under 16 and girls under 18 in factories using compressed gases is prohibited; in Italy, all boys under 15 and women under 21; in Switzerland, young persons under 18, when use is made of apparatus under pressure, etc.

In New Brunswick and Ohio, compensation is provided for injury caused by carbon dioxide.

***

Carbon Di-(or Bi)-sulphide

CHEMICAL PROPERTIES

Bisulphide of carbon, formula CS₂, is an acid anhydride or a sulphur anhydride, which, when purified, appears as a limpid, very mobile liquid, strongly refractive, almost colourless, with an ethereal smell resembling chloroform. In the crude state its yellowish colour is deeper the more impurities it contains. It then gives off a smell like rotten eggs. Its density is about 1.28 (at 20° C.); it boils between 46° and 48° C., giving off at an ordinary temperature abundant vapour very much heavier than air (1: 2.23 nearly) and thus it tends to collect at low air levels. If evaporation is rapid (as, e.g., by passing a current of air through it) its temperature falls to —60° C. (utilised in consequence for the production of cold). Extremely inflammable carbon bisulphide burns in the air, forming sulphur dioxide.

In ordinary air it takes fire at about 170° C. (Holleman says 232° C.). There is need, therefore, for every precaution in the packing, storage, and manipulation of the product.

The vapour readily ignites; hot metal (hot tubing, etc.) and even electric sparking can make it explode when the mixture of vapour with the air reaches 0.063 grm. of carbon bisulphide to 1 litre of air. It explodes also under the influence of detonating agents, of shock, but in such cases the explosion does not propagate itself. According to other authorities, air saturated with carbon bisulphide vapour constitutes an inflammable, but not explosive, gas.

Only slightly soluble in water (1 litre of water dissolves, at 0° C., 2.904 grm. of carbon bisulphide); it readily mixes with most of the commoner organic solvents in all proportions; alcohol, ether, ethereal water, solutions of phenol and chloroform, etc. It is soluble to 60 per cent. in oil.

It is a powerful solvent of certain substances which are insoluble in most others, such as fats, oils, waxes, resins (except lacquer), India-rubber, sulphur (dissolves its own weight of sulphur at 38° C.), white phosphorus, iodine, and a great number of inorganic substances.

It does not attack, or only very slightly, copper and zinc utensils at the temperature at which they are used for the extracting of fats, sulphur, and other substances.

Bisulphide of carbon undergoes change when stored especially under the influence of light (demonstrated by Berthelot) taking on a yellow colour and yielding an impure bisulphide of carbon.

INDUSTRIAL OPERATIONS

It is found in a natural state in coal tar and in grains of black mustard.

Industrially bisulphide of carbon is prepared synthetically by direct passage of sulphur vapour over carbons (charcoal or coke) at cherry red heat (800—900° C.), so that 88 to 90 per cent. of the sulphur becomes fixed. It is important to have the charcoal well heated before the sulphur vapour is passed over it.

Ordinarily it is made in steel cylinders or in iron or fireclay retorts heated in the usual way. The steel cylinders are arranged vertically in a furnace, provided at their lower extremity with a grill containing a chamber into which the sulphur is introduced by means of special tubes when all is ready. The whole is heated on a hearth and the sulphur vapour given out passes through the red-hot charcoal. The bisulphide of carbon is liberated and condensed in a series of receptacles half filled with water. This process is a discontinuous one and cannot be used for large quantities.

In other processes (Singer, Peroncel, Eckett apparatus) the sulphur is vaporised first and then led over the charcoal heated to redness.

By Taylor's process (see Thorpe's Dictiona ry of Applied Chemistry, 1921, Vol. II, page 77) the manufacture is carried out in an electric furnace with continuous production on a large scale and with great advantages as regards both convenience and safety. The furnace consists of a crucible in which four
Electrodes are placed on two perpendicular diagonals with a cylindrical hearth and a dome.

The last named has a charging flap valve and a pipe for the escape of the bisulphide. The furnace is built of masonry in fireclay bound by iron bands. The furnace crucible is fed with broken carbons and is regularly stoked from above. The sulphur is charged through a hopper, passes down into the retort and melts at the bottom.

The mollen sulphur gives off vapour which passes through the layer of incandescent charcoal producing carbon bisulphide. This then passes through the deep layer of wood charcoal, which fills the shaft of the furnace and gets partly cooled before reaching the dome.

**Purification**

The crude bisulphide obtained at the first condensation contains six to ten per cent. of sulphur, sulphurified hydrogen, sulphur dioxide, methylene bisulphate, various sulphides, carbon sulphurates, and small quantities of inorganic sulphur compounds (volatile sulphides). Purification is effected by lime or iron oxide (Leymann) and by repeated distillation at a temperature as low as possible, over vegetable fat, as the latter fixes the unpleasantly smelling impurities and the sulphur.

The carbon bisulphide, chemically pure, is prepared by distillation over mercury and by drying with calcium chloride.

The necessary purification depends on the uses to which it is to be put later. Storage of carbon bisulphide is effected in iron drums.

**Uses**

Carbon bisulphide is used industrially in a great many processes such as the following:

1. **As a solvent of the fatty bodies in essential oils and resins:** To extract fat from bones intended for the manufacture of animal black, and from coconut oil, oily grains, etc., or oil cake from certain plants (colza, rape seed, sesame, etc.), lanolin; to recover the fats from a large number of industrial residues, animal and vegetable residues; tow and rags (which have been used for cleaning machinery); muddy deposits of oils that have been treated by sulphuric acid, sawdust (that has been used to filter oils purified by sulphuric acid), brown residues from sulphuric saponification before the distillation of fatty acids, grease blackened by use in machinery, kitchen grease residues from the direct extractions of wax; tallow cracklings, residues from the melting of crude and pressed tallow, chemical cleaning of clothes; to degrease wool, skins, meat; to purify crude paraffin (Alcan method); to extract lanolin; to refine tallow from stearine; to extract certain perfumes; to treat spices, and to prepare soluble spices.

2. **As a solvent of other matters:** To extract sulphur from minerals and asphaltic rock bitumen; to dissolve phosphorus, in the manufacture of lucifer matches, of phosphorus for Roman candles, of certain explosives, liquid fire (i.e. solution of phosphorus in carbon bisulphide); for extraction, by solvent action, from tar in numerous industrial processes to remove the sulphur in the purification of gas; to purify potassium cyanide obtained by the Liebig process; to prepare certain wax varnishes; in solutions of wax to cover plaster casts and waxed papers; to dissolve india-rubber (making toy balloons); gutta percha (all rubber cements), rubber for holding air, Chatterton and rubber cements which must dry quickly; for cold vulcanisation of rubber; for manufacture of goods made of thin rubber sheeting; for vulcanising of certain articles or materials.

3. **As a chemical agent in the following processes:** Carbon sesquichloride, prussiate of potash (Gélis process), ammonium sulpho cyanide (to make Pharaoh's serpents). Camphor and different aromatic compounds. cellulose, potassium and alkaline xanthogenates, viscose, artificial silk (in the viscose process), chloride of sulphur, carbon tetrachloride, sulpho cyanide compounds, etc.; to make fire extinguishers and, lastly, as a manure (Hollemann).

4. **As a toxic material (in agriculture):** Against certain parasites and injurious animals (ticks, bugs, phylloxera); to destroy nematode worms attacking the root of beetroot (Molinary); in deratisation.

As a disinfectant and parasiticide it is used in the form of potassium sulphocarbonate which slowly dissolves in the soil giving rise to carbon bisulphide; or it is used in a spray in a 1 in 10 aqueous solution of gelatine.

5. **As a means of producing low temperatures:** It has been used to produce cold, but nowadays this is done by other chemical methods (see article "Refrigerating Plants").

It should be observed that modern technique is replacing carbon bisulphide in quite a number of its appli-
cations by other less harmful substances (e.g. carbon tetrachloride, and generally by the halogen derivatives of the saturated and unsaturated hydrocarbons of the aliphatic series).

DANGERS

The immediate dangers in the use of carbon bisulphide are explosion, fire, and poisoning.

The last named results from inhalation of vapours on contact of the substance with the skin or by its splashing on to the clothes. Conditions which favour its action are high temperature (hot weather, over-heated workrooms, work done stooping or near the floor). Nearly all industrial processes in which carbon bisulphide is used are carried on in closed apparatus.

In order of diminishing risk the industrial processes most affected are the following:

India-rubber industry.— The most dangerous process is cold vulcanisation of rubber, done by dipping the rubber into a solution of sulphur chloride dissolved in carbon bisulphide. The articles are then taken out of the trough and hung up to allow of evaporation in the air either in heated drums or in special drying chambers.

As is remarked in the article "Rubber or India-Rubber Industry", cold vulcanisation is now very little practised. Thus, for example, in Ohio (1920) of 78,000 workpeople only 0.5 per cent. came into contact with carbon bisulphide, and the most affected workpeople were those who made up the solution of rubber, filled the tubes and boxes and carried out the cold vulcanisation of the various objects, etc.

Carbon bisulphide is mostly replaced by dichlorobenzine, methane, carbon tetrachloride, etc. It is used to make carbonilide, an accelerator for vulcanising rubber, resulting from the reaction of carbon bisulphide on aniline oil. The manufacture of this material has already caused a fatality (Hamilton).

Extraction of oil and fats.— This is effected with carbon bisulphide, benzine, ether, etc., in hermetically sealed receptacles (to avoid evaporation), generally arranged as a continuous process.

Preparation and use of cements and mastic.— These dissolved in carbon bisulphide are used to repair shoes (invisible mending) and belts. This work formerly caused mental symptoms known under the name of "folie du cuir".

Preparation of viscose and artificial silk (see the article "Artificial Silk").

Workmen engaged in the manufacture and manipulation of carbon bisulphide are more rarely affected, as the process has reached such a state of perfection that vapour cannot escape in any large quantity. Further, as all the processes are carried on in closed receptacles and by continuous process under every possible precaution to prevent fire and escape of vapour, danger is reduced to a minimum.

Trouble is caused during the manufacture from escape of sulphur dioxide which is given off in large quantities from the retorts when the mixture of sulphur and charcoal is heated to 1200° C.

The nuisance created for the neighbourhood should not be forgotten as a result of the escape of carbonaceous and sulphurous gases coming from the hearths and retorts.

For the sake of completeness mention should be made, as a source of danger, the risk from evaporation from certain large vats and tanks in which carbon bisulphide is stored in a pure state or mixed with other ingredients, in all the operations where the bisulphide comes into contact with charcoal (heating metallic sulphides with charcoal, pyrites, pitch blends, antimony sulphide); heating carbon tetrachloride with sulphur or carbon tetrachlorobromide with flowers of sulphur; dry distillation of anthracite when illuminating gas or benzol has to be removed, formation of gas containing sulphuretted hydrogen by distillation in retorts and subsequent contact with glowing charcoal, etc.

TOXIC ACTION

Facts as to the toxicity of carbon bisulphide date in France from 1851-1860 (work of Payen, Duchenne, Beaugrand), when the Parkes method of cold vulcanisation was introduced. Delpech (1856) was the first to describe the symptoms: his work, which has remained a classic on the subject, was published in 1863.

Some authorities take the view that the toxicity of carbon bisulphide is due more to impurities than to the substance itself, because in the crude state it is notoriously very poisonous; but Lehmann has shown that carbon bisulphide possesses a toxicity of its own — a fact confirmed by numerous other writers.

With animals air containing one-twentieth of its volume of carbon bisulphide infallibly leads to death. Lehmann has shown that 1.5 mg. of carbon bisulphide per litre of air has no effect
on the cat after several hours excepting in signs of fatigue; at the end of eight hours with 2.6 mg. per litre of air its action is pronounced (as shown by inco-

ordination of movement, slight cramps,

paralysis), and still more in three hours

with 4 to 5 mg., in two hours with 7-8 mg., and in half an hour with 10-11 mg. Young animals are more susceptible than old. The phase of depression is always preceded by one of excitation. An animal absorbs about 20.6 per cent. of the vapour of carbon bisulphide which it inhales.

With man Althoff has found that a workroom atmosphere containing 0.7 mg. and even 0.2 mg. has effects on those at work for ten to twelve hours on end. According to Balthazard, acute effects become manifest when the air contains 1.5 mg. per litre of air and a dose ten times less can induce chronic effects in time. According to Lehmann 1 to 1.2 mg. causes headache in a few hours; in eight hours unpleasant effects (mental confusion) lasting for twenty-four hours; 1.5 mg. causes headache in half an hour. With 2.5 mg. effects show themselves quicker; with 3.5 mg. vertigo is present in half an hour and at the end of an hour and a half or two hours sensibility is affected. With 6.4 to 10 mg. a half-hour to an hour suffices to bring about serious symptoms, e.g. impending

narrowing, pins and needles feeling, feeling of deafness, sore throat, irregular respiration, and subsequent headache. A man absorbs about 22 per cent. of the bisulphide vapour he inhales. As regards the setting up of chronic poisoning Luig found that inhalation of 1 mg. per litre of air (0.8 to 1.4 mg., according to the number of days) was highly dangerous, when continued for fifteen days, with an nine-
to eight-hour day's work.

Sensitisation to carbon bisulphide takes place after a first attack. A case is described of a workman who, after having given up his work as a result of poisoning, had a relapse on living with a companion who came home with his clothes smelling of carbon bisulphide.

On the other hand, cases of relative acclimatisation (rare, it is true) have been described in the case of workmen who had suffered on first exposure, but were able thereafter to continue to work without hindrance in an atmos-

phere vitiated by bisulphide fumes. Addiction to alcohol is the most predisposing cause (Beaugrand), so much so indeed as to make some people ask to what extent the symptoms were due to alcohol and to bisulphide of carbon, especially in regard to the symptom of peripheral neuritis.

A first attack predisposes to a second. The persons attacked are said to be badly nourished, neurotic subjects, women (Delpech), and young persons.

Absorption takes place through two channels: the respiratory (from the great volatility of the substance) and the skin. Application even of liquid bisulphide of carbon on the skin causes a sensation of cold, followed sometimes by livel smarting. This substance, after dissolving the layer of fat on the surface of the skin, readily passes through it. Absorption in this way is very important from a practical point of view in the case of workpeople dipping their fingers in the liquid to soak or abstract articles, who often suffer from localised nervous affections in the hand and forearm. It has even been stated that bisulphide vapours collecting in the lower levels of a workroom exercise a local action on the legs and explain the frequent troubles of sensibility felt in them.

Elmination is effected mainly through the pulmonary tract (penetrating smell of bisulphide in the breath) and in the urine. Fehling's solution gives a brownish-black precipitate of sulphide of copper with urine containing carbon bisulphide on moderate heating.

Similarly, elimination of the poison takes place through the sweat and intestinal tract. Elimination is slow, whence a cumulative action, which partly explains the relative slowness in the appearance of the toxic phenomena observed.

Lehmann and his pupils have not detected blood changes either in acute or chronic poisoning such as have been described by some writers. Balthazard states that a destruction of leucocytes takes place.

The toxic action on the nervous system, especially on the peripheral nerve fibres, is favoured by the combination of carbon bisulphide with the nervous substance (analogous to that brought about by chloroform, chloral, and anaesthetics).

Similarly extravasations into the lungs have been observed, into the lin-

ing membrane of the stomach, pneu-

monias, degeneration of the liver cells, and splenic pulp; and lesions of the parenchymatous organs (large glands). Locally, carbon bisulphide has an irritant action. On contact with the skin it causes a sensation of burning and subsequently anaesthesia. It pro-

duces intense congestion of the membranes and a droplet spurting into the eye is sufficient to set up a simple or purulent conjunctivitis (Balthazard).
STATISTICS

Cases of poisoning from bisulphide of carbon, and especially severe cases, were not infallibly much more frequent formerly than they are now. They have been reported in the rubber industry, the manufacture of artificial silk and extraction of gum, etc.

In 1910 the statistics of the Sickness Insurance Societies of Leipzig and neighbourhood furnished the following cases: among 2,226 rubber workers 1,041 cases of sickness occurred with 20 deaths, 63 affecting the nervous system and 52 being due to poisoning. The total morbidity percentage was 46.7 per cent. and total mortality 0.896 per cent., cases of morbidity from nervous diseases 2.83 per cent., and from poisoning 1.40 per cent.

Of 8 cases reported by Briaux in 1912, 2 showed no signs of insanity, 1 of loss of control over the sphincters, 1 of mental hebetude, 3 paralysis of the legs, and 4 effect on the genital organs.

In 1914 Kober reported two acute cases in Ohio.

Terrien in 1920 published two cases of marked amblyopia in workmen employed in a large factory for making mustard plasters. They had been engaged for eight hours a day in spreading on to special papers a solution containing 2 kilos of rubber dissolved in 1 litre of essence of mustard flour.

Dubois de Lavigerie reported two cases of poisoning affecting men employed in making invisible patches for shoes, affixing them by means of a mixture of rubber and gutta-percha dissolved in bisulphide.

Dieluafy noted several cases of poisoning in perfume factories in which the bisulphide was used to extract the essences from flowers.

An enquiry by Dr. Vandermieren (Brussels) in 1920 covered workmen in a factory for making toy balloons who were using bisulphide for vulcanising purposes. The occupation of the 40 persons thus examined was distributed as follows: 11 mounters, 9 dippers, and 20 blowers. Of the 9 dippers 7 showed no symptom; one, a beginner, had suffered from obvious symptoms and another from serious signs (paralysis of the legs). At the time of the visit a dipper showed nervous involvement mainly (violent headache, muscular cramps, paralysis of the legs, vertigo, etc.): another, digestive and nervous symptoms; a third similarly characteristic though less pronounced symptoms, and a fourth paralytic, cramps and muscular weakness.

Among the eleven female mounters, fairly advanced in age, only two cases of paresia of the limbs were observed; digestive troubles (anorexia, vomiting, etc.) were more common. Six cases of violent headache and diminished visual acuity were found in five women mounters.

Sixteen of the twenty blowers stated that previously they had suffered from symptoms of bisulphide poisoning.

Mattei and Sedan reported two cases, one in 1921 and the other in 1922, in a factory for extracting the grease from rags. They described another case affecting a young woman, an engineering chemist in a large oil works in Marseilles, engaged in titrating samples of fatty substances and oil cake with carbon bisulphide.

In the course of preparation of solid carbon bisulphide in a beaker (in which it had been prepared with the necessary precautions), by making the product fall by drop into liquid air, a chemist in the Institute of Inorganic Chemistry of Hanover met with a severe accident (1926). Care, therefore, should be taken to avoid mixing inflammable organic substances with liquid air. They should be kept separate during cooling by means of a screen.

In 1924 three cases were reported in Great Britain, two in rubber factories and one (severe) in the manufacture of artificial silk. In 1925 three cases were reported, in 1926 one case and in 1928 one case.

SYMPTOMS

The poisoning shows itself in two forms: acute and chronic. The acute form is of short duration and gives way rapidly, even fulminating, manner. This is bisulphide inebriation described by Delpech and now very rare in factories. It is only likely to be observed when a vessel breaks. It resembles alcoholic intoxication, followed by a narcosis recalling that of chloroform. The consequences, however, are more lasting and severer: pallor of the face, flaccid arms and legs, sometimes even complete insensibility, diarrhoea, coma, subnormal temperature, and death at the end of twenty-four to forty-eight hours. Dilatation of the pupil is of bad prognosis.

In the ordinary acute form, the two most frequent signs were headache and sleepiness during, and immediately after, work, and to them Glorieux and Gilbert attach great importance. This form is of short duration and gives way rapidly to nocturnal insomnia, which is very persistent and attended by nightmare. The headache, generally the first sign to show itself, often only a few hours, days or weeks after commencement of work, comes on usually in the evening and disappears at night, only to reappear on commencing work. This symptom, which sometimes assumes the deceptive form of the classical neuralgia of the trigeminal nerve, disappears entirely on continuance at work. An equally important sign is genital hyperaesthesia, the appearance of which may lead workers to change their employment. Glorieux deems the first sign to be great muscular fatigue, most often localised in the
lower limbs, general weakness, and exhaustion. Slight psychical changes occur (hilarity, loquacity, agitation, irritability, etc.); sometimes hallucinations of sight and hearing.

Vertigo and sometimes even syncope occur, inco-ordination, automatic-like movements, definite titubation, the appearance of being drunk, etc. Peripheral neuritis follows, generally affecting the muscles of movement; sensory affections (pins and needles feeling, anaesthesia), cramp-like pains, and sometimes troubles of sensation (hearing is more often affected than sight).

Naturally, in the majority of cases, gastro-intestinal and circulatory affections accompany the more characteristic signs; cough, oppression, and discomfort.

The general condition may become serious; coma may appear imminent, but a fatal issue is rare. Sometimes the toxic symptoms are very slight, consisting only of headaches, vertigo, marked mental hebetude, general malaise with slowing of respiration. These signs are transient and disappear quickly on the patient going into the outside air.

Chronic poisoning is seen especially after prolonged inhalation of bisulphide fumes. Generally the acute form constitutes the initial period of poisoning from carbon bisulphide, of which the second is the chronic form. This may set in without any obvious distinctive episode after several weeks, months, or years of work, subject to surrounding conditions and individual susceptibility.

The headache and digestive trouble persist and become aggravated, the patient sometimes presents a blackish line on the gums (resembling the Burtonian line, but which disappears quickly), progressive emaciation, atrophy of the muscles, etc., circulatory and respiratory troubles, slight and without objective signs are never wanting, but generally a return to normal occurs on cessation of work in a few weeks or months according to individual susceptibility. Urinary affections are rare, whereas those affecting the genital organs are well recognised (but are much less frequent now owing to the smaller quantities of the poison inhaled).

In women the menses are excessive, whereas those affecting the genital organs are well recognised, especially their appearance after the general signs of industrial poisoning by bisulphide of carbon. The lower limbs are generally attacked first, with weakness, stiffness, heaviness of the limbs and tremor, locomotor inco-ordination, with strange, staggering uncertain gait, etc.

In an early stage the patient suffers from a feeling of cold, numbness, pins and needles, then pain in the region of the nerve centres affected by the poison. Finally, hyperaesthesia or hypoaesthesia, or anaesthesia — one or the other. Tendon and skin reflexes of the lower limbs are generally abolished. The polyneuritis then generally extends to the legs, although sometimes it comes on as the first sign — especially in workmen who have continually dipped their fingers in the liquid.

The lesion commences with deranged sensibility (slight anaesthesia of the hands from which recovery is rapid), but if contact lasts too long some degree of loss of sensibility remains (disappearance of the feeling of relief to touch) or anaesthesia of the hand and forearm (supplied by the ulnar nerve especially) may remain. Balthazard has described, further, loss of sensation localised in the pectoralis major. The fingers become stiff, movements less precise, the entire grasp of the hand and forearm attacked weakens. Paralysis predominates often in the group of muscles comprising the flexor of the hand and fingers and interossei, with diminution or abolition or even exagge-
rational of the tendon reflexes. The paraplegic form may be associated with psychical disturbance, and it may be difficult to distinguish the part played by alcohol when this is also present.

Oliver frequently found peripheral neuritis in rubber workers appearing, in several cases, weeks after the worker had left the factory. On the other hand, workpeople can continue their employment for three or four years without being attacked by paralysis. Loss of use of the limbs is often preceded by muscular inco-ordination. There is staggering gait. The vapour frequently causes drowsiness. During foggy weather the symptoms become worse. So far as relates to nervous affections in women, Oliver noted twice the following effects: vertigo, headache, lassitude, loss of appetite, and taste of the vapour in the mouth; in others the symptoms resembled those of drunkenness. After the day's work, women staggered home and before even touching their food they fell into a deep sleep. The following morning they complained of headache, felt nervous and tremulous, and only recovered themselves after an hour or two in the factory. Oliver found some workers intoxicated to such a degree as to be maniacal and threaten suicide.

Affections of the central nervous system are equally important. Some authorities have diagnosed (though rarely) the condition of poliomyelitis as due to bisulphide, and this has also been produced experimentally in animals. The intellect is first excited and then depressed — the most obvious and first observed condition. No joy in work, sadness, indifference, lack of courage, melancholia, fairly frequent sleepiness, mental dullness, loss of memory. Later there is tendency to hebetude, suicide, mania, of which bisulphide inebriation is a paroxysmal exaggeration with staggering gait, impulsive acts, often of a serious nature, and a change, more or less pronounced, in the system in general.

According to Laudenheimer, who collected the clinical histories of 50 cases of bisulphide madness, this comes on in the first weeks or months of exposure to the poison, very much more rapidly than the paralyses. There is frontal headache, vertigo, dull lassitude, transitory periods of excitement, slight delirium; then comes on profound depression, apathy, melancholia, and loss of memory. The somnolence sometimes takes the form of acute mania or melancholia, with persecution delirium. A cure takes place unless the affection is so severe as to become permanent.

Exactly how bisulphide acts in giving rise to the acute mania, and the different delirious conceptions, etc., is doubtful.

Marandon de Montyel is of opinion that only organic or primitive dementias, that is to say unprecedented by mental disease, ought to be attributed to the exclusive action of carbon bisulphide. According to him, furthermore, it is the patient's constitution and not the poisonous dose which determines the mental form of the psychopathy. The other affections (delirium and various forms of insanity) are due, similarly, not to the poison, but to the psychopathic predisposition of the workpeople who handle it.

**Ocular symptoms.** — Diminution of visual acuity is a very important early symptom. In a certain number of cases, however, the amblyopia develops early in the poisoning and progresses without pain, very much like tobacco amblyopia. Hence at fixation causes photophobia and watering of the eyes. The amblyopia is due to inflammation of the optic nerve, and is complete in three months' time if the patient continues at his work. If the attack has been severe, recovery of full vision is practically impossible. The trouble of fixation, the photophobia, the diminution in sight, and the watering of the eyes are obstacles to appreciation of changes in the visual field which, however, is found to be contracted. There is a central scotoma, for red, a rather inconstant feature, but which, if present, has great diagnostic value (Terrien). Dyschromatopsy and nyctalopy, sometimes xanthopsy (the most frequent), as well as choropsy and erythrospy, are almost constant. The prickling sensation in the eyes complained of by the workers disappears as soon as work ceases, and the patient gets into the fresh air; the amount of lachrymation is small without conjunctival hyperaemia. Some writers speak of an anaesthesia of the cornea which others have not found. The eye reflexes are normal. Lehmann has described sluggishness of the pupil and inequality in size. One single case (Litten) of total double ophthalmoplegia and of divergent bilateral strabismus (Golesciano 1907) has been described.

**Course.** — The slight cases of acute poisoning recover rapidly on withdrawal from the poison, and prognosis is favourable provided there is cessation from dangerous work.

So far as chronic poisoning is concerned prognosis is favourable in the matter of life, but bad in that of health.
never becomes a man again" (Delpech). The chronic phase progresses slowly and the general inclination is distinctly downhill; it is interrupted from time to time by acute relapses, which point to a period of excitement and are due to absorption of a larger dose than usual. After treatment, more or less long, the patient recovers his health, but relapses are usually more severe than the previous attack. The course rarely ends in death unless it be by cachexia.

The polyneuritic lesions get better as the poison is eliminated and no further exposure takes place.

The mental affections also get better easily; but the most severe forms are those in which there is a hereditary predisposition. Such are those with irreparable damage, such as eye changes, which come on with great rapidity, and once set up, are only with difficulty and very rarely cured. Hearing is re-established with difficulty as well as memory for words.

**Diagnosis**

Except the bisulphide inebriation, no specific symptom serves to stamp the nature of the poisoning; and in the case of that, as of all other effects of carbon bisulphide, absence of the history and of a complete clinical examination makes the diagnosis very uncertain.

Diagnosis depends on knowledge of the workman's occupation and of the conditions of his work; the suddenness, too, with which generally symptoms appear. Among the more important signs are headache, and diminution of visual acuity, the smell of the breath, and emanations of the patient, vertigo, digestive troubles, and excitability. The later depressive symptoms are less characteristic.

Differential diagnosis in the acute condition has to be made from poisoning due to aniline, petrol, benzene, sulphur chloride, carbon tetrachloride, sulphuretted hydrogen, carbon monoxide, illuminating gas, chloroform, ether, food poisoning, acute alcoholism, and psychic troubles, hysteria. It is made the more delicate as mixed effects may be present as, e.g. in rubber workers in whom the bisulphide poisoning is often complicated by the effects due to benzene, sulphur chloride, and carbon tetrachloride.

In chronic poisoning differential diagnosis has to be made from poisoning by lead, mercury, arsenic, various causes of paresia, such as locomotor ataxy, progressive muscular atrophy, hysteria, neurasthenia, chronic alcoholism with kidney disease, and failure of the mental powers with muscular weakness and loss of movement.

**Demonstration**

(a) In the air.—Qualitatively carbon bisulphide is readily recognised by the very peculiar odour (heavy and sweetish, resembling that of chloroform); quantitatively Lehmann recommends Gastine's method: pass finely-divided air into a saturated solution of 20 per cent. caustic potash in alcohol at 96° C. The bisulphide of carbon is fixed as potassium xanthogenate. The vessel in which it has been absorbed is emptied, it is rinsed with a mixture of water and alcohol in equal parts, and is acidified with weak acetic acid. Neutralisation is effected by adding an excess of carbonate of lime. A solution of starch is added and equal parts of water and an alcoholic solution of potash. Titration is then made with a solution of iodine containing 1.667 mg. per litre, until a faint blue tint appears. One cubic centimetre of the solution is equivalent to a milligram of carbon bisulphide. Lehmann has obtained good results with this method, and Laudenheimer has found by its means in well-ventilated rubber vulcanising factories 0.2 to 0.3 mg. of carbon bisulphide per litre, and in badly-ventilated 1 to 2.4 mg. Kohn-Abrest gives a variation of the method. After acidifying with weak acetic acid, a 1 in 20 solution of copper sulphate is added, when a yellowish-golden precipitate is obtained. In adding this solution carefully the moment is noted when, as a result of an excess of the copper salt, the liquid lying above the yellow-gold precipitate begins to get coloured.

The dosage is still done by utilising the reaction with sulphate of copper (Kohn-Abrest). The copper xanthate readily falls down, and the end of the precipitation is recognised without difficulty. An excess of alkali must be avoided. The carbon bisulphide is converted into xanthate, then saturated with cream of tartar or bicarbonate of soda. The 1 in 20 copper sulphate is added slowly. This last reaction has been used to determine the amount of carbon bisulphide in illuminating gas.

Ethereal solution of triethyl phosphine with an equal quantity of ethereal solution of carbon bisulphide gives a crimson crystalline precipitate.

(b) In the body (post mortem) carbon bisulphide has never been detected. The urine gives off a characteristic radish-like smell due to a derivative of carbon bisulphide. When heated gently with Fehling's solution the urine gives a special kind of precipitate; a brownish black colour (Gaul is noticed due to the presence.
ence of haematin coming from the destruction of the red blood cells.

HYGIENE

The manufacture, handling, and use of carbon bisulphide should be carried out as far as possible in airtight closed automatic apparatus.

Ventilation of the workrooms should be well planned. Fume removal should be effected by downward exhaust ventilation at floor level. Workers should stand on platforms and not work in pits or in a bent attitude. In general ventilation should possess two principal characteristics, i.e. should be powerful and should be applied as near as possible to the point of origin of the fumes.

These are the measures now generally employed, and they explain the relatively small number of cases of poisoning found, despite a much greater consumption of the substance than ever before.

Substitutes for carbon bisulphide with less toxic properties should be adopted whenever practicable, as, for example, carbon tetrachloride, trichlorethylene, dichloromethane, acetone, etc., according to the precise process in question.

Waterproof clothes, gloves, and footwear are necessary, but it should not be forgotten that clothes, walls, floors, etc., readily become impregnated and require to be frequently and thoroughly cleaned. Alternation of employment with rest periods or work in shifts should be arranged.

Personal hygiene resolves itself into abstention from excess in alcohol and tobacco. Milk should be taken. Monthly medical examination is called for, with an initial examination before employment so as to eliminate subjects likely to become affected and those with organic defects. Every workman showing susceptibility (tremor of the hands, weakness of the legs, visual defects) ought to be transferred to other work or rejected altogether. Susceptibility may manifest itself afresh even after prolonged treatment as soon as fresh exposure takes place.

Workers should be informed of the dangers incurred.

To prevent risk of explosion and fire the bisulphide should be delivered in drums and unloaded, guarding against violent shock. The drums should be discharged close to the place where they are to be emptied and in summer placed in the shade and watered so as to keep down the pressure inside, arising from the tension of the vapour. In industries using the substance emptying can best be done under water, as the difference in specific gravity between the two keeps them separate, and it might well be distributed by means of compressed air in pipes kept under water. Smoking must be prohibited. The motive power requires to be in a separate building quite isolated from the workrooms. Lighting should be by electric light in airtight globes. Gearing and fuses should be outside the building in closed boxes. Heating should be by hot water pipes as the bisulphide takes fire on steam pipes.

Fire extinguishers should be ready to hand.

LEGISLATION

Employment of women is prohibited in the manufacture of carbon bisulphide in Argentina; in stores and workrooms in which acid vapours are given off in France; employment of young persons of less than sixteen years and female young persons of less than twenty-one years of age in the manufacture in Belgium and Spain; in the use of bisulphide in the extraction of oils, soaps, bleaching, in varnishes made with rubber, etc., in Spain; young persons under sixteen years of age and female young persons under eighteen years in the manufacture in Greece; young persons of less than eighteen years in stores and in the manufacture and use when large quantities are in question and in workrooms in which dangerous gases are given off in France; in the cold vulcanisation process in Germany and Switzerland; young persons of less than fifteen years of age and women of less than twenty-one in the manufacture in Italy, etc. The Netherlands law only deals with work in premises where toxic vapours are given off to such an amount as to be considered dangerous to health by the inspector of factories. The Regulations of February 1895 deals with the employment of women and children in industries using carbon bisulphide.

In Belgium the Royal Decree of 23 February 1895 deals with the employment of women and children in industries using carbon bisulphide.

The Regulations of 5 February 1896 of the Permanent Committee of the Provincial Council of Brabant prescribes as further Regulations:

(1) Installation of a suction hood connected up with a fan opposite each receptacle. The hood should have a length equal to that of the vessel and a height of at least ten centimetres.

(2) The tables on to which the dipped articles are placed should be perforated and the perforations connected up with the same fan. The
same should apply in the case of tables on which the boards are placed for receiving the articles dipped in carbon bisulphide.

(3) A linear velocity shall be kept up in the hoods referred to in paragraph (1), and the openings in paragraph (2), of at least 20 cm. per second, that is to say, appreciable by the special Bürani anemometer used by the inspectors of factories.

In France the Decree of 10 May 1904 places obligations on the employer of taking measures to prevent poisoning by carbon bisulphide. The circular of 20 January 1909 relates to the manufacture of rubber.

In Germany the Order of 1 March 1902 (Reichsgesetzblatt, page 59) relates to the installation and working of industrial establishments engaged in the vulcanisation of rubber articles.

The principal requirements relate to the flooring (at the same level as the ground level), the opening (or windows in a must be made to open) capable of supplying sufficient air renewal, to mechanical ventilation, to the arrangements for preventing escape of vapour. Vulcanising workrooms must not be used as living rooms, for the preparation of food, warehouses, or drying purposes but only for vulcanisation. Remaining in rooms except as necessitated by operations connected with vulcanisation is prohibited. Cubic space must be 20 meters per person. Only such quantity of bisulphide as is necessary for the vulcanising processes going on shall be brought into the workrooms. Reception rooms must be airtight. Vulcanising and drying rooms must be heated by hot water pipes or steam. Artificial lighting by electricity is required to be installed under certain conditions. Vulcanising machines must be provided with hoods connected up to extraction fans, so that the air shall not contain more than \( \frac{1}{3} \) to 1 per 1,000 of vapour. Vulcanising must be carried on under hoods where the workman shall introduce only his hands and such as to prevent the vapour from reaching the face. Drying shall be done in special rooms or under aspirating hoods. Drying rooms shall be so constructed that it shall not be necessary for the workpeople to enter for the introduction or removal of the articles.

Not more than two hours’ continuous work at the most and not more than four hours in the day, with an interval of at least an hour, shall be allowed. The employer shall supply overalls. Washing and cloakroom accommodation (for both sexes) shall be provided, maintained in a clean condition and shall be capable of being heated in cold weather; provision of soap, towels, etc., and cupboards for keeping the clothing, monthly medical examination by a surgeon approved by the inspector of factories, with power to suspend from work workers showing symptoms of poisoning, shall be compulsory.

A Ministerial Circular (Prussia), dated 23 February 1910, deals with the manufacture, storage, and use of carbon bisulphide. German regulations prescribe that in the case of installation of inflammable liquids the piping must be underground.

In Great Britain the India-rubber Regulations of 31 March 1922 under section 77 of the Factory and Workshop Act, 1901, relate to processes in the manufacture of India-rubber, or of articles or goods made wholly or partly of India-rubber.

The regulations define “fume process” and “lead process”.

“Fume process” means any process in which use is made of carbon bisulphide, chloride of sulphur, benzene, carbon tetra-chloride, trichlorethylene, or any carbon chloride compound or from which the vapour of any of these substances is given off.

The Regulations prohibit employment of any person of less than 18 years of age in a fume process, and of any person less than 16 in any room in which a fume process is carried on, unless a standard ventilation of 30 changes of air per hour is maintained.

No person shall be employed in a room in which carbon bisulphide is used for more than five hours in all in any one day nor for more than 2½ hours at a time without a rest interval of at least one hour from any employment.

A fume process shall not be carried on in the open air or in any room the floor of which is in any part below the level of the surrounding ground. A fume process shall not be carried on without an efficient exhaust draught so contrived as to operate on the vapour given off as near to the point of origin as possible, except when the standard ventilation of the room provides for 30 changes of air per hour.

In the vulcanising of waterproof cloth the machine shall be so arranged that the mechanical feeding-in and delivery of the cloth takes place outside the enclosure. Further, the trough containing the vulcanising material shall be fed only by natural flow from the reservoir containing the solution. The reservoir itself shall be enclosed. Periodic medical examination shall be made by an appointed surgeon. General welfare arrangements are also enjoined.

Both in Belgium and Great Britain the periodic examination is required every month.

Poisoning by carbon bisulphide is statutorily notifiable in Great Britain, Bavaria, Western Australia, Pennsylvania, and the Netherlands. It is scheduled as a disease for which compensation can be obtained under the Workmen’s Compensation Acts in Germany, Great Britain, New Brunswick, Bolivia, Finland, Italy, Queensland, Western Australia, and in the United States (Minnesota, New York, Ohio), Porto-Rico, in Argentina, Brazil, Chile, and Switzerland.
CARBON MONOXIDE

BUSCAGIA. La medicina del lavoro, No. 11, 1925. Milan.

Prof. Balthazard

Carbon Monoxide

French: Oxyde de carbone.—German: Kohlenoxyd.—Italian: Ossido di carbonio.—Spanish: Oxido de carbono.

CHEMISTRY

Symbol: CO. Colourless, inodorous gas, not irritating, tasteless, containing 57.13% of oxygen and 42.87% of carbon. Slightly soluble in water, which dissolves only 25 c.c. per litre at 15° C.; liquefies at —141° C. under a pressure of 36 atm.; solidifies at —211° C. Specific gravity (in reference to air): 0.967. Limit of explosibility of a mixture of air with carbon monoxide (in contact with a flame): 16-17 per cent. of carbon monoxide.

Carbon monoxide results from incomplete combustion of carbon due to an insufficiency of air or oxygen. Combustible itself it burns with a blue characteristic flame becoming converted into carbon dioxide. It reduces a solution of palladium chloride precipitating black metallic palladium (not very characteristic), ammoniacal nitrate of silver (reaction increased by heat; not characteristic); liberates iodine from a hot solution of iodine pentoxide; is absorbed by cuprous chloride in ammoniacal solution and gives CuCl₂, CO₂H, O water of crystallisation; forms a very stable compound with haemoglobin which has been thus obtained in a crystalline state.

SOURCES OF POISONING

The sources of poisoning are very numerous; frequently the intoxication is the result of what has the character of a single accident or of repeated accidental exposures. When it is a question of heating and lighting by solid, liquid or gaseous fuel, the production of carbon monoxide is inevitable.

The most important sources of poisoning are:

(a) Coal gas (see "Gas works"), which contains up to 12 per cent. of carbon monoxide. If the gas is carburetted with water gas the percentage of carbon monoxide can reach 27 or even 29. Danger occurs from leaky pipes, accidental opening of taps, faulty installation of gas stoves etc., and wherever gas or gas fires without flues replace hearths (see under f), principally in the heating of small melting pots (e.g. in soldering, and in casting monotype and linotype characters). Gas works labourers, plumbers employed underground in installing or repairing gas mains, mechanics in charge of gas engines, and persons engaged in inflating balloons are specially exposed to risk. The toxic effect of other constituents of gas should not be forgotten: e.g. benzene (0.5 to 1 per cent. in gas) and the light oils (up to 5 per cent.).

(b) Industrial gases. Gaseous mixtures, such as water gas, blast furnace gas, power gas (Dowson, Mond, etc. — see "Industrial Gases") are very dangerous in view of their high content in carbon monoxide, which varies from 25 to 40 per cent.

(c) Iron and steel works. Blast furnaces. (See article "Iron, Pig Iron and Steel Industries".) The reduction of the ore evolves carbon monoxide \( \text{Fe}_2\text{O}_3 + 3\text{C} = 2\text{Fe} + 3\text{CO} \), and the gases which escape from blast furnaces contain a considerable amount (up to 30 per cent.). The danger is present during charging by hand (old style), tapping the metal or slag, and in puddling. Exposed to risk also are the cleaners and repairers of furnaces and flues, workmen attending to regenerating furnaces, especially when built below ground (old installations), etc.

(d) Coke ovens and wood charcoal. Carbon monoxide is given off in quantity, especially when the ignited coke is extinguished by water. The gases given off by the slag heaps of blast furnaces are also rich in carbon monoxide.

(e) Metallurgical and engineering industries. (See article "Mechanical Engineering".)

(f) Foundries (metallurgy of iron, zinc, mercury, silver, lead, etc.) where carbon monoxide is given off from
the furnace hearths of melting pots; dipping baths, vats, lime kilns, etc. Persons employed in the upper part of the shop (crane minders for charging the furnaces, glaziers, etc.) may be affected by the ascending gas, as also may tinsmiths soldering in badly ventilated places and using soldering pots heated by charcoal, workmen attending to the dryers in brass and iron foundries, etc. Cases have also been reported in blow-pipe welding from the small quantity of carbon monoxide in the compressed hydrogen (made with water instead of hydrogen obtained from compressed hydrogen (made with water quantity ed in blow-pipe welding from the small dried, etc. to the driers in brass and iron foundries, etc.). Heated by charcoal, workmen attending the smiths soldering in badly ventilated places and using soldering pots may thus be affected by the ascending gas, as also the crane minders for charging the shop (crane minders for charging the shop). Persons employed in the upper part of furnaces; in manufacture of celluloid and other synthetic substances (e.g., acetone, oxalic and sulphuric acid); in the dissection of animals, in the wool works, in the production of nitroglycerine, in the production of nitrocellulose, in the preparation of carbon monoxide, whether by the oxalic and sulphuric acid method or by that of sulphuric acid and ferroanide of potassium. In toxico-

Carbon monoxide

(l) Smoke containing a percentage of carbon monoxide which is higher than the normal gives danger during fires (see article "Firemen"), especially when the fire has not made its way to the open (also in tunnels), to man on passage ways and looking after the trolley lines, to chimney masons, chimney sweeps, cookers, etc. Smoke from mineral oil lamps or tobacco or stoves, etc., in badly ventilated premises is also dangerous.

(m) Dust containing carbon monoxide affects chauffeurs, cleaners of boilers and pipes of generators in the most diverse industries; workmen in coke ovens (frequently) and paper mills, persons employed in the dry distillation of rags, or their treatment by quicklime.

(n) Textile industry: cloth singeing, gassing rooms, etc.

(o) Exhaust gases from motors (petrol, benzene, etc.) containing a percentage of carbon monoxide of from 3 to 14 per cent. In 1922 an enquiry made at Pittsburg (U.S.A.), extending to more than 100 motor vehicles of the most varied description, brought out that the proportion of carbon monoxide in the exhaust gases was 0.5 to 14 per cent. Hence the danger to mechanics working in closed garages near a motor car kept running, especially at the exhaust outlet; and to chauffeurs who drive from the inside of closed cars because of the passage of exhaust gases to the inside in the absence of good ventilation. (Account must also be taken of the role played by the products of overheating of the lubricating oil.)

(p) Use of carbon monoxide on ships for destroying rats (apparatus proposed by Nocht and Giemsa). The persons engaged in disinfection as well as the sailors who enter the cabins, etc., after insufficient ventilation, run risk.

(q) Hearths with badly acting exhaust: owing to defective installation or accidental causes: obstruction in the pipes, ill-fitting doors or premature closing of the doors or of the dampers; cracks, faulty construction, defects in the draught owing to weather conditions (affecting cooks, watchmen, bakers, furnacemen, etc.).

(r) Scientific processes in laboratories, especially chemical, during the preparation of carbon monoxide, whether by the oxalic and sulphuric acid method or by that of sulphuric acid and ferroanide of potassium. In toxico-
logical laboratories in the course of experiments on the physiological effects of carbon monoxide.

TOXICOLOGY

Absorption. — Traces of carbon monoxide given off habitually in combustion may be considerably increased by a variety of causes affecting the draught, such as atmospheric pressure, wind, temperature, humidity of the air, etc. Further, the kind of fuel, and the way in which the fire acts, are important factors which should not be forgotten.

On the other hand, individual susceptibility varies with the general constitution of each person, the precise state of the organs, etc., as for example the respiratory capacity (deep respiration of the organs, etc., as for example the transformation of each person, the precise state of consciousness, with 0.4-0.5 per cent. and death, or at least loss of consciousness, with 0.4-0.5 per cent. (Case described by Deal.) The air would be highly dangerous at the end of an hour if 2 mg. per litre were present, and death would appear to ensue at the end of 20-30 minutes in presence of 4-5 mg. of carbon monoxide per litre; rapidly with 10 mg. per litre. Haldane considers that even 0.05 per cent. can cause symptoms.

A man at rest can breath an atmosphere containing 1 mg. of carbon monoxide per litre for two hours and a half before 50 per cent. of his blood is saturated, but if he engages in active work symptoms would show in less than an hour.

The Mines Department of the United States regards 0.18 mg. per litre as a dangerous limit, and as fatal, 0.48 mg. In cases of continuous exposure even a quantity of 0.06 mg. is looked upon as dangerous, in view of the cumulative action of carbon monoxide. In fire damp mines the Department fixes as the limit of safety a dose of 0.024 mg. in presence of good ventilation. Haldane in 1906 decided that the maximum to be permitted in the London tubes was 1/10,000, and Henderson of the New York Tunnels Committee is of the opinion that 4/10,000 can be tolerated without bad effects during three quarters of an hour.

The respiratory tract is the most important practical channel of absorption. Carbon monoxide is absorbed through the lungs into the blood and the transformation of the oxyhaemoglobin (HbO) of the red cells into carboxyhaemoglobin (HbCO) commences in the capillaries of the alveoli and depends on the rapidity with which the carbon monoxide passes into the blood vessels.

According to most toxicologists carbon monoxide can already be fixed by the haemoglobin if only minute traces are present (1 in 15,000) and is only displaced by oxygen slowly, depending

remembering the particular susceptibility of each individual and especially the condition in which the subject finds himself at the moment of poisoning (see above).

So far as the minimal dose is concerned no person would be affected if he breathed, even for an hour, air containing less than 0.30 mg. per litre of carbon monoxide (Mosso). The first symptoms would appear to come on at the end of an hour with a dose of 0.35-0.40 mg. per litre. Persons, however, who with great courage have submitted themselves to experiment have shown very serious symptoms in 30 minutes with a mixture containing 0.43 per cent. and death, or at least loss of consciousness, with 0.4-0.5 per cent. (Case described by Deal.) The air would be highly dangerous at the end of an hour if 2 mg. per litre were present, and death would appear to ensue at the end of 20-30 minutes in presence of 4-5 mg. of carbon monoxide per litre; rapidly with 10 mg. per litre. Haldane considers that even 0.05 per cent. can cause symptoms.

A man at rest can breath an atmosphere containing 1 mg. of carbon monoxide per litre for two hours and a half before 50 per cent. of his blood is saturat

The Mines Department of the United States regards 0.18 mg. per litre as a dangerous limit, and as fatal, 0.48 mg. In cases of continuous exposure even a quantity of 0.06 mg. is looked upon as dangerous, in view of the cumulative action of carbon monoxide. In fire damp mines the Department fixes as the limit of safety a dose of 0.024 mg. in presence of good ventilation. Haldane in 1906 decided that the maximum to be permitted in the London tubes was 1/10,000, and Henderson of the New York Tunnels Committee is of the opinion that 4/10,000 can be tolerated without bad effects during three quarters of an hour.

The respiratory tract is the most important practical channel of absorption. Carbon monoxide is absorbed through the lungs into the blood and the transformation of the oxyhaemoglobin (HbO) of the red cells into carboxyhaemoglobin (HbCO) commences in the capillaries of the alveoli and depends on the rapidity with which the carbon monoxide passes into the blood vessels.

According to most toxicologists carbon monoxide can already be fixed by the haemoglobin if only minute traces are present (1 in 15,000) and is only displaced by oxygen slowly, depending
on a number of physiological factors and taking at least several hours.

Carbon monoxide is not a poison of living protoplasm, but it acts by suppress the property that haemoglobin, whether globular or muscular, has of fixing the oxygen at the level of the lungs and of carrying it to the tissues.

The quantity of carbon monoxide fixed by muscular haemoglobin is slightly less than that fixed by globular haemoglobin. The affinity of carbon monoxide for haemoglobin is very great; it is estimated to be 210 times as great as that of oxygen for haemoglobin. It forms with this a relatively stable compound, even when it is brought constantly by the circulation into contact alternately with carbon dioxide and oxygen. According to Gréhant, at any rate not in any large number of physiological factors.

Carbon monoxide, therefore, is not a poison, since the combination which it forms with haemoglobin is fairly easily dissociated; it acts rather in the manner of an inert gas by diminishing the quantity of oxygen placed at the disposal of the tissues, thus producing anoxaemia. According to the personal experience of Haldane, this only commences to take effect (with cerebral symptoms) when about a third of the

toxic action on the organism. Those holding the first view, which tends to stress as of capital importance the mechanism of asphyxia, maintain (as explaining all the symptoms produced by carbon monoxide in the organism) that, at the moment of death in acute intoxication, the anoxaemia reaches the same degree as is the case in asphyxia; and that in artificially supplying oxygen to the tissues carbon monoxide cannot have a fatal result.

Importance is attached to the usefulness of determining what Balthazard and Nicloux have called the "coefficient of intoxication", i.e. the ratio of the quantity of haemoglobin rendered unusable, as a consequence of its combination with carbon monoxide, to the total quantity of haemoglobin for a particular volume of blood. This value is estimated between 0 and 1 and gives the exact measure of anoxaemia; multiplied by 100 it expresses the percentage of haemoglobin thrown out of action for the normal functions of the blood. Death supervenes when two thirds of the haemoglobin have become unfit to perform the function in question.

Carbon monoxide, therefore, is not a poison, since the combination which it forms with haemoglobin is fairly easily dissociated; it acts rather in the manner of an inert gas by diminishing the quantity of oxygen placed at the disposal of the tissues, thus producing anoxaemia. According to the personal experience of Haldane, this only commences to take effect (with cerebral symptoms) when about a third of the

---

1 In spite of the improvements proposed by Nicloux, this method is a delicate one and takes at least two hours.

Balthazard has just proposed (1924) a method of spectroscopic determination of the coefficient which takes less than a minute and requires only a drop of blood. It is based on the different position in the spectrum of the bands of oxyhaemoglobin and carboxyhaemoglobin. Considering only the left band, one determines with the spectroscope (spectroscope of Yvon) that the maximum intensity for oxyhaemoglobin corresponds to the wave-length 577, and for carboxyhaemoglobin to the wave-length 570. Mixtures of oxyhaemoglobin and carboxyhaemoglobin give a left band of which the maximum intensity corresponds to a wave-length intermediate between 577 and 570, and tending the more to approach the last value as the blood is the more rich in carboxyhaemoglobin.

It is sufficient, then, to dilute in a little boiled water a drop of blood from the body, to examine this spectroscopically and determine the wave-length of maximum intensity of the left band, which determination is facilitated by a ruled eye piece micrometer between the lines of which the band is circumscribed symmetrically in relation to the brightest part. A simple reading of the table standardised before by means of titrated mixtures enables one to know the coefficient of poisoning, examined. The error does not exceed 5 per cent.
haemoglobin is changed into carboxyhaemoglobin (about 8 c.c. of carbon monoxide to 100 c.c. of blood) no matter what amount of carbon monoxide there is in the air breathed. Serious symptoms show themselves when half the haemoglobin is saturated (12 c.c. per 100 of blood).

In practice the quantity of carbon monoxide contained in a known volume of blood is determined and one investigates the maximum quantity of carbon monoxide that this same volume of blood is capable of fixing; the quotient of the two values is then obtained.

The coefficients of intoxication in different persons are extremely variable because of a number of factors of which several readily escape us. But it is especially low in aged persons, little resistant to anaemia, and those who have been venereal lesions; it is increased, if the intoxication has occurred rapidly, in an atmosphere rich in carbon monoxide; and can be lowered if the duration of intoxication has taken several hours and in an atmosphere not very rich in carbon monoxide.

**Blood.** — Experimentally and clinically diminution in the oxygen and carbon dioxide contents of the blood has been found. The diminution in the latter would seem to be bound up with a diminution in the alkalinity of the blood; without any doubt the diminution of carbon dioxide is the cause of the lessened alkalinity of the blood (due also to default of oxygen).

There is an increase of sarcoldatic and other acids (especially sulphuric and phosphoric) derived from the destruction of albumin exaggerated by the carbon monoxide intoxication. Clinical examination of the blood as effected by various authorities has given rise to very contradictory results. If the haemoglobin is generally diminished, even with an increase in the red blood cells (up to 11,200,000), this is not the view of other authorities who have even reported a diminution of the number. The shape of the red blood cells is not affected. Sometimes red blood cells are found in which the reticulo-filamentous substance is of a bluish colour and the granular substance reddish violet; sometimes there are none of these young or immature forms; sometimes nothing special is observed about the platelets and sometimes notable increase of them, slight leucocytosis with increase of neutrophils and no cesinophilia, which according to some is said to be of serious import in prognosis; coagulability of the blood during life is increased.

**Elimination.** — If the affected person is withdrawn from the toxic atmosphere the carboxyhaemoglobin is broken up, and after a variable time the haemoglobin ceases to contain any carbon monoxide. Neither the degree nor the duration of the poisoning or the manner in which it occurred have any constant relation with the elimination of carbon monoxide — a thing dependent on the rapidity of intervention. Whether this takes the form of supplying fresh air or especially pure oxygen for inhalation, it has been proved that at first the affected blood readily gives up the poisonous gas. But later this yielding becomes more difficult, the chemical combination probably becoming gradually more stable.

Hence the importance of early intervention of prolonged artificial respiration and especially inhalation of a mixture of oxygen and carbon dioxide (8-10 per cent.) — a mixture which induces deeper breathing and favours elimination of carbon monoxide at a rate 5 to 6 times as rapid as would normal air, even when 30-40 per cent. of the haemoglobin is in combination with carbon monoxide.

**Statistics**

Many writers maintain that the majority of cases of carbon monoxide poisoning remain unknown and that only the serious ones appear in statistics. The Health Office of the German Empire considers that no data as to conditions in industry could state with certainty what the occupational risk from carbon monoxide was. German statistics on the occupations most liable to this form of poisoning (firemen, gas workers, miners, etc., excluding the victims of explosion) do not show high figures. In the United States, of 112,987 iron and steel workers in the Illinois Steel Company during five years (1916-1920) 271 (with 13 deaths) were reported as poisoned by carbon monoxide.

In Great Britain the reported cases, i.e. cases in which incapacity lasted one whole day, were:

1. The fatal cases are given between brackets.

The mortality has been, therefore, 12.7 per cent. for the period 1908-1912, 16.4 per
 Poisoning can take three forms: massive, acute, and chronic.

(a) Massive intoxication. — Massive intoxication occurs by rapid inhalation of large amounts of carbon monoxide—at the moment of tapping blast furnaces, cleaning and repairing gas mains, especially when underground. It is characterised by almost instantaneous falling down, loss of consciousness and rapid death. In the event of survival there may be long continued nausea, vertigo, headache, convulsions, etc.

(b) Acute intoxication. — The premonitory symptoms often pass unnoticed and in the first stage the individual has violent frontal headache, feeling of constriction about the temples, nausea, sometimes vomiting, hallucinations of sight and hearing, dyspnœa accompanied by retro-sternal and precordial pain. At first the affected person may have retarded respiration, and then or later convulsions, Cheyne Stokes breathing, with weak and irregular pulse. A characteristic of the second stage before loss of consciousness—constantly preceded by tendency to sleep—is the diminution or abolition (especially in the lower limbs) of the power of movement, the intellectual faculties remaining intact. At times there is euphoria and even psychical excitement; at times sub-normal temperature followed by a rise (not necessarily associated with lung complications). The face at first pale becomes carmine red; the skin is lived, or shows pink patches. Loss of consciousness can pass into coma, but in some cases there may be motor excitement (tremor, clonic and tonic spasms, sometimes tetanic with opisthotonos and trismus) which have been known to appear even in the first stage.

If the second stage does not terminate in death it is followed by a third in which the dyspnœa becomes very marked, respiration superficial, irregular (Cheyne Stokes), stertorous, and the pulse feeble. The temperature falls, the face becomes cyanotic, the mucous membranes congested, the pupils dilated and the reflexes diminish or disappear. If intoxication has been pushed very far, the coma persists and death is delayed. In cases of recovery return to life takes place with retrogression of the symptoms, and after a variable length of time a cure is effected which, however, is not always complete.

Among the sequelæ the most frequent are motor troubles (paralysis, hemiplegia due to cerebral softening, myelitis, polyneuritis, etc.), or trophic (œdema, ecchymoses, bullæ, eschars, etc.), or psychical (frequent and severe: mental confusion, amnesia, which may last and go on at times to dementia, maniacal seizures, etc.), or simply neuropathic or cardio-pulmonary (pneumonia, congestion, œdema, haemoptysis), or digestive affections. Wasting is also reported or a general asthenia with intense anaæmia, albuminuria, glycosuria, etc. If the typical forms are as thus described not a few cases are atypical in a high degree by reason of the personal factor. Among these atypical forms of acute intoxication the "abortive" form should be remembered with its reduced clinical picture, due to an intoxication of short duration with rapid recovery, and rarely showing the presence of carbon monoxide in the blood; or a "relapsing" form in which the symptoms recur after some days or weeks, and lastly a "late" form in which the signs do not appear until after some time.

(c) Chronic poisoning. — The question of the existence or not of this form has been much discussed and is not yet settled. In any case one should be very cautious before assigning the signs observed to the action of carbon monoxide because the connection is often far from clear. On the other hand some authorities consider that the action of small doses of carbon monoxide cannot be without effect on the organism—not only on the blood and the blood forming tissues but also on metabolism. They consider that 80 per cent. of the cases of poisoning by carbon monoxide remain unrecognised because the sufferers complain of indefinite symptoms that remain incurable and cannot be diagnosed. Errors in clinical diagnosis of these affections would appear to be pretty easy, and cases of meningitis, typhoid fever, etc., have been ascribed to carbon monoxide.

Possibly former hygienic conditions have been so defective (ventilation, heating by open braziers, etc.) that poisoning showed itself with symptoms which to-day are only met with more or less rarely or under quite exceptional circumstances. In this way one can understand the cases described in cooks (by Moreau in 1869 and by
Sée in 1873, under the name of "madness of cooks"), in ironers, tailors, etc. Nowadays chronic cases are reported among persons employed in places where heating and lighting are defective or where heating and lighting are defective or the mains or pipes allow escape of gas.

A certain number of stigmata of this intoxication are described but at all events the symptoms vary very much from the simple headache (at times intolerable) to nausea, vertigo, neurasthenia, and marked loss of muscular power. Occasionally digestive troubles are mentioned (dyspepsia, nausea, vomiting, anorexia, etc.), circulatory affections (palpitation, oppression, angina pectoris), disturbances of sight (amblyopia, choroidal congestion, diplopia), nervous complaints (insomnia, sleep during the day, change in the character, anxiety, irritability, neurasthenia, amnesia), trophic, vaso-motor or vascular changes. But the most remarkable and most frequent symptom is said to be a degree, more or less variable it is true, of anaemia. In this connection one must remember that in the daily round of work such symptoms as have been enumerated above are not convincing.

Occasionally the analysis of the air of the place, because it can happen that the individual who has succumbed was found still alive when the atmosphere had ceased to be dangerous. Often it is very difficult if not impossible to visualise the conditions under which the accident has happened. Certain factors are not slow in disappearing, like the gas itself, and others escape altogether.

**DIAGNOSIS**

In those who have survived acute poisoning search should be made for the symptoms described, for sugar and albumen in the urine, and a spectroscopic examination of the blood made (see later). In obscure and slight cases examine carefully such reports as there are, enquire of the fellow workmen, examine the site, analyse the air, observe the behaviour of birds or mice placed at the spot. Do not forget careful search for other morbid causes (alcoholism, syphilis).

Diagnosis is still more difficult in chronic cases, especially in such cases when they are described as slight. Remember the important role often played by other factors or the other compounds in the gas containing carbon monoxide. Remember also that the spectroscopic examination of the blood is a method insufficiently sensitive for determining small quantities of carbon monoxide (i.e. when it does not exceed one-seventh of the total haemoglobin). Absence of notable traces of carbon monoxide in the blood does not prove absolutely that the patient has not died of carbon monoxide poisoning. Sometimes victims are withdrawn still living from the fateful surroundings only to die after having eliminated entirely what might be called the fixed carbon monoxide.

Similarly account must be taken (but with a grain of salt) of the results of the analysis of the air of the place, because it can happen that the individual who has succumbed was found still alive when the atmosphere had ceased to be dangerous. Often it is very difficult if not impossible to visualise the conditions under which the accident has happened. Certain factors are not slow in disappearing, like the gas itself, and others escape altogether.

**DEMONSTRATION OF CARBON MONOXIDE**

A. In the air:

1. For qualitative examination:

   1. Make the air bubble through a solution of chloride of palladium or expose filter paper soaked in palladium chloride by means of a platinum wire in a jar containing 10 litres of the air under examination. The surface of the paper becomes covered with a black film after some minutes if the air contains about 0.5 per 1000 of carbon monoxide and only after 12-24 hours if the proportion of carbon monoxide per 1000 is 0.05. The reaction is not characteristic because ammonia, hydrogen sulphide and acetylene can give it.

2. Reactions based on the stability of HbCO, among which the following will suffice:

   a. Shake one part of blood (diluted with 20 parts of water) with an equal quantity of a solution of caustic soda (30 per cent. strength); a red coagulum is obtained. At first there is a whitish turbidity, then a reddish coloration or a fiocculus, the precipitate separates and the liquid remains slightly pink. At the end of 24 hours the precipitate redissolves and the liquid becomes bright red.
(b) Weizel’s reaction: Shake 15 c.c. of a solution of blood (10 c.c. of blood and 40 c.c. of water) with 1 c.c. of a 10 per cent. solution of chloroform from a dropper and 5 c.c. of a mixture of 1 volume of glacial acetic acid and 2 volumes of water. The precipitate which forms after agitation is, in the case of normal blood, blackish brown and with the HbCO blood intense bright red.

(c) Another Weizel reaction: 10 c.c. of blood are treated with 15 c.c. of a 20 per cent. solution of ferro-cyanide of potassium and 2 c.c. of a mixture of one volume of glacial acetic acid and 2 volumes of water. The precipitate which forms after agitation is, in the case of normal blood, blackish brown and with the HbCO blood intense bright red.

(d) Spectroscopic examination of the blood: Properly used the spectroscope enables a positive statement to be made as to the presence of carbon monoxide in the blood, but a negative result is not sufficient to conclude that the gas is not present. In the spectrum bands D and E two absorption bands are seen—not so close to the D line of Fraunhofer as that of HbO. The space between the two bands is fainter in the case of HbCO. When reduced (with ammonium sulhide) the two bands do not give place to the single band of Stokes, as happens with HbO (a preparatory reaction, this, but very sensitive). For details of spectroscopic researches the reader is referred to special treatises.

II. Quantitative examination.

The amount of carbon monoxide in the air can be determined by the method with chloride of palladium or that of iodine pentoxide heated in a bath of air to 90°. The iodine set free is dissolved in some c.c. of chloroform from a dropper and colours it red. In passing 1 litre of air per hour the amount of carbon monoxide is estimated (after 4 litres of air have been aspirated) by the tint of the chloroform when compared with a range of shades sent out with the apparatus (apparatus of Levy and Pecoul). An apparatus suggested during the war by Desgrez and Labat as a colorimetric scale is made in a test tube similar to the scale tubes of 1 c.c. of a solution of potassium citrate or 0.05 per cent. sodium fluoride. 0.1 c.c. of the blood to be examined and 1 c.c. of equal parts of 1 per cent. tannic acid and 2 per cent. pyrogallic acid. Comparison is then made with the control scale. They have put up in a small box the equipment necessary for carrying out the reaction.

Prophylaxis

(See article “First Aid”)

The medical man alone should be the judge as to whether treatment should be varied in particular cases. But certain measures are common to all cases of poisoning by gases and fumes: e.g. eliminate if possible the cause of the poison, remove the victim from the noxious atmosphere (bearing in mind that rescuers can even become affected at considerable distances — more than 15 meters), slight anaesthetisation with ether where convulsions occur; artificial respiration (see “First Aid”) and prolonged inhalation of pure oxygen; keep up the circulation by friction of the skin; diaphoresis, etc.; bleeding, injecting caffein, camphor, etc. Recently (1923) the advantages of transfusion have been pressed; it should not, however, be done in cases that are in extremis. The above treatment, even in desperate cases, has given surprising results. But when poisoning has gone on for a long time and is profound, failures are comprehensible.

In poisoning by carbon monoxide the HbCO, stable as it may be, can be displaced by the use not of oxygen pure but oxygen containing 5 per cent. of carbon dioxide. Experiments carried out
enable one to say that this mixture excites deep and rapid respiration and makes elimination of carbon monoxide 5 or 6 times as quick as when normal air is employed, even when the victims have 30-40 per cent. of their blood combined with carbon monoxide.

Persons affected who are not attended by medical men should be made to inhale pure oxygen for 20-40 minutes at least. But every surgeon should use the O and CO₂ mixture, administered as early as possible.

Quite recently (1924) a new German preparation, "Lobelin Ingelheim", has been reported on favourably by the Imperial Health Office which claims to stimulate the respiratory centre in the bulb paralysed by carbon monoxide without affecting other organs. After intramuscular or subcutaneous injection of 3 to 10 mg., or in dramatic cases after intravenous injection of 3 mg., recovery is said to be very rapid. If the heart's action is embarrassed the usual cardiac therapy is brought to bear. Lobelin was used in cases of carbon monoxide poisoning following on a coal dust explosion in a German mine in 1923. The Ministry of Commerce is continuing its researches into the product.

The measures to be taken vary with the different industries (see each industry). In addition to the usual precautionary measures against toxic gases such steps should be taken as make for good ventilation and efficient exhaust in workrooms, periodic and methodical control of the heating apparatus, distribution of gas, taps, and leaks in pipes. Before cleaning operations are carried out or flues and pipes underground entered there should be preliminary energetic ventilation, and workmen should always be made to carry suitable respirators. (See article referring to special industries, e.g. "Mines ".)

If the precautions are insufficient to protect the men against prolonged inhalation of carbon monoxide (especially in minute quantities), redaction in the hours of labour should be considered.

As indicators of risk use should be made either of special apparatus (colorimetric indicator) or of canaries or mice which are very susceptible to carbon monoxide (symptoms shown with 0.0012 per 1000).

Workmen should be instructed as to the risk of poisoning and of the measures to take both at work and in rendering first aid.

**Legislation**

For the protection of women and children see "Gases (Industrial) and Fumes ".

Compulsory notification: Netherlands and Switzerland (which countries treat carbon monoxide poisoning as an accident).

Compulsion is dealt with in the German Bill and may be considered as included in the general heading adopted by the legislature of Missouri (1913—" Poisoning by toxic gases ") and that adopted by the legislature of Ohio and Massachusetts (" all illnesses caused by occupation ").

Acute poisoning is generally treated in law as being an accident.

It is included in the lists of diseases subject to compensation in the following countries: Finland, Germany, New York, Queensland, Switzerland, U. S. S. R., and Western Australia.

**Bibliography**

See especially the work of L. Lewin: Die Kohlenoxydvergiftung. Ein Handbuch für Mediziner, Techniker und Unfallrichter. Verl. J. Springer, 1920. (A volume of 380 pp. where the question is analysed in most detailed fashion from the point of view of the technician, the chemist, the toxicologist, the clinician, and medico-legal expert.)

See also the Bibliography of Industrial Hygiene, published quarterly by the International Labour Office.
anhydride are formed. It is the least toxic of the series of organic chlorinated substances adjacent to chloroform. It appears nevertheless with the latter product in certain orders regulating the sale of poisonous substances (Kohn-Abre). Carbon tetrachloride dissolves resins, gums, and fats.

It is got by the reaction of chlorine on carbon disulphide in the presence of a catalyst such as iodine, antimony, or aluminium chloride, or by the action of sulphur chloride on carbon disulphide in the presence of powdered iron, the sulphur being again transformed into chlor-ride by the action of the chlorine. It is also got by direct chlorination of ethylene.

The crude tetrachloride is purified by washing in dilute rectified soda.

**Sources of Poisoning**

**In course of preparation.** — The workers may be exposed to the combination of chlorine, carbon disulphide, and methyl chloride.

**In course of usage.** — (1) In the rubber industry, where it is used alone or mixed with other products in the preparation of rubber elements or mixtures in place of carbon disulphide, which is more poisonous and more inflammable, though less expensive. When the mixing is done by hand in open receptacles, there is risk of the fumes being inhaled. In modern installations this operation is generally effected in mixers. The workers engaged in filling the tubes with mastic or cement are also exposed to a similar risk. (2) In using the product as a solvent of acetate of cellulose, in the preparation of varnish for aeroplane wings. (3) In dry cleaning. (4) In making fire extinguishers (under the name of “pyrene”). Fieldner and Katz report that the use in mines and enclosed places of carbon tetrachloride extinguishers in the absence of sufficient ventilation may cause liberation of fumes containing not only ordinary products of combustion such as carbon dioxide and carbon anhydride, but also carbon tetrachloride, hydrochloric acid, and phosgene in such quantities that anyone exposed for five or ten minutes to the fumes may suffer, if not from serious effects, at least from persistent discomfort.

**Toxic Action**

Industrially carbon tetrachloride would not appear to have a powerful action. According to Marshall and Starr (1898), it exercises on the circulation and respiration the same toxic action as chloroform, only stronger.

According to other authors (Waller and Veley) it is twice as toxic. Lehmann, on the contrary, on the basis of laboratory experiments, says it is only half as toxic in strong doses, and equally toxic in small doses. Ramhusek considers that its narcotic action is half that of chloroform, but that it is much more irritating.

Rabbits can acquire chronic poisoning from it, and generally die after three or four days of bronchitis or broncho-pneumonia after 8-10 mg. inhaled during eight hours. Five to 10 mg. may be inhaled during six and a half to eight hours without other ill-effects than torpor, weakness, and semnolence. With 20 mg. a strong semnolent effect is noted amongst animals; 40 mg. cause narcosis preceded by sneezing, irritation of the eyelids, loss of equilibrium, and muscular contractions; 60 mg. cause impotence, and at the end of seven hours complete loss of consciousness; 80 mg. bring on profound narcosis, and 240 mg. death after two hours.

According to Fros, 15 mg. per litre of air cause, in the case of human beings, narcosis, headaches, and vomiting. According to Graham, carbon tetrachloride causes, in the case of animals, more pronounced necrosis of the kidneys than that due to chloroform. The explanation of this is found in the liberation of a greater quantity of hydrochloric acid during decomposition of the constituent products of the substance, similarly to what occurs in the case of phosgene poisoning, poisoning by tetrachloride being in certain conditions true phosgene poisoning.

**Statistics**

Starr (Ohio) reports that 22 out of 27 women workers engaged in a millinery establishment presented signs of poisoning after using a mastic containing 66-70 per cent. of carbon tetrachloride, 34-30 per cent. of benzene, and traces of carbon disulphide. Specific symptoms not having been observed, however, there is a possibility that the troubles noted were rather to be traced to the benzene, though the irritation of the eyes and the throat noted amongst the workers seemed more marked than is usually the case with benzene.

In Germany in 1923, in the Erfurt district, a case of very marked narcosis was reported as affecting a man engaged in gluing soles with a mastic, having as its solvent a liquid chiefly constituted of carbon tetrachloride. In 1924, in the Düsseldorf district, 4 cases of poisoning were reported amongst workers engaged in coating barrels and vats with a product containing carbon tetrachloride. The
sufficient to produce in crises, but thinks that a few mg. per litre of air only suffice to produce in an enclosed space, unless the person using them is provided with a gas mask. The formation of phosgene is held to be due in great part to the action of steam on the carbon tetrachloride, and the oxidation of the latter is not thought to constitute an important factor in this formation. It results therefrom that danger in the use of these extinguishers depends on the humidity of the atmosphere, and the greatest precautions should be taken either where water is used simultaneously, or where it is applied later for watering the smoking material.

Protective measures for workers exposed to the inhalation of carbon tetrachloride fumes are similar to those outlined for substances which liberate toxic fumes.

LEGISLATION

No special legislation exists in relation to this product. In general the legislation which would apply is that relating to the chemical industries (see article "Chemical Trades").

Injuries due to carbon tetrachloride are liable to compensation as an occupational disease in Switzerland and in the countries which grant compensation for disease due to gases and fumes.

Carpets, Hangings, and Table Covers

French: Tapis. — German: Tapeten; Teppiche. — Italian: Tappeti; Tappezze. — Spanish: Alfombras; Tapices.

Woven tapestries are made by hand on different kinds of looms varying according to the product required. There may be distinguished tapestries for hangings, high warp tapestry (Gobelin), and low warp tapestry (Aubusson, Beauvais, Felletin); table covers and various covers used in furnishing.

Amongst carpets and covers made of wool may be distinguished Aubusson carpets, plush or pile carpets (carpets with knotted stitch, oriental or Turkey carpets, Smyrna carpets, high warp pile carpets, long pile carpets), cut pile carpets, printed warp carpets made by previously printing the threads in colour according to the design required. Amongst the cheaper categories of carpets may be mentioned felt and pile carpets and carpets made from various printed materials.

The raw materials used are very different according to the kinds of carpet required: wool, cotton, hemp, flax, jute. The wool used in the carpet industry usually consists of short, thick ends.
Several different fibres are often used in making the same carpet. In certain establishments the raw materials are sorted, carded, twisted and woven whilst in others they arrive completely prepared. The bales of thread are opened and passed to the weaving room. Once woven, ordinary factory-made carpets undergo a shearing process — which serves to equalise the length of the different threads — and then they undergo brushing, which serves to raise the pile of the carpet. Amongst the finishing operations should be mentioned “rentering”, which consists in damping with the needle the parts missed in machine manufacture, and “hurling” or “picking”, which consists of removing with pincers irregularities, knots, and straw from the carpets.

Needle run tapestries are embroidered tapestries done by hand, worked on canvas stretched on an embroidery frame and sewn with thread (wool, silk, etc.) of different colours, either by counting the stitches in copy of a printed design or by following a design first printed on the canvas (see article “Lace”).

Beating of carpets is rarely done by hand and is most frequently executed in closed beating machines. In the case of certain carpets, the operation is completed by dry cleaning with suitable solvents (see article “Dyeing”).

Sources of Risk

The possible sources of risk in the carpet industry are as follows:

Dust. — The weaving of carpets involves the same risk from dust as is met with in the textile industry. The opening of the bales of thread, freeing these from dust on arrival, shearing and brushing of carpets after weaving and thereafter beating are particularly dusty operations.

Apart from the irritant action exercised by dust, it offers particular risk when toxic colouring agents have been used in dyeing the threads employed. In order to diminish this risk, the State of Massachusetts has, since 1901, limited to 0.10 grains per square yard the amount of arsenical pigments to be used; aniline colours have besides been substituted to a large extent for chrome and lead colours.

Mention should be made of the risks from infectious diseases in the course of carpet manufacture: cases of anthrax due to contaminated wools in the course of the beating of old carpets which have come in contact with various germs in the places in which they were used.

Other sources of risk derive from the working posture, from the concentration required for avoiding and detecting defects, whilst further causes of ill-health are connected with unsatisfactory working conditions (insufficient lighting and ventilation and overcrowding of workshops, etc.).

It is finally necessary to refer in passing to exposure to fumes from toxic solvents when carpet beating is completed by dry cleaning (see article “Dyeing”).

Statistics

Available statistics are very few in number. The Factory Inspection Department reports anthrax cases and max which occurred in 1922 in a carpet factory in Saxony, probably due to infected wool. Thomson has reported several cases of anthrax amongst carpet weavers in New York. In a carpet factory at Yonkers, New York State, there occurred in 1927 3 cases of anthrax, 2 of which were fatal; these were also due to infected wool.

Neisser quotes 3 cases of poisoning by benzene amongst workers occupied in cleaning carpets.

The weaving of carpets is a difficult operation, but nevertheless the mortality rate amongst workers is comparatively low in relation to that of other industrial groups in the textile industry. The British statistics show a relative mortality of 873, or 8 per cent, below the standard figure. The mortality figure for tuberculosis is 22 per cent, above the average and for other diseases of the respiratory system 11 per cent, higher than the average. Hoffmann’s statistics based on 155 deaths amongst workers in carpet factories show a relative mortality of 15.2 per cent, to have been due to phthisis and 16.9 per cent, to other diseases of the respiratory system.

Pathology

For pathology see the following articles: “Textile Industry” (for diseases due to dust) and “Solvents” and “Dyeing” (for diseases due to the solvents used).

Hygiene

The usual precautions should be taken against the liberation of dust when the bales of thread are opened and freed from dust, as well as in the course of the operations of shearing and brushing the carpets. Closed apparatus or efficient systems of localised exhaust should be used where appropriate, and completed by good general ventilation.

Carpet beating establishments in certain countries (France, for instance) have been brought within the category of scheduled establishments (dangerous, unhealthy or noxious trades — causes of risk: noise and dust), and are, in consequence, liable to a certain number of restrictions: enclosing of the estab-
lishments within sufficiently high walls to prevent the dust gaining access to houses in the neighbourhood, prohibition of beating in the open air, compulsory installation of impermeable flooring for the workshops, compulsory coating of the walls with a smooth finish and even the application of a coating medium dissolved in oil; compulsory beating by means of mechanical beaters hermetically closed and provided with powerful dust exhaust so disposed as to prevent the dust causing inconvenience to the workers or gaining access to the exterior; compulsory impermeability of the flooring of courts in which beating by hand may be carried on; frequent washing with a hosepipe of the flooring, walls and glass frames placed above the beating tables; machinery to be kept at a distance from common walls with a view to avoiding inconvenience for neighbours; removal by drains of waste water from washing. The use of dust exhaust devices now makes it possible to replace very easily work of this kind done by hand by mechanical processes.

LEGISLATION

Decree of 17 December 1923 relating to the protection of workers in the manufacture of carpets in Kerman (Persia) and Baluchistan. — The chief measures prescribed are as follow: limitation of the working day to eight hours; fixing of the age of admission to work at eight years for boys and ten for girls; compulsory separation of boys and girls for the two sexes; prohibition of the utilisation of damp basements as workrooms for carpet weaving; compulsory provision of windows with southern exposure in order to provide adequate lighting, placing of weaving looms at a height of one metre from the floor of the workrooms with a sufficiently high seat to permit of the children carrying on the work under the best possible conditions; prohibition of employment or retention by owners of factories of workers affected with contagious diseases; monthly inspection of the factories by the chief of the health service or municipal doctor. In the case of contravention of the health and hygiene regulations laid down, these medical authorities are called upon to furnish a report to the competent authorities, who must immediately intervene.

It should be noted in passing that these measures were in part adopted thanks to the action taken by the International Labour Office, which in 1920 found it necessary to attract the attention of the Persian Government to the deplorable working conditions in which children were employed in the carpet industry of Kerman.

In other countries legislative provisions call for the exclusion of boys under six-

teen (Quebec, for instance) or of young persons under eighteen (France) from the operation of carpet beating when dust is freely liberated in the workrooms. 

***

Celluloid

French: Celluloid; German: Zelluloid, Zellhorn. — Italian: Celluloid. — Spanish: Celuloide.

Celluloid was prepared industrially for the first time in 1889 at Newark (United States) by the brothers Hyatt; it is finding more and more and more numerous spheres of application because it is easily worked and may be put to many uses, particularly as a substitute for ivory, horn, tortoiseshell, amber, and bone.

RAW MATERIALS

Celluloid is an intimate mixture of weakly nitrated cellulose, natural or artificial camphor and alcohol.

Risk exists for the workmen who make or manipulate this product by reason of the easily inflammable nature of some of the materials used.

Cellulose is derived from cotton, paper, or textile; the acids used are nitric and sulphuric; the solvents are ethyl alcohol which is replaced for reasons of economy by methyl alcohol, petrol, benzol, ether, acetone, acetate of amyl, etc., and even by such mixtures as amyl acetate with alcohol, and petrol or benzol with methyl alcohol.

Celluloid factories very often rectify the used alcohol but this operation is usually done without danger in automatic apparatus.

When natural camphor reaches a high price it is replaced by different substances, such, for example, as synthetic camphor, phenyl phosphate, or ethyl phthalate.

As pigments, colours may be used with a chromatic base, aniline, and bronze-colours, some properties of which may cause skin irritation. As materials for filling up, dioxide of zinc, gelatine, colza oil, etc., are used. In order to diminish its inflammability, celluloid is treated with salicylic acid, magnesium chloride, sulphate of aluminium, etc. The composition of celluloid and its properties are fairly variable.

Generally the celluloid of commerce contains (according to Will and Dubovitz) 50-70 per cent. of nitro-cellulose, 15-35 per cent. of camphor, and 0-15 per cent. of colouring and filling up materials. Celluloid is inflammable and unstable, usually in proportion to the strength of nitro-cellulose it contains. These properties
are, on the contrary, diminished when the strength of the camphor increases: the celluloid becomes stabilised. Without the addition of colouring materials celluloid is almost colourless; in thin sheets it is as clear as glass and quite transparent. Its specific gravity is from 1.3 to 1.4. In the cold state it is unaffected by most chemical products and is very solid. It cannot be broken, but fairly thick pieces can be cut, planed, sawn and twisted, like wood, horn and amber. Thin slabs and small sticks it can be bent and rolled, but afterwards it resumes its original shape.

Heated to 60-65° C., celluloid acquires plasticity which is indispensable for numerous purposes, e.g., for the making of dolls; this plasticity increases with a rise of temperature.

Celluloid is used particularly in the making of combs, toothbrushes, dentures, the handles of walking sticks and umbrellas, ornaments used in hair dressing, collars and cuffs, buttons, boxes, pianoforte keys, pipes, toys, stereotype plates, artificial flowers, and all kinds of articles of practical utility.

Besides all these uses it is constantly employed in the manufacture of films (with nitrocellulose obtained from a more highly nitrated celluloid) and, on account of its solubility in acetone and other solvents, in the preparation of: cement for shoes and of other mastics, such, for example, as the lacquer "Zapon" (solution of celluloid in acetone and acetate of amyl); waterproof or oilproof coatings, used for the wings of aeroplanes; and also of lacquer for various objects (see also article "Nitro-cellulose").

**Industrial Operations**

The principal operations are the following: preparation of nitrocellulose, and bleaching; reduction to a fine powder; introduction of colouring matter; preparation of camphor or its substitutes; mixing of nitrocellulose, camphor and the solvent; introduction of stabilisers if the product is required to be transparent; partial drying of the paste; recovery of the solvent; desiccation under pressure; cutting up and moulding; final drying; and utilisation of waste.

The cotton required for the manufacture of cellulose is prepared in special factories, the celluloid works receiving the cotton already defatted, bleached and washed.

The nitration of cellulose is carried out as for the preparation of nitrocellulose used for making artificial silk (see articles "Nitrocellulose" and "Artificial Silk"). Cellulose nitrate six to nine times with a strength of 10-12 per cent. of nitrogen seems to be that most suitable for the manufacture of celluloid.

The nitrocellulose is hung up to dry and, after two or three crushings, there is added to it camphor and opaque and colouring materials. The crushing is continued until the mass becomes quite homogeneous.

In order to expel the water which has been used in the mixing, the mass is at this stage moulded in a hydraulic press; in this way are obtained sheets having a thickness of some millimetres. These sheets are separated by thin layers of coarse blotting paper and are subjected to the energetic action of the hydraulic press; this operation is repeated until the desired desiccation is obtained, changing the blotting paper each time. The sheets, which have a thickness of 3 mm. and are cut, planed, turned, polished, and burnt and amber, are broken up by means of cylinders furnished with teeth. The broken material is brought into contact with pure alcohol and mixed with toluene for twelve hours. Colours, soluble in alcohol, are added at this stage if it is desired to colour the paste.

After maceration the mixture is passed into a rolling mill heated to 50-80° C. and converted into homogeneous sheets which, superimposed in several patterns, are compressed for twenty-four hours by means of a powerful hydraulic press heated to 80° C. by the circulation of steam. The sheets are thus welded together and form blocks of celluloid which are cooled at once in water-cooled vats. According to the German method, the camphor is first dissolved, chiefly in alcohol, allowed to settle and cool, then the solution is poured into vats which contain dried nitrocellulose. The contents are mixed; the vat is covered again for a certain time, and then the whole is passed into a mixer at 90° C. in order to ensure the closest possible blending. The vapours of alcohol are removed and recovered in a condenser. After purifying, the product is subjected to a hydraulic press and then rolled flat. The rolling, however, gives a product riddled with bubbles of air which must be removed to obtain a homogeneous celluloid. This is done by submitting the sheets to the hydraulic press (see above).

The working of celluloid resembles that of india-rubber; sheets and blocks are cut, planed, turned, polished and shaped by means of heat to preserve the shape obtained.

For polishing celluloid, in addition to heat and pressure, sheets of brass are used, placed between the sheets of celluloid.

The sheets and moulded articles are dried in a stove at 60-65° C.; stoving
CELLULOID

may be required for several months, depending on the thickness and the nature of the articles. Celluloid is then worked like wood. A product which has an analogous composition and which in addition contains castor oil is "pegamoid", used for making artificial leathers, oil-cloth, etc.

Recovery of Celluloid

Some works do not chiefly engage in the manufacture of celluloid or celluloid articles, processes which may exist alongside, but carry on recovery of the worn-out article. This industry makes use of the fact that celluloid deteriorates by losing camphor. After soaking in a tank of hot water and macerating in a solvent, camphor and colouring materials are added to waste picked over and reduced to pulp. It is mixed and rolled white hot; thus sheets of celluloid are obtained, which are welded together by hydraulic pressure. The product is a celluloid of second or third quality.

Dangers

Dangers from fire and explosion arise from the raw materials used in this industry, i.e. cellulose, acids and solvents. Cotton, paper, and tissues may cause fires, especially during the operations of drying and weighing. Acids may explode in reservoirs or retorts, or become decomposed, especially when nitric acid is slightly heated — by exposure to the sun for example — or mixed with other concentrated acids, or may set free nitrous and sulphuric fumes when they are subjected to severe jolting: in acid stores, nitration apparatus, presses, drying rooms, or during the transport of freshly prepared nitrocellulose.

Solvents may easily cause fires or explosions, in stores, during transport, in the processes of dissolving camphor, nitrocellulose or scrap celluloid, and of crushing and pressing.

Alcohol is only used when dehydration of nitrocellulose is carried out. The danger is serious not only when it is poured upon nitrocellulose, but also during the processes of pressing and drying. The rectification of alcohol is not dangerous, for it is automatic. The danger is only real when cracks in the piping or apparatus lead to chance accidents.

Bronze colours may also cause fires or explosions; it is notorious, as a matter of fact, that certain of them are spontaneously explosive. As the quantity of colours used is very small, the danger is not great. It is however advisable to prevent the raising of dust in the workroom by damping the colours with alcohol.

As regards celluloid itself, it is practically insensitive to pressure, shock, shakings and ordinary lighting. According to Will, it is also equally stable when subjected to an electric current. It does not exhibit any great susceptibility to moderate heat, when the preparation has been properly carried out, using sound raw materials.

On the contrary, celluloid takes fire easily in contact with incandescent bodies, such as incandescent lamps and the electric arc, as well as with naked lights. Once alight it burns rapidly, with leaping jets of flame, producing a high temperature and may catch fire, according to Will, 1,500 to 2,000° C. Quite apart from the composition of the celluloid, inflammability increases with its state of division and the thinness of the sheets. For this reason the risk of combustion, even from electric sparks when they are strong enough, or of rapid spread of the fire is very great, particularly, for example, with the dust from polishing. In some circumstances, notably with varieties insufficiently stabilised, the sensitiveness of celluloid increases a good deal, up to decomposition when the temperature is high. Sometimes decomposition occurs at about 100° C., the body then catches fire with an explosion. With good qualities of celluloid this phenomenon only occurs between 150-170° C. Combustion is usually very rapid and accompanied by bursting jets of flame and the setting free of poisonous gas which is explosive when mixed with air. Once the decomposition has commenced, it may very often continue without flame even after apparent extinction of the fire. Explosive gases may in a short time reach situations of rapid spread of the fire. As regards celluloid, sometimes passing by exhaust ducts for the extraction of dust. If, for any reason, they become ignited, they may cause serious damage. This decomposition, which gives off an evil-smelling gas, continues when burning, properly so called, is extinct. According to circumstances an explosion may still be feared even when the celluloid which is supposed to be in course of decomposition has been immersed in carbonic gas or steam.

The limits of explosion for this gas with air are 9 to 40 per cent. It is composed especially of carbon monoxide and minute carbon dioxide, 14 pounds of nitrogen hydrogen and methane, as well as of small quantities of hydrocyanic acid. According to
Lodemann, combustion of a gramme of nitrocellulose film sets free about 600 c.c. of gas, of which 260 c.c. are carbon monoxide, 150 c.c. oxide of nitrogen and 5 c.c. hydrocyanic acid. According to the earlier tests of Will, the proportion of hydrocyanic acid is considerably higher.

The English enquiry of 1913 showed that the gases disengaged by the burning of films protected from the air contained 26.3 carbon monoxide, 7.3 carbon anhydride, 0.7 carburetted hydrogen and 28.5 dioxide of nitrogen.

It is well known, however, that during combustion, cellulose sets free carbon monoxide in particular.

One thousand grammes of burning celluloid, protected from air, at 0° C. and 760 mm. of pressure, set free 17 to 18 litres of gas, that is to say, from 4 to 7 litres of carbon monoxide, 3 to 4 litres of carbonic dioxide, 7 to 9 litres of oxide of nitrogen, 0.7 grammes of hydrocyanic acid, as well as traces of acrolein and camphor.

In the presence of air, burning celluloid liberates greater quantities of hydrocyanic acid (about 1 to 2 grm.) as well as oxide, dioxide and tetraoxide of carbon.

Kockel has shown that combustion of 5 grammes of celluloid wool, which is about the weight of a little comb, sets free sufficient hydrocyanic acid to kill a man. Under such circumstances it is not astonishing that very serious poisonings may result from conflagrations of celluloid. But this opinion is not shared by most experts, who consider that the toxicity of the fumes is essentially due to the presence of carbon monoxide. Will and some Austrian experts record that there are already many kinds of celluloid which under certain conditions, in particular when under poor quality and spontaneously inflammable at about 100° C. From this point of view the following experiment is particularly important: a little piece of celluloid was put, with air freely circulating, on a glass tube, through which was passed a current of steam at 100° C. The specimen at once became soft, then give off a great quantity of gas, and at the end all that was left was a carbonised mass resembling a sponge. Flame only appeared when the celluloid was placed on the glass tube wrapped in paper: this paper became carbonised and, in consequence of better contact with air, combustion occurred with the appearance of flames. These experiments furnish some explanation of how decompositions and flaring, due for example to heating by steam and appearing at first incomprehensible, can be produced. There is no need to infer always that the celluloid was wrapped in paper, but it may very well happen that some rag or paper were deposited, along with celluloid, for example, in a waste-bin. Allowance must also be made for some very easily inflammable papers, for example grease paper used for lunches, being deposited in the side of celluloid debris on a steam heater or in its vicinity. The probabilities of fire are still greater when heating pipes are filled with steam at high pressure and in consequence overheated.

Celluloid fires can also be caused by very hot gas escaping from internal-combustion engines; by heat radiating, for example, from incandescent lamps or heated bearings, and, in some circumstances, by driving-belts becoming charged electrically. Its handling and shaping are more dangerous than its manufacture. Fires have been caused by coveringing machines, saws, and emery grinding wheels revolving very rapidly (sometimes during the removal of the layer of hard celluloid covering these wheels), or by sparks from electric fuses, or even from drops of melted metal falling from electric lamps. Fire has sometimes been due to the addition of large quantities of organic or inorganic substances to certain varieties of celluloid in order to obtain a watered cloudy appearance or other effects of colouration. Sometimes also little splinters of steel, sand or flint or nails become embedded in celluloid owing to flaws in manufacture. When worked with saws and reamers, or on wheels revolving very rapidly, sparks may be produced and set fire to the dust produced by these tools which is particularly unstable and inflammable.

When celluloid is of poor quality it sticks to the grinding wheels and forms a hard layer. It is necessary then to scrape it from time to time by holding against the wheel a piece of flexible sheet iron. This operation is not done without sparks which may in some cases cause fires.

This danger exists during reaming and sawing, in brush and comb factories, sometimes even when the upper part of the saw is being cooled by water and the lower part is plunged into oil. In one Swiss comb factory 33 deaths occurred, that is to say, a tenth of the staff employed: the extent of the catastrophe was determined not only by the great quantity of celluloid which took fire, but also by the bad arrangement of passages, doors and windows, with a lack of exits and especially by the defective state of the dust exhaust.
Radiant heat has been a cause of serious accidents, e.g. manufacture of celluloid, and chiefly during pneumatic sprinkling or immersion, workmen often experience torpor, giddiness, headaches, attacks of coughing, oppression, and nausea, especially at the commencement of work. In places where the ceiling is high and which are well ventilated, these effects are scarcely noticeable (Zäuner).

Dermatitis caused by the use of chlorid of lime or chrome colours, or aniline has also been described (Zäuner).

Heim, Agasse-Lafont and Feil have studied the morbid manifestations of workmen employed in making and handling celluloid. The investigation was carried out in a workshop for shaping celluloid, an annex to an accumulator factory, where small boxes for holding pocket accumulators were made.

After having excluded the existence of lead poisoning, the authors turned their attention to morbid manifestations due to celluloid and its solvents. The workmen used celluloid dust which contained camphor, and a paste containing acetate of amyl and acetone.

Nearly all the workmen complained of headaches, worse during the first months of work and especially towards the end of the working day. Medical examination only revealed the existence of eosinophilia equal to or above 4 per cent. which the authors attributed to acetone or acetate of amyl, whilst the headaches were caused by camphor.

Some control investigations, made upon other workmen handling the same substance (film perforators), confirmed the result. However, the authors do not consider that the haematological condition in question could be interpreted as characteristic; but it might well be an indication of a poisoning or at least of a reaction of the system to the poisons in question. Boulin has described a case of lead poisoning due to the use of a paste containing minium (red lead) and used to give celluloid the appearance of tortoiseshell.

Persons who have been the victims of fire or explosion from celluloid have been noticed to suffer from vomiting, cyanosis, dyspnoea, sugar in the urine, vertigo, and headaches which last a long time. The picture is characteristic of poisoning by carbon monoxide. In the corpse the blood is a bright red.

HYGIENE

All these occurrences and the investigations which have been made into
the causes of these accidents have stimulated enquiries into means of prevention and have raised the question of the preparation of substitutes for celluloid, which is too easily inflammable and so dangerous on account of its gas of decomposition.

These attempts have not been without result; there are actually a very large number of substitutes for celluloid: galalith, secourid, bakelite, faturam, gommalite, elfenite, cellone, cellite, etc. In spite of certain very excellent qualities, these substitutes are, either from one point of view or another, inferior to celluloid, for example, as regards the ease with which it can be shaped, resistance to light, air and humidity, or the possibility of colouration. They are sometimes less elastic, they stick more easily to tools and cannot be so readily shaped as celluloid on treatment with warm water, or stuck together, or welded by means of acetone. Some change colour in the air and cannot be shaped into slabs or tubes. Others are not only dearer to prepare, but they are also harder and more brittle.

An attempt must therefore be made to avoid in another way the dangers which the use of celluloid presents and the following precautions seem the most deserving of attention:

(1) During the construction of a factory account must be taken, from the laying of the first foundations, of dangers from fire, decomposition and explosion. Workshops which seem too large must be subdivided; and passages, doors, windows and emergency exits must be conveniently arranged. A large number of fire extinguishing appliances must be provided, and very great care exercised in the arrangement of warehouses, especially as regards stores for scrap. Holding unduly large stocks must be avoided.

(2) Particular care must be exerted during the installation and use of heating and lighting apparatus, including electric apparatus, as well as during the use of acetone, benzol and other inflammable products.

(3) Different workplaces must be screened off so as to prevent fire from spreading.

(4) The installation and also the use of reamers, saws, emery wheels and other appliances which may give off sparks, must be supervised. It is advisable also to take precautions against overheating of driving shafts and also against the production and spread of conflagration by driving belts or exhaust apparatus. It must be possible to shut off chambers for dust and shavings installed in the basement which are difficult to supervise and almost impossible to clean completely.

Official investigation undertaken in Germany as to the advantage or disadvantage of extracting dust in celluloid works has not completely solved this problem. In practice it is necessary to consider, on the one hand, the evacuation of dust, and, on the other, the danger from fire spreading. It has been established that flames can spread in exhaust ducts against the current of air and that they may thus come to set fire, under certain circumstances, to dust which is in front of the exhaust opening. The objection may be made and must be borne in mind that good installations prevent precisely any dangerous accumulation of dust and exclude in consequence risk from fire. After some accidents it has been reported that danger from the production of gas and decomposition is much greater with celluloid or finely divided debris than with tubes, sticks or other bigger pieces.

(5) Apparatus should be ready and in order for protection against gas or for reviving victims, so as to be able to assure first aid in case of fire.

(6) So far as is possible, quarters, workshops or offices occupied by a number of persons must not be located above processes which present a great danger of fire.

Among extinguishers the “Minimax” apparatus has sometimes shown itself efficient, but, on other occasions, has not worked effectively. It is the same with the “Grinel” vaporisers. Dry extinguishers have sometimes been used successfully. Extinguishing bags (sacs d’extinction) have given very good results, particularly in fighting danger from sparks arising during reaming, sawing, or other mechanical process. Similarly pieces of cloth, kept ready in a bucket of water placed in the workshop, have been used with success, provided that they are spread out immediately on the place where the fire originates. Moreover, decomposition and dangers which arise therefrom are not always completely avoided even when the measures taken appear to have been adequate. In the manufacture of such articles of celluloid as combs and large teethed-combs (for wool combing), soaking in acetic acid, generally in acetic acid, in order to polish the internal surfaces of the teeth, is a disagreeable operation, especially in
winter, for the work is done in hot and stuffy workshops. The vats containing the acid solution should be placed under an exhaust shaft with an exhaust flue and supporting a drying board on which are placed the dipped combs. The heating should be effected by a stove pipe coming from the outside, while the exhaust draught must be strong enough to prevent lacrymation and smarting of the eyes.

Of course it is not enough that all these arrangements be installed, but it is essential that they be kept in good order and absolutely ready for use, and it ought not to happen, as has sometimes been the case, that the extinguishers or buckets have not been properly filled or are not ready to hand, or that there is not sufficient pressure in the water mains.

**Legislation**

Knowledge of these dangers has naturally led to official measures for dealing with them and most countries possess arrangements for the prevention of fires and for safety in celluloid factories. Thus, for example, at Leipzig, following the fire of 1900, a committee consisting of representatives of the police in charge of buildings was set up and entrusted with the control and supervision of installations of gas, of lighting and for fire fighting. Later the Market Committee of the Chamber of Commerce had occasion to take up this same question, for it was necessary for the market to have sufficient stocks of celluloid.

In Austria, fires which broke out at Vienna and elsewhere led to very complete official investigations, as well as to publication of rules based on those investigations. The Austrian Ministerial Ordinance (1908) on celluloid traffic and celluloid articles and waste, which appeared following these events, comprised as many as 66 paragraphs. Almost at the same time there appeared in most of the States of the German Empire similar Ordinances more or less comprehensive. The "Collection of Instructions for the Protection of Workmen in the German Empire" quotes no less than 15 publications of this kind (pp. 179-180) among which must be noted the Bavarian Ordinances (of 9 and 23 March 1912) and the Prussian Ordinances (of 7 May 1910, 11 December 1911, and 24 April 1920), this latter being much fuller as regards films. Almost at the same time there appeared in most of the States of the German Empire similar Ordinances more or less comprehensive. The "Collection of Instructions for the Protection of Workmen in the German Empire" quotes no less than 15 publications of this kind (pp. 179-180) among which must be noted the Bavarian Ordinances (of 9 and 23 March 1912) and the Prussian Ordinances (of 7 May 1910, 11 December 1911, and 24 April 1920), this last being much fuller as regards films. Almost at the same time there appeared in most of the States of the German Empire similar Ordinances more or less comprehensive. The "Collection of Instructions for the Protection of Workmen in the German Empire" quotes no less than 15 publications of this kind (pp. 179-180) among which must be noted the Bavarian Ordinances (of 9 and 23 March 1912) and the Prussian Ordinances (of 7 May 1910, 11 December 1911, and 24 April 1920), this last being much fuller as regards films. The floors must be cleaned wet and there must be a supply of buckets of water for extinguishing purposes. Contractors are responsible for giving warning by means of notices to home workers of the dangers which the handling of celluloid presents.

**Great Britain**

On 28 November 1921 laid down Regulations for factories and workshops or parts of factories and workshops where celluloid is manufactured, manipulated or stored, or where articles are made entirely or in part of celluloid.

**Hungary**

On 28 June 1923 published a Ministerial Ordinance dealing with the construction and working of factories where celluloid is produced or handled and also for shops and depots of celluloid.

**Switzerland**

Provides measures of security by section 30 of the Factories Act (3 October 1914).

An Ordinance concerning the handling of celluloid, of celluloid articles and scrap was introduced in Czechoslovakia in March 1925.

The labour of women in celluloid factories is forbidden by the Austrian legislation.

NEBULONI, in La Medicina del Lavoro, No. 1, 1927. Milan.
Cellulose

Properties

Cellulose, the principal constituent element of the cellular tissue of plants, of which it forms the skeleton, is habitually associated with other different encrusting substances, except in the case of cotton, where it is almost pure. The most important kinds of cellulose are ligno-cellulose (wood, jute) and pecto-cellulose (linen, hemp).

Chemically, cellulose is a hydrate of carbon with the formula \( (C_6H_10O_5)n \). In the pure state it is white, with a specific gravity of 1.54 with 6 to 12 degrees of humidity, which it loses at 100°C, re-absorbing them again in the air.

Fibrous and colloidal, cellulose is unaffected by air and water (a fact which explains its numerous uses). It is insoluble also in alcohol, ether, etc.; it resists fairly well the action of acid solutions, and even better, dilute alkaline solutions. Treated, however, by a 20 per cent. solution of soda lye, it is converted into alkaline cellulose \( \text{C}_{12} \text{H}_9 \text{O}_{16} \cdot 2\text{Na} \cdot \text{H}_2 \text{O} \), which easily loses its alkaline quality on washing in water, leaving the cellulose in the form of a hydrate: \( \text{C}_6 \text{H}_9 \text{O}_5 \cdot \text{H}_2 \text{O} \). Applied to cotton, this treatment makes the fibre more brilliant with a greater affinity for colouring matters (mercerising).

Alkaline cellulose fixes carbon bisulphide yielding xanthate or trio-carbonate of cellulose (the principle of the manufacture of viscose; see the article "Artificial Silk").

With nitric acid, cellulose yields nitrocellulose, which is a nitric ether, and with acetic acid, aceto-cellulose or cellite (see these articles).

Oxidising agents, especially when warm, yield an oxy-cellulose, which reduces Fehling’s solution. After bleaching by chlorine, therefore, the excess of chlorine must be got rid of with the greatest care to avoid the formation of this product. Cellulose dissolves in a 40 per cent. solution of zinc chloride; in Schweitzer’s solution (solution of copper oxide in ammonia) it is converted into the condition of oxy-cellulose up to 5 or 10 per cent. of the weight of the solution.

Generally in industry the term cellulose is given to the purified product — usually the extract from the chemical pulp.

The separation of the pure product from the compound celluloses is effected by treatment with bisulphites and alkalies. It is thus that it is usually prepared from wood pulp, especially when pure cellulose has to be used (as in silk-viscose, nitro-cellulose, etc.).

Processes

Cellulose is manufactured by two processes: one is mechanical, yielding the mechanical pulp, or wood pulp, or milled pulp, and the other chemical, i.e., the action of chemicals on the vegetable fibres, and especially on the wood yielding the chemical pulp.

Mechanical Pulp

The processes actually used date from about 1860, when Keller Voelter first tried them in Germany. They have been unceasingly perfected since then.

The raw materials are fresh fir of the best quality, aspen and poplar (which yield a white pulp with shorter and more expensive fibres than that obtained from the wood of conifere), etc. Pine wood cannot be used because of its content in resin, which makes the pulp liable to break. It can, however, be used alone or with fir to make what is called the brown pulp.

The wood is cut into small cylindrical pieces of about 50 centimetres: the bark is removed by a machine, and the wood pulped. The “pulp grinders” carry horizontal and vertical axes supporting grindstones against which the wood is pressed by hydraulic pressure of 7.5 to 8 atmospheres. Light pressure with slow rotation per unit of time gives a better quality of pulp, but not so large a quantity as is obtained by high pressure and rapid rotation. Machines recently put in use allow low pulping of the wood to be done in the direction of the fibre and thus to obtain a better quality of fibre, both longer and stronger.

Pulping is done under a stream of water either strong (cold pulping) or weak (hot pulping because normally it causes a rise of temperature between 30° and 80°C). The heat generated
facilitates the pulping and yields a longer and more supple fibre. The temperature, however, ought never to exceed 80° C., or else the pulp goes brown. The Behrend method subjects the wood to a preliminary treatment with low pressure and steam to soften it and facilitate pulping. A high temperature and the kind of wood used leads to a brown discoloration of the pulp which cannot be bleached, but is more resistant.

The pulp is then laid out in water, then sieved in a series of revolving sieves: a coarse sorter (which eliminating the large fibres, etc.), a fine sorter with transversal and centrifugal movement, which continues the elimination of impurities and the bundles of fibres that have not been separated. Sometimes the pulp is reground in a refiner (a fixed and a revolving grind-stone), and the mush thus obtained is again submitted to sorting and then led to a machine in which it is drained. This operates in such a way that when, by the rotation of the drum, a layer of drained pulp sticks to the outside and upper part of the cover, it is then led on to a felted belt which, again, directs it to rollers, where the greater part of the water still remaining is removed by pressure. The material, which adheres more readily to the iron than to the felt, rolls itself round the roller, in layer after layer, until it has attained suitable thickness.

A wood paste is thus obtained, containing about 70 per cent. of water, which is cut into sheets which, after passing through a hydraulic press, do not contain more than 40-50 per cent. water. This "commercial wet-wood pulp" becomes wood pulp if the content of water is reduced to 10 per cent.

These two products can be subjected to chemical treatment either before or after the moment when they reach the state of pulp and become named commercially "raw pulp" or "bleached pulp".

**Chemical Pulp**

At the commencement the process was essentially mechanical; then, boiling the paste was carried out without pressure, adding milk of lime and a little ash or soda lye. Later, boiling under pressure was done, which led to the development of the chemical process and the manufacture of chemical pulp. The raw materials used are straw, esparto grass, and wood (white fir, pine, poplar, aspen, etc.).

According to the nature of the fibre to be treated, the chemical pulp is made by the caustic soda method or the bisulphite. Other processes have been tried, but without yielding practical results, although some day one or other of them may play an important role.

1) **Caustic soda method.** — The disadvantage of the soda method and the necessity of producing cellulose at a lower price than that obtained by the bisulphite, have stimulated the technical experts to recover the lye and to use the sulphate of soda method which, in conjunction with the soda method, is to-day a process allowing of a larger production of pulp which has also the advantage of being easily bleached.

In the sulphate process the wood, after the bark has been removed, is reduced in chopping machines to chips of equal size. It then passes to a disintegrator, then to a sorting machine which separates the chips from twisted bits of wood. (The coarsest residues are used to make an inferior quality of pulp or used as fuel.)

The chips are then introduced into vertical or horizontal boilers, either fixed or rotating, heated by indirect or direct steam under a pressure varying from 6 to 11 atmospheres. The contents of the boilers are "blown" to diffusers, where lye continues the pulping process.

The washed pulp is led, under a current of water, into receptacles where it is stirred, and then pumped into purifiers (which keep back the knots and the bits which have not been submitted to boiling). Next it passes over sieves, where the other impurities (unpulped fibres, bark debris, etc.) that have escaped the purifiers are removed, and these are utilised to make a very coarse pulp.

After sieving, the pulp passes to the mixers for dilution, then to another stirring vat, and lastly to the centrifugal driers, which convert it into paste board very similar to the condition of mechanical pulp.

Pressing and drying eliminate a quantity of water up to amounts eighteen or nineteen times the weight of the dry fibre. In this way the paste becomes fit for transport.

The cellulose obtained has a brown colour and requires to be bleached before being used for certain purposes. The soda lye is recovered; the by-products used are recovered (methyl-alcohol, turpentine, liquid resin).

2) **The Bisulphite Method.** — This is most used at the present time, either because it is the most economical, or because, by means of this method of
treatment, the albuminoid and resinous matters are got rid of, and because, by the sulphurous gas liberated, a partial bleaching is effected.

The wood, after removal of the bark, pulping and sieving, is boiled in large cylindrical vessels lined with stoneware bricks (to prevent attack from the sulphurous anhydride), with the "acid", a solution of calcium bisulphite of a strength of 4% to 5% B. and containing sulphurous anhydride in a free state.

The lye for boiling is prepared as follows: the sulphurous gas obtained and chilled traverses, after passage through water, a tower made up of a series of chambers, one above the other, filled with limestone. The calcium sulphite thus formed and dissolved in water yields the liquid called "acid".

Boiling is carried out either with weak or strong acid according to the methods adopted or a combination of both. After boiling is over, pressure is lowered by letting off the steam and the excess of sulphurous anhydride in the bisulphite apparatus, and then the bisulphite solution is discharged. The woody matter passes with much water into great washing vessels, from which the pulp, after washing, passes through the operations described in the previous method.

The pulp goes to a mechanical sorter, to a press, and emerges with a content of about 18 per cent. of water. Bisulphite pulp can be used directly for the manufacture of ordinary white paper, but, for really good qualities, it is subjected to bleaching by chloride of lime.

The method of chlorination is based on the substitution of an atom of chlorine for the nearest hydrogen in the ketone or aldehyde groups contained in the non-cellulose part of the fibre in order to form a corresponding chloride. This, made soluble by an alkaline treatment, yields cellulose in a state of purity.

The process is as follows: the cellulose matter is treated slightly with soda in a closed vessel; after washing, it is subjected to the action of free chlorine. Hydrochloric acid is formed and reaction takes place with substitution between one atom of chlorine and one of hydrogen from the molecule of lignose or pectose.

Chlorination can be alternating (Cataldi process, in which use is made of electrolytic gaseous chlorine) or continuous (De Vains process, employing the hydrate of chlorine). The chlorinated matter is subjected to basic treatment either with a solution of caustic soda, caustic potash or sodium sulphite. Thereafter purification, bleaching, etc., are carried out.

To recover the soda from the wash liquor, the liquids are evaporated in special apparatus until the required concentration is reached; the juices are incinerated in continuous revolving furnaces by which a reddish product more or less mixed with cinders is obtained, called "salin". This, when broken up and dissolved in washers, yields a more or less weak solution containing sodium carbonate, etc. The liquids are filtered and heated in causticisers, where the liquid, mixed with lime, is converted into caustic soda with formation of carbonate of lime.

The filtered juice is sent to the receptacles for keeping the lye used for boiling.

A by-product in the manufacture of cellulose by the soda process is the Swedish resin ("Talloil"), which is obtained by cooling the black wash coming from the separation of the cellulose. The constitution of this resin is not well-defined, but it yields — on distillation, hydrogenation, or oxidation — several fatty acids.

Uses

Cellulose is used especially in the manufacture of paper, artificial silk, acetate of cellulose, nitrocellulose, varnishes or cellulose enamels, etc. (see these articles; see also the article "Varnish and Lacquer Manufacture ").

The by-products obtained from the washing are used in the manufacture of furfurol, bakelite, etc.

Dangers

Injuries to the health of the workers engaged in this industry are not numerous. There are the effects of dust (wood, vegetable fibres), and of the gases used (chlorine, sulphur dioxide, etc.) or given off during the various processes and getting into the atmosphere from leaks in pipes or apparatus that is not airtight. These risks, however, are very slight when the installations are well made and well maintained. In the department for the production of sulphurous anhydride, the emanations are very unpleasant, although the workpeople easily become acclimatised to them.

The gas first causes cough and irritation of the mucous membranes; but these troubles disappear quickly. Only anaemic workpeople complain of gastric trouble and nausea (Beintker).
Humidity is a worse trouble, and particularly the damp heat prevailing in certain departments.

In 1913-1914, the Swedish Ministry of Labour instituted an enquiry into the hygienic and sanitary conditions in cellulose factories; it was conducted by a particularly competent inspector of factories and a medical man. The enquiry extended to 37 of the 84 factories existing in the country.

In general, the conditions were good as regards lighting and cubic space. In certain cases, however, the air was hot and damp, very suffocating; and, in others, there was, in addition, the action of dust and sulphurous vapour.

The number of persons employed in the factories visited was 1,138; 229 were found to suffer from latent pulmonary tuberculosis; and 20 cases of bronchitis were reported, while 6 workers showed albumen in the urine, and 31 suffered from rheumatism. Four men who had inhaled large quantities of sulphur dioxide gas had suffered from acute symptoms; one man had had several attacks of lead poisoning.

The works' surgeons attached to 27 factories stated that the health of the workmen coming into contact with cellulose was no worse than that of the rest of the population, and might even be rather better, because in this branch of industry the higher salaries would allow of better food and healthier housing.

The surgeons also said that some workmen were sensitive to the action of sulphur dioxide, complaining of respiratory distress, while others seemed to be completely refractory to it.

The enquiry showed that there was no special risk to health in the industry in question, provided the equipment was on modern principles.

The enquiry made by Beintker in Prussia also showed that, in general, the workmen remained in good health, even after many years' employment.

For further details, see the articles "Bleaching", "Rag Industry", and "Paper Mills".

Hygiene

The construction of the factory must correspond, in its details, with the conditions demanded by the special processes carried out in this industry.

Thus, the floors should be impermeable, having a slight fall, and ribbed so as to allow the water, so largely used in the manufacture, to run off quickly. Necessary precautions must be taken against excessive humidity, gaseous emanations, whether toxic or merely unpleasant, in the working of the wood, chopping the fibres (locally applied aspiration and ventilation for the removal of dust, prevention of accidents and fire), in work with lyes or involving exposure to sulphurous vapours, etc., which should be done in closed apparatus under a negative pressure. The furnaces for making the sulphur dioxide ought to be rationally installed, the vapours emitted should be condensed, and there should be complete absorption of those which escape condensation.

One of the most serious inconveniences in the manufacture of cellulose with sulphate arises from the disagreeable smell which is given off from the different organic combinations of sulphur (especially of mercaptan), produced in boiling. A factory producing 16.5 tons of cellulose per day sends into the atmosphere 4.5 kg. of mercaptan and 0.73 kg. of methyl sulphide.

The unpleasant smells are usually absorbed by wood or straw to which chlorine is added as an oxydiser. Such deodorisation allows the proportion of sodium sulphite to be increased in the manufacture, and consequently permits of the production of better qualities of cellulose.

At the same time, this method has been improved by using an apparatus based on the principle of a barometric condenser. The vapours reach the apparatus at the top where they come into contact, at various stages, with one or more atomisers. These allow of very intimate contact between the vapours and the water. The sulphurous gases are oxidised by the air and the unpleasant smell destroyed.

Another trouble — and a very serious one some years ago — is that of the residual waters, which damage the streams with the bisulphite wash and may give off sulphuretted hydrogen gas.

The recovery, however, of the by-products (ethyl and methyl alcohol, cumol, turpentine, lignosol, tanning extracts, charbon de sulftte, etc.) has made these waters less injurious today.

A method proposed by Kumpfmiller and Philipp, in operation in a German cellulose factory working the bisulphite process, concentrates the wash waters under a vacuum until they are of a syrupy consistence and, on addition of certain chemicals, obtains tanning extracts which, however, cannot be used as such. Although this method does not solve the question completely,
it allows of a practical solution in several particular cases.

As an example of what can be made out of the wash waters, Lehmann has shown that nearly 80 grm. of solid substances contained in them, 4.5 are of an organic nature. If they cannot be utilised as raw materials for the products indicated above, it is best to evaporate and then burn them. König is said to have proposed the use of the evaporated residue for manure. (See also article "Industrial Waste Waters".)

The "Gulf" malady (Haffkrankheit), which attacked fishermen in a gulf in East Prussia in 1924, is said to have been caused in all probability by arsenic contained in the residual waters from a cellulose factory (see article "Arsenic").

**LEGISLATION**

In Finland Regulations for factories using the bisulphite process, dated 30 December 1924, and others for factories using the sulphate process (of the same date) are in force.

The first Regulations require, among other things, that the temperature of the workrooms should not fall below 15° C. nor exceed 20° C. during working hours, so long as technical conditions and the nature of work allow it; that efficient means should be taken to remove steam, gases, injurious vapours, and dust from the workrooms in order to prevent them getting into the air of other workrooms; that warmed air should enter the workrooms in cold weather; that piping, ducts, boilers, sulphur furnaces, reservoirs, and receptacles generally should be quite airtight and provided with the necessary safety devices; that efficient measures should be taken in the manufacture and preservation of the chemical products and by-products (sulphur dioxide, chlorine, inflammable and toxic volatile liquids, etc.); that preventive measures be taken against the risk of poisoning and fire in the manufacture of methyl alcohol, cumol, furfuro1, etc., as well as special measures in stripping the bark (accident and fire prevention), for work at the boilers, preparation of acids, distillation, etc. The Regulations also prescribe welfare arrangements and personal hygiene (spittoons, washing accommodation, working clothes, etc.), first-aid work for children and young persons, etc.

The Regulations for the sulphate process prescribe practically the same provisions. They require a further point, however: namely, that the manufacture and preservation of the products and by-products shall not be carried on except in a part of the factory specially constructed for the purpose; that the gases, vapours, and inflammable liquids, volatile or toxic, shall not be treated in reservoirs or receptacles open to the interior of the workrooms properly so called.

The uncondensed gases coming off when the gases are discharged, in extinguishing a furnace, should not be allowed to pass directly into the outside air, or into streams, or into rooms occupied by workmen, or into the immediate vicinity of the factory, but should be led to a chimney. The Regulations require special measures for the residuary wash waters, as well as for vapours and gases containing alcohol or oils to be kept or eventually dissociated.

Finally, another Order, dated 30 December 1924, has dealt with warehouses for the by-products of sulphate of cellulose factories. Detailed measures are laid down for emptying, cleaning, and scouring condensers, reservoirs, receptacles (the workpeople must not go inside to carry out these operations); for the purification of turpentine; for the use of sulphuric acid in the cleaning of certain receptacles (danger of boiling over or explosive reaction); of certain receptacles containing alcohol and intended for the manufacture of methyl alcohol; in the rectification of turpentine, etc.; in the handling of soap eliminated from the wash water in the manufacture of sulphate of cellulose, for the manufacture of liquid resin, etc. A supply of masks and breathing apparatus is required for certain processes, etc.

Norway excludes young persons under eighteen years of age from cellulose factories. See also the article "Paper Mills".

**BIBLIOGRAPHY**

Mr. Aksel Atterbom and Prof. Wirgin (Sweden).

---

**Cements**

Cements are substances analogous to lime (see that article) which, when mixed with water or immersed under water, set...

1 It should be remembered that under the name "cements" other materials are spoken of, such as: mixtures of fatty matters, resins. magnesia, zinc, oxide, fine sand, etc. These are really pastes, or putties, or a kind of "Solvents", and are used for repairing broken porcelain, glass, etc. It should be borne in mind that several of them contain white lead, litharge, or red lead.
CEMENTS

in such a way as to acquire the hard consistency of stone. They are, however, made from substances containing more clay than lime, so that after burning they contain no more quicklime but components of lime and silica. Their setting, which is much more rapid than that of hydraulic lime, which takes place with the disengagement of heat, is due to the formation of a double silicate of aluminium and calcium or of a silicate and an aluminite of calcium.

The chief characters of cements are: their density, the time they take in setting [which can vary from a few minutes (quick setting cements) to more than an hour (slow setting cements)], their resistance and the consistency of their volume, the relative proportions of the constituents (lime, silica, alumina), the methods of burning and preparation which determine their more or less great hydraulicity and quickness in setting.

Cements take the form of very fine powder, generally of a grey colour inclining to green, and are put on the market in sacks weighing 50 kg. or in barrels of 100-250 kg. (for transport to a distance and for export).

INDUSTRIAL PROCESSES

These vary according to the kind of cement.

(1) Portland cement, the commonest, is a cement which sets slowly, of which the raw materials consist of lime, clay, and silica. Its manufacture varies with the country of origin, but natural Portland is obtained by burning directly a clayey marl. In Great Britain, where there is much chalk, this is used with other substances containing silica or alumina. Artificial Portland cement is made by mixing in suitable proportions marl, lime, and clay. Its composition generally falls within the following limits: lime, 57 to 67 per cent.; silica anhydride, 19 to 28 per cent.; alumina, 4 to 10 per cent.; ferric oxide, 2 to 4 per cent.; magnesia, 3 per cent.; alkalis, 0.2 to 3 per cent.; sulphuric anhydride, 0.2 to 1 per cent.

The raw materials are crushed between fluted rollers, then pulverised by grindstones or smooth rollers, or in crushing machines, which are of two types: quick running mills (in which the crushing is effected by steel balls or flint pebbles driven by centrifugal force against the metal walls of the apparatus) or by slow running mills (cylinders revolving round their horizontal axis and also containing steel balls or pebbles but acting only by their weight). Some of these apparatus are not completely closed, so that the dust coming from them is a danger for the workers.

Mixing is done either by a wet or dry method.

In the "wet method" the mixture is placed in tanks of water provided with stirrers. The resulting clear boiled slurry passes first into dosing tanks, then into settling tanks, which allow the paste to be recovered when the water is got rid of by decanting. The slurry goes directly into rotatory kilns; but in other types of kilns (continuous kilns) it has first to be made into bricks (by drying, passage through a perforated plate, cutting into length, and drying in a drying tunnel).

The "dry method" is used when the very hard raw materials must first be completely pulverised. They are then placed in rotating cylinders (provided inside with paddles for ensuring intimate mixture) or they circulate in a contrary direction to the hot gases. The mass is then made into bricks by compression in special brick-making machinery.

Burning is done at 1,400° C.; the lime reacts on the clay and forms aluminate and silicate of lime. The mass begins to vitrify and forms "clinkers." Hard pieces of a greenish-brown colour.

Among the many kinds of kilns, the commonest are the continuous kilns, comprising those with a short flame, similar to those used for lime (Aalborg or Schneider kiln), or automatic kilns (Maenstaedt type).

The placing of the bricks in the furnace is often done mechanically by means of travelling bands, automatically closing hoppers, etc., the Hofmann kiln similar to that used in the manufacture of pottery; the Dietzsch, commonly used, is a kind of chimney the width of which increases from above downwards and provided with openings which allow the vitrified portions sticking to the walls to be detached by means of tools; firing is effected half way up the kiln. Rotatory kilns are by far the most used at the present time. This type consists of a great steel cylinder, 40 to 80 metres long and 2 to 3 metres in diameter, lying horizontally at a slight inclination and heated by coal dust, mazout, or gas.

The slurry to be burnt passes directly into the uppermost end of the kiln and, as a result of the rotary movement, slowly moves down the slope to the lower end. In its course it meets with the hot gases traversing the cylinder in

1 Sometimes the bricks are made with slaked and sifted lime, mixed with a quick-setting cement into a double burning or Schneider kiln, which slow the paste to be recovered when the water is got rid of by decanting. The slurry goes directly into rotatory kilns; but in other types of kilns (continuous kilns) it has first to be made into bricks (by drying, passage through a perforated plate, cutting into length, and drying in a drying tunnel).
the opposite facing, by which it is first dried and then burnt.

On removing from the kiln the lumps are sorted to remove those that have not been completely burnt. Travertine and those that have been over burnt are rejected. Those which have received the desired amount of burning are kept, and all the lumps before being crushed and mixed are powdered. The powdered lumps are carried to a point where they are obtained, and, being ground with a screen 200 mesh per square centimetre, a residue from a sieve of 400 mesh is the square centimetre of more than 0.1 per cent. Pulverisation is intended by crushing and mixing with hydraulic lime the first-pavement residue obtained from the setting of heavy cases, because the cement is most in this case, 23 to 24 per cent., and water, and consequently one of the most hydraulic.

2. The slag of blast furnaces composed of sheets of lime and a small amount of basic cement is also used to manufacture cement, by exposing the hot furnace the slag is received into water, where it solidifies in the form of granulated stone. It is ground, sieved, and mixed either with lime in revolving cylinders.
off contain sulphurous anhydride. After having been collected in dust chambers, these gases are sent to the sulphuric acid factory, where they are treated by the lead chamber process or by the contact process.

(5) Pozzuolana, i.e. cement of volcanic origin, is analogous to cement from its composition, but it is very poor in lime. Artificial pozzuolanic cements are obtained by burning and crushing natural clays. Mixed with lime these natural or artificial products yield very quick-setting cements.

(6) Among the other kinds of cements may be cited mixed cements, a mixture of the non-pulverulent residue obtained when hydraulic lime is slaked with natural cements, or Portland cement with hydraulic lime; magnesian cements, prepared by starting from calcareous dolomites and used in submarine construction work; Scott’s cements, a mixture of lime and roasted gypsum; aluminous cements, obtained by fusion in the electric furnace or in a water-jacket of a mixture of bauxite and chalk, or of bauxite and lime (called also “fused cement”, “electric cement”), etc.

**USES**

Natural Portland cement is used for the manufacture of moulds, drain pipes, facings, etc., for building of every kind, submarine work, etc.

All the other cements are used for constructional purposes mixed with sand or gravel, and for making mortar, concrete, and reinforced concrete.

**Mortar** is a pasty material, drying rapidly in the air, obtained by mixing cement (or hydraulic lime) and sand, and then slaking with water. **Concrete** is a mixture of mortar and broken stones (about the size of pebbles on a road). **Reinforced concrete** is a mortar of slow-setting cement around a skeleton of iron (trellis or grill made of interlacing bands). They serve for the construction and utilisation of reinforced concrete, which every day becomes more and more widely used.

**Sources of Injury**

**In the Course of Manufacture**

There is, above all, the heat, which in the proximity of the continuous kilns reaches a temperature of 40-48° C. (from 18° to 25° C. near the rotatory furnaces), the outside temperature being 10° C.; then there are the draughts and poisonous gases given off in the course of manufacture from the coal used. Analysis made in a Russian factory gave an average of 0.0065 cubic metre of sulphuretted hydrogen gas and sulphuric hydride and 0.072 cubic metre of sulphurous anhydride per cubic metre of air.

The principal danger, however, comes from the dusts given off either by the raw materials when they are broken up or from sifting, mixing, or from the final product, cement.

Seen under the microscope, the coarse cement dust consists (according to Koelsch) of rounded particles of about 4 to 5 microns, the dust of finished cement consisting of larger hexagonal grains of 10 to 12 microns. The quantities of dust contained in a cubic metre of air in cement factories varies from 55 to 1,720 mg., with an average of 87 to 1,920 mg. per cubic metre in old factories, and 55 to 450 mg. in more modern factories, in which evidently the quantities of dust were less. Koelsch gives the following figures: removal from the annular kilns for burning the chalk, 155 mg.; sack packing rooms, 353-685 mg.; barrel packing...
rooms, 1,176-1,720 mg. Similarly, Ahrens found a content of 130 mg. of dust when the crushing apparatus was not working and 224 when it was.

The rotatory kilns produce enormous quantities of dust (up to several tons a day), which are drawn away in the gases and may cause serious injury to persons in the vicinity of the factory. The dusty processes are many; removal from the kilns; turning and lifting the material; charging the wheelbarrows; grinding, sifting, transport, bagging, and packing in barrels. The dust created in the course of grinding and sifting is the most dangerous because it is the finest.

**In Use**

The damage is due to the cement dust (see Uses, page 388).

The caustic action on the skin and mucous membranes from the cement dust is due to its hygroscopic property. It is explained by its composition: lime dust is due to its hygroscopic property. It is explained by its composition: lime, 62 to 65 per cent.; caustic lime, and silicic acid. Besides this chemical action it sets up a mechanical irritant action.

**Statistics**

Workers in cement factories show a pathology such as is common to the majority of workmen: wounds, intestinal troubles (especially constipation), rheumatism, boils, respiratory affections, bronchitis, etc., poisoning from fumes, etc.

While in Bavaria the morbidity was not higher than the general average, that published by the Sickness Insurance Society of Leipzig showed a high rate among cement mixers and hodmen: 1,338 sick days per 100 members.

According to Koelsch and other German writers, catarhal and respiratory affections constituted 30 to 40 per cent. of all the maladies from which cement workers suffer.

Other figures supplied by the reports of the Prussian factory inspectors (1911) and relating to 25,000 workmen show the following figures:

In the United States, according to statistics of Hofmann, 47 per cent. of cement workers die of respiratory diseases, tuberculosis representing 19.3 per cent.

An enquiry was conducted recently (1927-1928) by the Federal Service for Public Health in a large Portland cement factory, one of the most dusty in the industry, with a view to ascertaining the injuries due to cement dust. All data regarding absences, cause of illness, and quantities of dust in suspension in the air in the various workrooms were carefully collected. The workers were also medically examined, including radioscopic and, where necessary, radiographic examination.

The enquiry proved that the dust raised in the course of industrial operations in the factory does not predispose workers either to tuberculosis or to pneumonia. On the other hand, workers presented a high rate for diseases of the upper respiratory passages consisting chiefly of colds, acute bronchitis, pharyngitis and tonsilitis, as well as cases of influenza and grippe. Cases of the above diseases sufficiently serious to involve absences of two consecutive days or more were met with amongst workers in the most dusty departments amounting to about 16 per cent. more than in the case of workers in departments where relatively less dust was produced. Lime dust seems to be slightly more harmful than that of cement.

Work in the open air, such as that of stoneworkers, exposes the system to dis-
cases of the upper respiratory organs to a much greater extent than in the case of indoor exposure to cement dust. In the open-air operations in a cement factory the workers presented a higher percentage for rheumatismal affections. An enquiry revealed the fact that this work also involves exposure to certain skin diseases, to conjunctivitis and to ear affections (deafness). When the quantity of dust does not exceed about 10 million particles per cubic foot of air, it is doubtful whether the above-mentioned diseases occur with an incidence which exceeds the average.

For Italy, see article "Lime".

An enquiry made in 1925 in Russia in the cement factory of Erinsk over a period of two years among the furnace workers revealed the following maladies:

Another enquiry made in 1927 relating to 1,116 cement workers showed the great frequency of atrophic rhinitis and polypi, as well as of purulent otitis. The cement dust, which "rises" readily, dispersed itself throughout the factory and especially in the grinding workroom, where analysis of the air yielded 133 to 504 mg. per cubic metre.

In Switzerland the lesions set up by cement notified to the National Accident Office, numbered 3 in 1919; 4 in 1920; 18 in 1921; 24 in 1922; 40 in 1923; and 54 in 1924.

As regards mortality, the enquiry of Koelsch showed an average rate (over ten years) of 0.62 per 100 workmen, as compared with one of 1.67 for the male population generally. The mortality from tuberculosis was, in Bavaria, 0.22 per 100 living (in 1907) as contrasted with 0.99 for the male population.

Authorities agree in laying stress on the slight frequency of tuberculosis and the rather low rate from respiratory diseases, which seem to be contrary to what one would expect from the enormous quantities of dust present in the atmosphere of the factories. Certainly, slight cases of bronchitis and asthmas escape report, but the small number of cases of tuberculosis may partly find an explanation in the chemical constitution of cement dust. This is composed of lime and siliceous acid — substances which are of some use in the treatment of tuberculosis, calcium having the property of increasing phagocytes, and siliceous acid helping to increase the growth of connective tissue, which favours the healing of tuberculous foci. According to Pesenti, cement dust is said to arrest the development of tuberculosis.

**Pathology**

Besides the maladies due to the high temperatures, the brusque changes in temperature and strain, and fatigue from kilnmen especially suffer (rheumatism, neuralgia, respiratory and cardiac diseases, etc.), the effect of the industry shows itself especially in mechanical and chemical action on the skin and mucous membranes.

The various forms of dermatitis, known under the name of "cement itch", commences with a fine papillary eruption, accompanied by intense pruritis, which increases with heat especially when in bed. Martial, who has described 78 cases, and Ascher, who has studied several, are of opinion that the lesion starts from excoriations of the skin, and that in appearance it resembles scabies very closely. An enquiry by Berger and Helwer (1892-1899) found it present in 10 per cent. of cement workers. The dermatitis is localised preferably on the hands and fingers (especially in the interdigital spaces) and over the joints, but in the absence of precautions or from other reasons it may extend to other parts of the body: thorax, axilla, forearm, elbow, face (infra orbital region, etc.). Then the papules get rubbed and covered with a crust which, when it falls off, leaves the skin raw. Sometimes there is oedema of the hands.

In this state the lesions will rapidly heal under appropriate treatment; but if the patient does not cease from exposure to the action of the dust the eruption gradually becomes eczematous with formation of crusts, and is accompanied by an intense pruritis involving at times constitutional symptoms such as sleeplessness, etc. If the patient does not give up his work quickly or recommences it before the first attack has been completely healed, the lesions, at that time limited to the superficial layers of the skin, penetrate down to the chorion and then give place to thickenings and cicatricial infiltrations of the whole of the skin, to such an extent that they appear as islets of skin of a thickened character and covered with vesicles, pustules, and rhagades. This is sometimes accom-
panied by fever, especially when the pustules or vesicles are developing. In all chronic eczemas, the lesion extends to the ears and eyebrows, tending to give a sad and set expression to the patient's face. If the malady is not arrested in time the development leads to a chronic thickening of the whole of the skin.

Cement itch may assume numerous forms according to its localisation. Thus among porters carrying sacks of cement, Pappanti-Pelletier has described a dermatitis situated especially on the scapular and clavicular region of the nape of the neck, but able also to spread to all parts coming into contact with the cement sacks. This dermatitis is characterised at its first stage by widespread hyperaemia of the epidermis, with slight desquamation and infiltration of the follicles. In the second stage of development, which lasts longer, all the follicles of the affected region become hypertrophied and stand out in relief above the interfollicular parts, giving the skin a "goose skin" appearance. The dryness of the skin is due to the absence of sweat and the alteration of the functions (secretion) of the sebaceous glands; the red colour of the skin is due to hypertrophy of the follicles induced by a thickening of the horny layer and retention of the sebaceous products. In the third stage, produced rather late, suppuration of the papules takes place and uniform pustules. Gross has described a case of necrosis of the skin localised to one of the legs; Neugebauer has seen several cases of eczema and even of superficial ulceration localised on the hands.

In the industry of modelling with cement other modifications of the skin have been described: the epidermis of the fingers whitens very rapidly, becomes softened, wears away literally visibly, and becomes at length the seat of minute, very painful ulcers attributed (Baudouin) to grains of silica acting like a raspat. On the other hand, the rapid alteration of the epidermal cells is explained by the caustic action of the lime present in the cement.

Among the lesions of the mucous membranes mention should be made of that of the nose: irritation, sometimes painful ulceration, which bleeds easily, and even perforation of the septum. Of 600 workmen examined by Koelsch, 17.3 per cent. had inflammation of the turbinals, 9.3 per cent. perforation, 1.7 per cent. perforation of the septum. One-third of these examined had, therefore, more or less severe lesions of the nasal mucous membrane. The presence of rhinoliths is rare. They are due to:

collections of cement dust forming calcull of varying size. Koelsch saw one weighing 0.75 grm. and measuring 34 x 15 x 4 mm. in a man who had worked for ten years. Betz found them in 7 to 10 per cent. of the men. Jurass in 1 per cent. only. (See above for the Russian data.)

Diffuse conjunctivitis, quite definite, sometimes occurs and necrosis at the points of the conjunctiva where the cement dust has alighted. Healing, when it occurs, does so with adhesions and serious functional troubles. Damage to the cornea is more serious. While in slight cases this is only superficial, showing itself as a speck of whitish colour like ground glass or porcelain, cicatisation generally leads to an indelible corneal opacity due to the organic combination of the lime with the albuminoids of the tissue. In serious cases the parts affected spherulate and cause not only reduction of sight but also sometimes perforation of the eyeball and loss of the eye. The cicatisation takes place with expectation of the eyelids—in or ectropion, trichiasis, etc. Of the 600 men examined by Koelsch, 12 per cent. had conjunctivitis.

In the mouth the cement particles may cause very small ulcers, but always visible to the naked eye.
According to Legge, cement dust affects the upper air passages, leaving the lungs unaffected. As a matter of fact, the respiratory affections present nothing specific; tuberculosis is not frequent. Occasionally broncholiths have been found in the large bronchi and even incrustations of the mucous membrane. (See also article "Lime").

A blood test made amongst cement workers by Saleck (1927) provided the following results: no punctate basophilia as in cases of lead poisoning; increase in the number of polychromat red cells, and in the case of a limited number of workers, red cells with fine and very fine granulations. These modifications of the blood were not accompanied by cutaneous lesions which would obviously have explained the modifications of the red cells noted by Saleck.

HYGIENE

The kilns should be arranged so that they are away from main roads and dwelling houses. The openings should be on the sides away from the public road. A stone or brick wall to act as a screen should be sufficiently high to prevent the glow of the kilns from being seen. The chimney stack should be very high to prevent the smoke from incommoding the neighbourhood. Fuel giving rise to unpleasant or unhealthy emanations should be avoided. Fuliginous gas should be burnt. Steps should be taken to afford protection from the radiant heat and smoke; from the danger of asphyxiation (avoid every pit or passage unprovided with an exit where toxic or asphyxiating gases can collect) or of fire (the store of fuel should be isolated from the hearth of the furnaces), metal gauze should be applied over the outlet of the chimneys; the kilns should be isolated, etc. All adequate measures should be adopted to diminish or suppress useless noise and vibration. A good system of ventilation should be installed, either general or locally applied, to remove the dust.

The water used should undergo decantation before being turned into the sewer or stream.

Excellent technical methods are now available for capturing and removing the dust, for ridding the smoke of dust (see article "Dusts, Fumes and Smoke"). The processes of breaking, grinding, sifting, sieving, bagging and barrelling, etc., can be done in closed apparatus with exhaust device (transport and filling should be carried out by mechanical means: elevators, travelling belts, etc.). Bagging machinery now permits not only of the filling of the sacks, but the weighing and automatic tying of them. Completely closed metal receptacles, into which the bags to be filled are introduced and fixed to the feeding mouth, allow the dust to be removed as soon as the cement has passed from the silo to the sack, thanks to a slight negative pressure maintained in the inside of the receptacle.

The dust caught by the locally applied systems of ventilation is carried to depositing chambers or to cyclones where it is thrown down and recovered.

Most works also have installations for freeing the sacks of dust which are then repaired.

Good locally applied exhaust ventilation naturally diminishes the risk from dust to workmen. According to Wittgen, in a German factory this means has reduced the frequency of respiratory diseases by one-third in the space of five years; the number of sick days were reduced from 2,742 to 812. In another factory an adequate plant for the removal of dust reduced the morbidity from respiratory diseases from 9.3 to 3.3 per cent.

Cleanliness must be emphasised as an important factor in prophylaxis. The persons employed, therefore, should have suitable and sufficient means for personal hygiene (wash basins, douches, baths, overalls, etc.) placed at their disposition. A little ointment containing lanoline should be rubbed into the hands before and after work (pig's fat and rancid fats should be avoided); goggles should be worn and respirators consisting of a piece of linen over the mouth; work should be given up in case of dermatitis until a complete cure has been effected. The treatment of cement itch belongs to the practising physician.

LEGISLATION

Women are prohibited from employment in grinding and sieving cement in the Netherlands. Young persons of less than sixteen years are prohibited from crushing, grinding, sifting, bagging, as well as from grinding mills, unless the dust is removed by mechanical means, in Belgium and Spain; of less than eighteen years of age in France, the Netherlands and Norway when dust is discharged freely into the air of the workroom; female young persons of less than eighteen years of age in grinding and bagging in Quebec; boys of less than fifteen years in Italy, if dust is given off freely; women of less than twenty-one under the same conditions in Spain, Italy, etc.
Regulations in some countries require the necessary measures to be taken to prevent escape of dust in workplaces and of toxic gases from the kilns: in France the Decree of 1 October 1913 lays down requirements as to the use of quick-setting cement, and the Decree of 9 October 1913 indicates what hygiene precautions are to be adopted in the use of cement:

I. With a view to protecting the hands and arms and face, workmen are recommended to make use of means such as brassièrês, ointments suitable for counteracting the effect of cement, goggles for work done on platforms, etc. Employers are advised to place these means at the disposal of the persons employed.

II. Workmen are strongly urged to make use of the means for personal cleanliness (which the irritating action of cement makes particularly necessary) at the place of work; the means for doing this are placed at their disposition by the employers.

III. When a cement worker is affected by extensive irritation of the skin he should be medically examined as soon as possible.

In Norway the Royal Decree of 30 October 1919 lays down the hygienic measures in regard to cement factories. Eczema and dermatitis and ulceration of the buccal and nasal mucous membrane are compulsorily notifiable in the Netherlands; dermatitis from cement is so also in Japan and in those countries where specific maladies or injury due to irritant and caustic dusts and liquids are named.

Fig. 99 is reproduced from a photograph kindly supplied by the Belgian Factory Inspectorate.

---

Cerium

French: Cérium. — German: Cerium, Cer.
— Italian and Spanish: Cerio.

CHEMICAL PROPERTIES

Cerium — symbol Ce, atomic weight 140.92, and specific gravity 6.72 — belongs to a group of metals found in very rare kinds of earth. It is a metal, iron in colour, capable of being cut by a knife like lead, melts at 623° C. and oxidises in the atmosphere, becoming covered with a black coating.

Cerium forms two series of salts: cerous salts, obtained from the oxide Ce₂O₃, and ceric salts, obtained from the bixoxide CeO₂, which are yellow or brown in colour.

INDUSTRIAL PREPARATION

Metal cerium is obtained by electrolyzing chloride of molten cerium with a small quantity of chloride of potassium. The graphite anode is suspended vertically in the axis of the bath; the cathode traverses the bottom of the bath. The metal obtained only contains 50 per cent. of pure cerium, the great difficulty being in fact to obtain a pure cerium salt. Cerium is accompanied in all ores by the metals of its group, from which it is difficult to separate it; monazite (a phosphate of cerium and other rare earths, particularly of thorium), cerite (hydrated silicate of cerium, lanthanum and didymum, etc.), gadolinite and orthite (likewise complex silicates).

The ores are first heated with sulphuric acid in order to render the silica insoluble. It is later eliminated by filtration. Oxalic acid, which only precipitates rare earths, is added to the solution.

A separation may be continued according to various methods: elimination of the thorium by maceration of the oxalates in the ammonium oxalate; precipitation in the state of phosphate insoluble in dilute hydrochloric acid; rendering insoluble the sulphate of cerium in the state of a double salt by means of a solution of sulphate of sodium; fractionated precipitation of the metals by means of ammonia or by chromate of potassium; by heat treatment of the nitrates (the nitrates of the various rare earths present an unequal resistance to heat) and elimination by water of the salts not transformed into oxide, etc.

See article "Incandescent Mantles" for the method of treatment of monazite to obtain salts of thorium and cerium.

USES

Cerium, when rubbed with a file, gives rise to violent sparking, not being, however, sufficiently hard for use alone in the manufacture of lighters; ferro-cerium is used for this purpose (70 per cent. of cerium and 30 per cent. of iron). This is prepared by melting the cerium
under a layer of chloride of barium, in order to protect it against the action of the air, then introducing gradually the pure iron into the molten mass.

Nitrate of cerium is a constituent of the liquids used for impregnating incandescent mantles. It is in fact transformed by calcination into oxide of cerium, which possesses a lighting capacity of a high order (see article "Incandescent Mantles").

TOXIC ACTION

According to Löwý, the toxic action of this product is without importance from an industrial point of view. Cerium precipitates albumin solutions in concentrations of average intensity. It has an astringent and vasoconstrictive properties. It causes tissue necrosis, paralysis of the central nervous system and of the heart and diminishes blood pressure. Administration of products with a cerium basis causes dryness of the mouth and a diminution in the secretion of the sweat glands.

According to Löwenthal, the red corpuscles suffer injury by cerium similar to that due to lead. There should also be mentioned the action of cerium on the skin of workers who have to manipulate it.

Hara recently (1926) has studied the toxic action of this metal and its salts on animals: smooth and striated muscles, nervous system, etc. He found that it caused loss of appetite, intense thirst, loss of weight and falling out of hair, etc.

In the course of its extraction from chloride, for preparing the compounds in combination with iron, at present much utilised for lighters, there is an abundant liberation of chlorine, capable, where adequate precautions are not taken, of causing serious injury to the worker and to the residents in the neighbourhood.

***

Chemical Trades

From the scientific point of view, the term "chemical industries" ought only to be applied to industries the products of the manufacture of which are obtained from chemical reactions. These products then have a composition different from that of the original materials. In this respect the prototype of chemical industries might be taken to be such manufacture as that of sulphuric acid, soda, chromates, superphosphates, aniline, etc.

At the same time, common acceptance, legislation, and industrial statistics in different countries habitually envisage under the term "chemical industries" numerous other industries — often such as do not involve any chemical operation and frequently even have nothing to do with chemistry. This is the case, for example, with the manufacture of blacking, tallow melting, bleaching of wax, manufacture of mineral waters, etc.

It is impossible to make a complete picture of the characteristics and processes of work of the chemical trades, as they are very different and are being continually modified. It should be remarked that the number of products is extraordinarily great and is increasing daily.

Numerous chemical products, both the raw materials used in their manufacture as well as the intermediate substances and their residues, can either exert a caustic action or cause burns or skin affections, or have a toxic action or possess, finally, other properties injurious to health either immediately or gradually. Such substances are also made or handled in other branches of industry, but their number is always small. On the other hand, in different chemical undertakings their number is relatively high. It should be understood that this applies only to certain big industries and, in particular, to the manufacture of intermediate products and aniline colours, because the majority of the chemical industries are confined to the manufacture of a single product. Thus it is, for example, in the manufacture of soda, sulphuric acid, hydrofluoric acid, and superphosphates.

The manufacture or treatment of injurious or toxic substances is by no means necessarily accompanied by injury to the health of the workpeople. In almost all cases it is possible to avoid, or at least to diminish, the risks, thanks to adequate regulations and arrangements. Actual knowledge of the facts indicates that in general it is only certain recognised substances which are particularly dangerous. In the first rank of these must be placed those which act on the organism or undergo absorption without the victim being aware of it.

The majority of lead compounds come under this head: litharge, red and white lead, chromate of lead, etc. These substances are only slightly soluble and do not possess any taste; that is the reason
why particles of these substances can be absorbed by the respiratory or digestive tract without knowledge, and it explains why these substances so readily cause poisoning.

Acetate of lead is soluble, but has a pronounced and peculiar taste; hence it cannot be swallowed without knowledge, and consequently poisoning by it is rarely reported.

The very great danger from carbon monoxide and mercury vapour similarly resides in the fact that these bodies are without smell or taste.

The most dangerous substances are those which can be absorbed by the unbroken skin. Among these nitro- and amido-derivatives of the aromatic series should be mentioned, of which the chemical industry manufactures and treats large quantities. Manipulation of them in the different departments requires the greatest precautions. Contact with them under certain conditions can be attended with the gravest consequences. But obviously it is not easy to protect the workmen handling such substances against all contact. It is therefore easy to understand that the manufacture and treatment of these matters gave rise in the early days to numerous and severe cases of illness. Since their method of absorption has been better known, the manufacture and treatment has become so little attended with danger that illness rarely occurs unless repair work requires to be done or accidents to the plant or the like develop.

It is always highly dangerous to enter vats or apparatus containing substances injurious to health. Permission to enter them should only be allowed on condition that the greatest precautions will be adopted and after care and cleaning. The persons who enter first should have a rope round their waists; further, a mate should always be close by the apparatus as long as anyone is inside.

Various attempts have shown that it is as difficult to give an account of the raw materials, processes of manufacture, and products made in the chemical industry as it is to give an exact picture of the state of health of the workpeople. The conditions vary in the several branches of the industry and even in the different factories and different countries.

However, so far as the industry in Germany is concerned, it is possible to give a sufficiently accurate account by using the data supplied by the Federation of Chemical Industries. It comprises the average number of full-time workers employed during the periods 1908 to 1910 and 1924 to 1926; the proportion of accidents notified, accidents compensated, and fatal accidents to the total number, and, further, all the data separately for all the causes mentioned under the headings (a) to (f) above.

Table I shows that in the period 1908 to 1910, 490 accidents were due to substances and toxic gases which caused absence from work for more than three days (col. 17), of which 113 received compensation, and of which 47 were fatal (col. 18). The corresponding figures for 1924 to 1926 were: 1,041, 110 and 45.

Acids, alkalis, etc., caused in 1908-1910, 2,840 accidents (cols. 15 and 16), of which

1 During the first thirteen weeks the expenses incurred by illness are borne in Germany by the sickness insurance societies.
292 (6 fatal) received compensation. In the years 1924-1926, there were 3,983 accidents, of which 244 (9 fatal) received compensation. Of the total numbers of accidents (col. 3), about 14 per cent. were due to substances and toxic gases and about 93 to 74 per cent. to acids and alkalies.

The number of accidents calculated as having occurred per 1,000 workpeople employed (which is also given in the accompanying table) yields still more precise information than do crude figures. In 1908 to 1910 there were 56.7 accidents per 1,000 full-time workers (of which 8.3 (0.55 fatal) received compensation (cols. 9 and 4)). From 1924 to 1926 the corresponding figures were 59.4, 5.21, and 0.47, respectively.

In 1908-1910 substances and poisonous gases occasioned, per 1,000 workpeople, 0.73 accidents, of which 0.17 received compensation, and 0.07 were fatal; whereas the figures for 1924-1926 were 1.00 accidents, of which 0.30 received compensation and 0.04 were fatal. As is seen, the number of accidents due to substances and toxic gases was not very high; on the other hand, the proportion of fatal accidents is relatively great.

Table II, also drawn up from the data supplied by the Federation of Chemical Industries, gives the number of accidents for which compensation was paid, distributed according to the different branches of the chemical industry. The number of reported accidents is not known. At the same time the figures in cols. 7 to 18 of the main chemical industry (col. 2) and for the aniline and aniline colour industry (col. 3), that is, of “inflammable, hot, caustic and poisonous substances”. In consequence of insufficient data it has not been possible to subdivide them. Whatever may be the reason, the frequency of accidents due to these causes is less than that of acute intoxications due solely to toxic substances.

In studying table II it should be borne in mind that cols. 3 to 9 give the arithmetic mean for the years 1924 to 1926.

Leaving out of account the small branches of industry, the number of accidents caused by inflammable, hot, caustic and poisonous substances is 1.1 per 1,000 for the main chemical industry (col. 2) and for the aniline and aniline colour industry (col. 3), and 0.8 per 1,000 for chemical, pharmaceutical and photographic products (col. 3), that is, for the last group a figure less than that of acute intoxications.

The fatal cases mentioned in col. 9 deserve special mention because, on the basis of the statistics in table I (cols. 18 and 20), one can consider what the probability was of the (approximately) three-tenths of the fatal cases of the whole group (table II, col. 9) having been similarly caused by poisonous gases in the period 1924-1926.

If the figures arranged in proportion to 1,000 workmen (col. 9) are examined, leaving out of account the small groups of workpeople (Nos. 14, 15, 18 and 19) which, in view of their small number, do not give an exact idea of the conditions, it is seen they are highest for the main chemical industry (line 2, col. 9) and the industries of pharmaceutical and photographic products (line 3, col. 9), that is, 0.2 per 1,000. Next comes the coal tar industry with 0.18 per 1,000. For the aniline and aniline colour industry, the proportion of fatal accidents is 0.16 per 1,000, which is very small when compared with the chemical industry as a whole, except medicines and manufacture of indiarubber and mineral waters.

The last reports of the Federation of Chemical Industries furnish data which complete the above-mentioned statistics, because they contain similar information on the industrial diseases which are not due to acute intoxications. As a matter of fact, eleven industrial maladies were treated as accidents by Order of the Minister of Labour dated 12 May 1925. This Order required the companies to give compensation to persons incapacitated as the result of the diseases in question in the same way as though they had been accidents. Consequently the industrial disease cases had to be reported to the companies.

Table III, which is based on the reports made in the course of the year 1926, has been taken from the annual report of the Federation of Chemical Industries. In studying it attention must be given to the following facts:

(a) Account only is taken of the reports on occupational diseases mentioned in the Order as maladies for which compensation must be awarded.

(b) Col. 1 gives the total reports made by medical men, employers, or workpeople.

(c) As a rule, no examination or complementary proof has been attempted to determine if the reports were correct except for the cases mentioned in cols. 6 and 10 — col. 6 containing all the reports regarded as correct, and col. 10 those that were not regarded as being an industrial malady.

(d) So far as what is stated in cols. 2 to 5 is concerned, the need of determining whether or not they were compensable industrial diseases does not arise, because in those cases recovery of their capacity to work had taken place within the thirteen weeks. It is not stated whether there had been revision of the cases.

In examining table III, when comparing cols. 6 and 10 — see above paragraph (c) — it is apparent at once that the reports based on initial examination were very uncertain. While the control medical examination supported, in 68 reported cases of lead poisoning, the diagnosis that lead intoxication was present, in 60 cases this diagnosis was not upheld. The 3 diagnoses of phosphorous poisoning were erroneous. Similarly, 8 out of 9 cases of mercurial poisoning, 10

out of 11 cases of benzol poisoning, and 30 out of 46 cases of poisoning by carbon bisulphide were wrong.

If acceptance were given to the opinion — which is certainly going too far — that the reports of cases of illness settled without complementary examination (those comprised in cols. 2 to 5) were all correct, the total number sent in in 1926 in the chemical industry would have been 521, of which 469 were cases of lead poisoning, 3 mercury poisoning, 12 arsenical poisoning, 2 benzol intoxication, 17 poisoning by nitro- and amido-derivatives of benzene (of which 1 was fatal), 16 carbon bisulphide poisoning, and 2 cases of soot, tar and anthracene cancer, etc. On the other hand, if half only — and this doubtless is much more likely — of the reports included in cols. 3 to 5 are correct, the number of industrial maladies would be only 298. As regards lead poisoning, a fairly large number of cases relate to paint and colour works: similarly, a large proportion of the cases of carbon bisulphide poisoning relate to the India-rubber industry. From this point of view, it would appear that the number of diseases for which compensation had to be paid in the chemical industry — taking this in its limited acceptation — was not very large. To the 521 or 298 industrial maladies there would still require to be added for the year 1926 (table I, col. 17) 398 acute cases of poisoning set up by gases and poisonous substances, that is, a total of 947, or 624 which involved incapacity from work for more than three days. According to table II, the number of workpeople employed in the chemical industries, leaving out of account medicines, rubber and aerated water factories, was 280,000. This makes 3 or 2.2 industrial maladies per 1,000 full-time workers. But these figures are only averages and have not great value for particular undertakings or branches of industry.

The statistics of the German sickness insurance societies comprise in general all cases of sickness which have caused incapacity for work of more than three days. Among the statistics of morbidity relating to the chemical industry in Germany, drawn up on the basis described, account should be had of those of Grandhomme in his work Die Fabriken der Farbewerke Meister Lucius und Brüning in sanitärer und sozialer Beleuchtung.
those of Leymann which appeared in *Concordia*, 1906, pp. 101-107, 114-124, and 131-136, and in *Concordia*, 1910, pp. 355 et seq., and lastly the valuable statistics of Curschmann in his annual reports of the Federation of Chemical Industries for the years 1909, 1910 and 1911.

Grandhomme, who included in his statistics all cases, even where they did not give rise to incapacity, found that in departments making sulphuric and nitric acid and intermediate products, aniline colours and anthracene, in the years 1893 to 1895, there were 15 cases of occupational disease per 1,000 workers, including the cases treated in consultations.

Leymann found in a factory for sulphuric, nitric and hydrochloric acid, organic in intermediate products, organic chlorine compounds, etc., 13 cases of poisoning per 1,000 workpeople, and in an aniline colour factory not preparing intermediate products 1.2 cases of poisoning per 1,000 workpeople. For the period 1909-1910 Curschmann found in the main chemical industry, omitting the manufacture of lead colours, 2.1 cases of poisoning per 1,000 workmen. These figures sensibly resemble those drawn up by the Federation of Chemical Industries, especially if consideration is given to the fact that in the material Curschmann dealt with the number of cases of lead poisoning was 18 per cent. only, while in the statistics mentioned above they numbered 30 or 50 per cent. of the cases.

Grandhomme's and Leymann's figures can be readily understood to yield higher figures than those of Curschmann because the manufacture of intermediate products, especially of nitro- and amido-derivatives of the aromatic series, readily give occasion for poisoning, at any rate during the years under review. Examining the data given, it is noticeable that in the chemical industry the number of industrial diseases involving incapacity for work for more than three days is relatively less than that of accidents with incapacity lasting more than three days. The figures in the case of 1,000 workers for industrial diseases are 2 to 3 as compared with 59.7 for accidents. Similarly, the total number of industrial diseases was small in comparison with the total sickness. In the years 1909 and 1910 Curschmann found 54.9 cases of sickness per 100 workmen per annum, of which 0.21 were professional intoxications, a proportion of 0.4 cases of occupational diseases per 100 cases of illness generally. Grandhomme's proportion was 1.63 per cent. and Leymann's 1.67 and 0.2 per cent.

To understand the figures it must be understood that: (a) they are the average and that conditions are very different in different branches of industry; (b) the figures do not include asphyxiating actions, burns or diseases of the skin; (c) the injurious action of the materials handled shows itself very often in an increase in the diseases of the digestive tract and other organs. Leymann's statistics bear on this point, but as they relate only to one factory and fixed conditions it is not fair to generalise from them.

The data presented above relate exclusively to the German chemical industry, which in general, and especially in the large works, possesses efficacious means for protecting the workpeople. Equally satisfactory statistics are not obtainable from other countries. As a matter of fact, the *Annual Report of the Chief Inspector of Factories in Great Britain* contains, it is true, statistics of great value, but they do not specify the chemical industry only.

In the State of New York the number of accidents in the chemical industry was, in 1925, only 3.8 per cent. of all industrial accidents. Compensation for accidents per 100 cases was as follows:

- Motors, transmission machinery: 5
- Transport installations, lifting hoists, lifts: 11
- Poisonous and caustic substances: 14
- Explosives, electricity, burns: 18
- Falls, shocks: 29
- Fall of objects: 6
- Transport of objects: 9
- Tools: 4
- Various causes: 4

In the U.S.S.R. Shapiro-Aronstamm visited, in 1925, 218 workmen of the Polewo chemical factory (sulphuric, hydrochloric, nitric acids, etc.): 100 of these workmen were occupied in processes of manufacture, 39 per cent. being from twenty to twenty-nine years of age, and 3.7 per cent. over fifty; 43 per cent. had worked in the trade for one to three years; 25 per cent. from three to ten years, and 9 per cent. for more than ten years.

Among the diseases reported were first and foremost those of the respiratory tract: 56 cases (25.7 per cent.) were early forms of tuberculosis; 21 (9.6 per cent.) were in the second stage. There followed, in order of frequency, diseases of the circulatory system (mainly functional lesions), neurasthenia, diseases of the eyes. Twelve per cent. of the workmen had suffered accidents with temporary incapacity, which reached 21.2 per cent. among the apprentices. Burns, especially of the hands, iron acids showed a relative value of 38.

In the same year, Pachomyczew studied the health of 2,318 workmen and salaried employees in eleven chemical works in Moscow (soap factories, scent, glue, colours, etc.). Here also respiratory diseases were the most frequent, especially in the groups working at a high temperature (60 per cent. of the men, 61.6 per cent. of the women), in the departments where gases were given off (sulphuric and sulphuric anhydride, hydrogen sulphide, chlorine, acid and nitrous vapours, etc., 46.8 per cent.), humid departments (56.4 per cent. of the men, 54.3 per cent. of the women), dusty sections (40.4 per cent. of the men, 18.9 per cent. of the women). Of the total in all sections, respiratory diseases figure with a relative value of 33 for men and 25 for women.

Diseases of the circulatory system showed a value of 23; those of the lymphatic system (adenitis) one of 46.2 per cent. for men and 11.5 per cent. for women in...
the glue factories, while the ratio was 6-8 for men and 2 for women in the other factories.

In the colour factories 26.5 per cent. of the men and 33.3 per cent. of the women showed diseases of the nervous system. They related mainly to persons engaged in making sulphur, azoic, and nitrated colours. In general the women were less affected by illness than the men; 7 to 20 per cent. of the workmen complained of muscular weakness; 18 to 35 per cent. were ill-nourished.

Schwarz, of Kazan, visited, in 1927, 2,400 workmen in the chemical factory at Bondshuga, where 804 workmen were engaged in chemical processes. Five per cent. only were from seventeen to twenty years of age; 1.3 were above sixty years.

Sickness was very high among the skilled workmen (25 per cent.), much less among the unskilled. He found especially cases of bronchitis, rhino-pharyngitis, myocarditis, varicose veins, diseases of the skin, flat feet, and conjunctivitis. Chlorine acne was not found, perhaps because the Weldon method was used.

In Switzerland the statistics of accidents relating to about 10,885 persons employed in the chemical industry during the period 1920-1921 gave 2,040 cases, of which 31 were fatal.

While transmission and other machinery, etc., accounted for 421 accidents (20.6 per cent. fatal), transport of loads by hand or machine were responsible for 479 cases (23.5 per cent.), falls of persons or of weights on them for 330 cases (16.2 per cent.), hot, caustic substances and explosives for 344 accidents (27.6 per cent.), and industrial diseases for 102 cases (5 per
Rust also collected about 900 cases, so that these or do not protect the eyes sufficiently. In these cases the goggles are awkward to wear and ducts have to be pressed, because in these accidents the protective goggles are not worn carefully for each individual, almost always prevents phylaxis is possible, and replies that in intervention.

describes the clinical picture, course and possible sequelae, and the data for diagnosis, for expectant treatment, and for intervention. The author asks if prophylaxis is possible, and replies that in the majority of cases it is; thus, the wearing of goggles, if carefully selected for each individual, almost always prevents accidents. Naturally, this precaution is not often applicable in departments where the temperature is very high, or the products have to be pressed, because in these cases the goggles are awkward to wear or do not protect the eyes sufficiently.

Egli collected 475 cases of poisoning and injury caused in the chemical industry — a number which later he raised to 742. Rust also collected about 900, so that these two experts analyse in their work a total of 1,600 cases.

Failure of attention and sometimes carelessness, it is interesting to observe, have been the cause of serious accidents, even to trained persons. Naturally, ignorance has been the cause among pupils from secondary and preparatory schools (experiential courses in chemistry). Cases of injury are numerous also among university students and assistants in institute. Ignorance, inhalation of toxic gases, etc. Many professors have been laid up with serious injuries due to accidents from the chemical substances used in their researches as, for instance, Durong injured in 1811 by chloride of nitrogen, Guttermann, Meyer, Pebal, Hantzsch, Ramberger, Cur-tius (by hydrobromic acid), Liebig, Peckmann (by diazo-methane), Bruhl, Net, Pictet, 'Scheele (by hydrocyanic acid), Standinger, L. Wohler (by the compounds of tellerium and cyanides), Will, etc. Fatal cases are also numerous, among which mention should be made of A. F. Gelen (1815, at Munich, from arsenic-related hydrogen gas), Britton (at Dublin from the same gas); C. Heumann (in 1894, after suffering for eleven years from the effects of the inhalation of chlorine vapour); G. Matzuske (from mine gases); the two young English assistants, C.U. and T.S., from mercury dimethyl, of which the toxicity is not yet known; etc.

This is the reason why (in France, for example) chemical engineers are also accepted for compensation from accidents and diseases of industrial origin.

The hygienic conditions of the chemical industry in Italy have been studied by Loriga and Legnelli in the report presented to the second conference of the International Association of Chemistry (Brussels, 1921). They brought out clearly the complex form under which the causes of danger present themselves in this industry. Certain substances which are formed during reactions, remain partly unknown because the analysis required to detect them requires too much time, too much research, and too much apparatus. In small works the director is more a manager than a qualified chemist. The difficulties in the way of studying the action of impurities and reactions are in this case even greater.

Hygiene

Hygiene has for its object the protection of the neighbourhood against the dangers and unpleasantness of industrial operations on the one hand, and, on the other, the protection of the workman himself against the agents which menace his health while at work. These dangers may be classed as follows: transmission of toxic fumes; emission of flames and particles set alight by furnaces and chimneys; danger of fire and explosion not only from explosives but also from gas, smoke and even dusts; deposit of smoke and soot coming from coal and wood furnaces; production of smoke which often becomes converted into clouds when combined with the dust; production of smells and disagreeable exhalations, diffusion of irritating and encrusting dusts; infiltration of irritating, corrosive and toxic gases; contamination of the soil, subsoil or surface by water, by substances used in dyeing or toxic substances or by substances setting up fermentation, polluting the atmosphere or contaminating the water in such a way that it becomes no longer palatable to man or animals, cannot be used for domestic needs or for industrial use and will not allow fish to live in it.

Legislation

Generally speaking, women are excluded from chemical factories. Young persons of less than fifteen years are excluded in Japan from operations bringing them into contact with a long series of products (prussic acid, cyanides, mineral acids, caustic soda, phenol, etc., and other caustic and poisonous substances and everywhere where emanations and vapours are given off: prussic acid, fluorine, aniline, or chrome from chlorinated their compounds or other analogous toxic substances); in the chemical industry in Poland; under sixteen years in France (distillation in the manufacture of petrol on a large scale, benzenes and hydrocarbons in distillation rooms and storehouses); young persons less than eighteen years in electro-chemical factories in Norway, etc. Statutory measures, therefore, for the prevention of injury in the chemical industry are of great importance. These measures have been carefully studied by experts in different countries...
and large works have derived great benefit from them. Among others, note should be taken of the measures drawn up by the Association of the German Chemical Industry for the prevention of fires, explosions and poisoning. In the prophylactic work much assistance has been given by the Association of Factory Surgeons in the chemical industry created in 1905. Great Britain, the United States, etc., have contributed much to this cause.

The German Association prepared the regulations for health and safety for nineteen groups of chemical industries. These regulations relate to the construction of the factories, the best arrangement of the various departments and apparatus, the lighting and heating, the installation of electric motors, general and localized ventilation, etc. Very detailed instructions are given also as to the capture, removal and neutralisation of poisonous gases, the precautions to prevent dust (risk of poisoning, fire and explosion), handling of caustic and irritating liquids, etc.

Special Measures. — These are numerous in Germany, Great Britain, etc., and are drawn up for several industries, such as matches, chromates, carbon bisulphide, india-rubber, tar, nitro- and amido-derivatives, mineral oils, explosives, etc. (see these articles).

These regulations provide for the suppression or minimising of all causes likely to cause collisions, concussion, accumulation of static electricity, heat, etc., arising from fire, explosion, etc., of the substances in question. The best means of installing heating, the placing of boilers, electrical motors, the piping for hot water, steam, etc., have especially been carefully thought out. Not less important are the measures to be adopted to minimise or prevent injury to the workpeople. Instructions relative to the risks run should be mentioned: exact knowledge of the means of protection, their use and objects; collaboration with the staff in the work of prophylaxis; placing at the disposal of the workmen all means of ensuring good personal hygiene; supervision to ensure that these are used; adequate medical supervision at the commencement of employment at periodic intervals, in the selection of workpeople, and advice as to the best way of employing them, with continuance of their training in health matters; adequate first aid provisions and instruction of the personnel in ambulance work (while awaiting the arrival of the doctor); posting up of placards and distribution of leaflets for propaganda. Health and safety precautions generally are laid down for different industries in Government Factories Act: aniline; nitro- and amido-derivatives; chromates; phosphorus; lead; carotting; arsenic; mercury; etc. At the same time there are general regulations applying to certain groups of the chemical industries. Thus, for example, in Germany, sections 16-25 of the Industrial Code deal with installation and alterations in chemical works; in Great Britain the Regulations of 11 July 1923 deal with the manufacture of chemical substances (manufacture or use of carbonates, chlorates, chromates, hydrates of potassium or sodium, iron, cobalt, nickel, arsenic, etc.; ammonia, mineral acids, organic compounds as well as their metallic or organic salts; compounds of cyanogen; electro-chemical industry; and other articles; hydrogen sulphide; chlorine for bleaching powder, distillation of tar, its use as well as the substances distilled, refining of shale oil, manufacture of nitrogen compounds, including explosives).

The Regulations lay down the requirements concerning every fixed receptacle: tank, vat, containing dangerous matter and uncovered, in such detail as to avoid every ordinary risk; locally applied, exhaust ventilation in certain processes for the removal of injurious vapours and dusts (lime, for example). The Regulations prescribe also the provision of breathing apparatus, of compressed oxygen, safety belts, and even the precautions to be taken before entering places (tanks, boilers, etc., where there might be risk of the accumulation of inflammable gases. Measures are laid down for the entire immersion with cold water of persons splashed by corrosive liquids or strong acids; installation of cloakrooms and first aid boxes; medical supervision and measures for personal cleanliness. A portion of the Regulations is limited to parts of works where use is made of caustic pots, or where chlorate or bleaching powder is made; where tar is distilled, or nitro- and amido-derivatives are made, or shale oil refined, etc.

In México (State of Jalisco), sections 205 et seq. of Decree No. 2308 (13 August 1923) deal with the measures to be taken in industries using chemical substances. In Norway the Royal Decree of 20 September 1920 deals with the hygienic conditions in the electro-chemical industry; that of 29 June 1923 regulates the factories making sulphuric and nitric acid, ammonium nitrate without making use of electricity.

In U.S.S.R. the mineral salt and acid factories are governed by the Regulations of 10 April 1922.

So far as concerns the work of women and children, reference is made to the different chemical products, the diseases to be notified and those for which compensation is to be awarded.

BIBLIOGRAPHY

Bigielli and Lorita, in La Sicurezza e l'Igiene nell' industria, 1922, No. 4, pp. 86-90. Milan.

The period from twelve to sixteen or eighteen years of age, when occupational work begins, generally includes the most active stages of bodily development as regards growth and puberty.

The question is all the more important since children and young persons — and, indeed, women as well — are chiefly occupied in industries where the hygienic or special conditions are the least favourable for work.

Whilst it is true that legislation tends more and more to limit the employment of children in industry, so that in Germany, for instance, only 10,271 children below the age of fourteen years are to-day being employed, on the other hand it is none the less true that children are too often employed on domestic work under hygienic conditions certainly less favourable than those found in large factories.

**Physiological Facts**

The phases and laws of normal growth are summarised in an important report presented by Pende to the Italian Congress on Internal Medicine in 1927. This expert agrees with Godin that from the clinical point of view the first period of growth is from one to four years; that is the period of the *turger primus* of the ancients. The second period, that of "the second childhood", is from four to six and a half years; that period includes such important changes that Pende calls it the period of "small puberty", commonly called *proceritas prima*.

The third period is from six and a half years to the commencement of puberty (fourteen and a half years for girls, fifteen and a half years for boys). Pende divides this period into two parts; during the last phase, from thirteen and a half to fifteen and a half years, which may be called more strictly prepubertal, some important evolutionary changes are taking place, to wit, changes which easily pass into the realm of illness.

The fourth period is that of puberty, properly so called, which lasts two years: in girls from fourteen and a half to sixteen and a half years and in boys from fifteen to seventeen and a half years.

The fifth period is the inter-puberty-nubility period of Godin, which extends from the termination of puberty to the period of nubility (twenty-one and a half years of age for women, and twenty-three and a half for men); it is the period of so-called youth, of sexual maturity, but it is not that of body maturity. This is why German experts fix the cessation of growth between ages of twenty-five and twenty-eight.

---

**Children and Young Persons**

**Employment of**

The movement in favour of legal protection for children and young persons is of comparatively recent date, for it is well known that in the early stages of industrialism no one troubled either about age on admission to factories or the conditions under which work was carried on.

It suffices to recall here that in the case of Great Britain these conditions were so serious, that to-day no objection is raised to the principle of stricter intervention than has been hitherto adopted by certain countries.

The movement then spread to the continent and from that time onwards experts, technicians, and employers' and workers' associations have been continuously contributing to advance this work of social improvement.

Moreover, the effect of occupational work on young persons, still in the period of physical development, is so marked, and is attended by consequences for the individual and the community which are so serious, that to-day no objection is raised to the principle of stricter intervention than has been hitherto adopted by certain countries.
Pende emphasises the existence of a sixth period of growth, which is of clinical import. Although very slow it is the last stage in increase of height of the body, a period extending from the twenty-fifth to twenty-eighth year to the thirty-fifth to fortieth year, the *constans aetas* of the ancients. This is the period of body maturity, both in shape and functions. Without entering upon the important question of the three fundamental laws of growth, it is enough to say that by their effects permanent characters either of the race or individual, just as if each function and each physiological reaction traced its individuality more or less deeply upon the skeleton (Testut).

Without going fully into details, it is enough to recall that the period of ossification is all important to the problem of growth. As early as 1909, Bosch, of Harvard University, in order to ascertain exactly the stage of development of children under fourteen years, had the idea of making radio-

---

**Fig. 30.** — Increase as shown at corresponding points of the body during the period of growth in young boys of 13-17½ years of age (according to Gouin).

Normal changes in the intensity and rapidity of growth, as well as in its rhythm, may be interpreted either as a whole or in their elements. Deviations from this intensity, from this rapidity, or from this rhythm, when they exceed the limits of normal variations, appear as diseases of growth.

Progress in the formation of the bony skeleton determines the basis upon which the shape of the human body is formed; it reflects very clearly the grams of the bones of the wrist. According to this author, no other part of the body exhibits better and more easily than the wrist the changes, which occur during the period of childhood; hence the physical and physiological fitness of a candidate for definite work can be checked.

The fitness of children is decided in practice by facts relating to size, weight, chest measurement and by manifestations of puberty.
Still, age, race, sex, mode of life, personality, and even the methods of measurement adopted, as well as those for grouping and presenting the collected facts, are all possible causes of error, of which account must be taken. The formulae proposed for establishing the state of nutrition will be described later (under Hygiene).

In the rhythm of growth the periods of second childhood, from eight to fifteen years, and of adolescence are mainly of interest.

The following pages are confined to consideration of size, weight and puberty.

Height. — The body grows in males continuously up to twenty years and beyond, but the curve presents phases sometimes of increased, and sometimes of abated, activity. The intense development which occurs from birth to the sixth and seventh years is followed by a phase of relaxation till the eleventh and twelfth years. At this age, or later, increased activity in growth occurs which continues till about the sixteenth year, after which a fresh period of quite definite abatement in the progress of growth follows.

The height in females presents a similar curve, but the complete duration of each phase is slightly less, commencing and finishing two years before that for males and only rarely lasting beyond the twentieth year.

Weight. — From birth to the end of the third year weight increases following the same curve as height, and the annual amount of increment is almost constant till seven to eight years. Then follows a phase of annual increases, slow but regular, which lasts till the age of fourteen. Starting from the fifteenth year, the increase becomes more rapid and continuous till the seventeenth year; then follows a phase characterised by definite and progressive slowing down.

In the case of women, the period of the rapid annual increase commences as early as the eleventh year, but it ceases at the fifteenth year.

If these curves are compared they are found to be parallel for the two sexes up to the third year. Starting from that age up to adolescence the curves of growth move in opposite directions, but become parallel again after that. But at the period of rapid growth the curve of height for men precedes that of weight, whilst in women the curves are superimposed, the curve of height stopping a year before that of weight. During the period of one or two years preceding the period of rapid increases in weight no trifling increases occur.

Growth from second childhood to adolescence, as far as the height is concerned, is marked by a sharp rise, but in regard to weight it is marked by an accelerated and uniform rhythm.

It may then be said that the body first lengthens and subsequently gathers weight.

By his researches, Godin has been able to present a complete picture of
the adolescent type and to supply proof of the aphorism: “growth during puberty is chiefly muscular, and before puberty chiefly osseous”.

All experts agree on the point that important increases in weight, in chest measurement, and in the biacromial diameter are spread out over a greater period than that of height, and that they are still displaying continuous activity for some years after annual rates of increase in height have attained their maximum.

The period of puberty may be placed between the twelfth and eighteenth year. Height, according to most authors, reaches its maximum of increase some months before external signs of puberty; but other experts say that these two points in the physical evolution of adolescents coincide. Weight, on the other hand, displays its important increase at the time of puberty, an increase which lasts during its whole period.

Nevertheless, the age at which puberty appears varies according to race, environment, season, social class and the individual. It is besides necessary to take into account, when defining the time of its appearance, not so much the manifestations which accompany it, as the well known physical signs of puberty. This is all the more important on account of the fact that puberty — the manifestation of the development of the body — occurs by different phases in the course of different periods: amongst women, for example, the appearance of the signs of puberty are accompanied during all this period by a regression, one might even say by an arrest of the processes of organic oxidations.

Experts have emphasised the very close association which exists between the development of the figure and the first menstruation, as well as the very high rates of increase during the two years preceding the first menstruation.

The same phenomena may be stated to occur in men who, however, in temperate climates, show signs of puberty two years later than girls, that is between fifteen and sixteen years.

The fact must be emphasised that the appearance of these signs does not signify the completion of puberty, but only that it has reached its maximum.

Adolescence commences one and a half to two years before puberty and finishes one and a half to two years after. According to Godin, young persons of seventeen and a half to eighteen years are still adolescents.

According to this author, if the two sexes are compared, girls are found to come level with boys as regards weight at about the tenth year, and as regards height at the twelfth year. After this period girls pass the boys in both height and weight up to the fourteenth to fifteenth year; but thereafter it is the boys who lead, first in height and then in weight.

Choosing from among the numerous investigations made into the development of children reference is restricted to the following (see also later under Work and Growth and Pathology of Growth).

A comparative study by T. Yagi, of the Japanese Institute for the Study of Labour, directed by G. Teruoka, has emphasised that up to the age of twelve years the height and weight of girls employed in factories and of pupils in school are almost the same, but from that age the physical development is impeded in the case of the former, so that the difference between these two groups becomes greater each year.

In the same Institute, H. Kirihara has studied mental development in the young girl at school and at work. Starting from the twelfth year, he found that development was very good in both groups, but that it lastest in the case of the pupils till the sixteenth year, whilst in the case of the working girl development declined each year after the thirteenth year. Kirihara considers that girls enter factories at too young an age, and that monotonous work carried on under bad hygienic conditions further aggravates the position (see article “Women’s Work”).

In 1922, Tagliaferro, Clark, Sydentricker and Collins examined the height and weight of 14,335 white scholars, aged from six to sixteen years, in the States of Maryland, Virginia, and Carolina. Their investigations revealed the average heights of girls aged from eleven to fourteen years and of those aged from twelve to fourteen years as being higher than those of boys of the same age.

The index W/H, i.e. weight divided by height in inches, for the girls exceeds that for the boys, both at the age of twelve to fourteen years, and at the age of fifteen years, whilst at other ages it is higher for boys than for girls.

The annual increase of weight for girls from eight to thirteen years exceeds that of boys; for the other ages, it is greater for boys. However, if the annual increase in weight per inch of height is taken into consideration, one finds that, after the sixth year, it is at any age greater for girls
Principal Medical Officer of New South Wales gives the results of examining more than 200,000 children of school age. It supplies sufficient data either for determining standards of weight and height or for the more general study of growth.

Among problems which arise from the subject of growth, one of the most important and most delicate is that of poor nutrition, which is manifested in the

age. But, omitting the effect of variation in height, after the eighth year, girls vary in height more than boys of the same age.

In other words, girls after their eighth year vary more in weight than boys of the same age and of the same height.

A report for the year 1918-1919 by the most varied terms, and generally gets classed among constitutional types, rather than among diseases.

In this way, an index of nutrition has been established, based upon the relation between weight and height, and observed physical deficiency is expressed as a percentage and not in bald figures. The figures indicate a
superiority in the case of boys up to eleven and a half years, then in the
case of girls up to fifteen and a half years, followed again by a superiority
for boys. Whereas girls cease to grow towards their eighteenth year, boys con-
tinue to grow for some years later. This finding is, however, less useful than
that of growth calculated in percentage, that is to say, the relation that is
obtained by dividing the increase of growth for a definite period (twelve or
six months) by the height or the weight taken at the commencement of the
period under consideration.

The facts relating to children and adolescents at work will be dealt with
later on.

SOCIAL DATA

Advantage may be gained by mentioning here some facts relating to the
descendants of working-class families. Whilst taking into account the dif-
"iculties which occur in bringing together and comparing the facts in ques-
tion, as well as the lack of accuracy and errors which may weaken these
statistics, it is none the less true that they offer interesting results. By the
aid of data found in medical literature and of those collected by the consulta-
tion department of the Labour Clinic at Milan, Carozzi in 1913 published
statistics dealing with 16,918 working-class families:

The high death-rate among the child-
ren of working-class families can be explained by several causes, among
which social conditions come first.

It is not possible to determine the part which is due to ancestral factors
and the part due to environmental factors. These latter react on the con-
stitution of the parents, and, during pregnancy, by the intermediary of the
mother, on the foetus; thus they are confused with pure by ancestral factors.

Studies in pre-natal infant welfare bear witness to the effects which the
social conditions of the pregnant women exert on the foetus.

Without going into fuller details regarding the effects of environment,
either natural or social, it is enough to note the importance of climate on the
viability of the newly-born, whether legitimate or not, and the age of the
child at which social factors act the most powerfully, i.e. during the first
months of life. The mortality of the newly-born of the working class is
highest in the first weeks, while in the leisureed class it is quite low. Weakly
children die when they pass from the intra-uterine temperature to the ex-
ternal temperature, according to Schloss-
smann and Zanchi. Funck, Eller and Zanchi have proved that this influence
also lasts throughout the first year, becoming much less in the following
years; but Bertillon, Verrijn and Stuart consider that this effect continues to be
felt during childhood and adolescence. It is well known that mortality from
infectious diseases, in particular from tuberculosis, is more frequent among
the children of the poor than among the children of the rich. If the social con-
dition of the parents is low, then the mortality of the infants is high. Illeg-
imate children, being the poorest among the poor, while the sufferings of the
mother during pregnancy and confinement also exert a detrimental
influence, naturally show the highest rates. After birth, these conditions continue to act. In addition, the following factors come into play: lactation, whether at the breast or artificial; early weaning; bad and wrong feeding, and housing. It is important here to refer to the enquiries of Villermé, Bertillon and Eichelberg, who found at Gladbach that the mortality among the nurslings of working class families varied according to whether the conditions of housing were up-to-date and hygienic, or old and insanitary, poorly lighted and badly ventilated. Similar results were collected by Villermé in 1839 for the town of Mulhouse. There must further be taken into account such factors as: hours of work; and wages, that is to say, economic conditions; the sanitary conditions of the town; the price of milk; the existence in the town of schemes for infant welfare. Obviously, the effects of all these conditions are ameliorated if the infant is fed at the breast instead of artificially.

Another feature of the problem which should be referred to is that of fertility. The fact is that lowest birth-rates are found in towns where malthusian practices are more generally adopted than in the country, and where marriages are less frequent, and, above all, do not take place so early. The frequency of marriages among working women was in Italy actually half that for the whole female population, and the frequency of confinements about a third. Jones, in Great Britain, years ago found that the average of births in seven towns, where there were hardly any women employed in factories, was 35.48 per 1,000, as against 28.15 in seven centres of the textile industry.

Moreover, the low birth-rate in industrial centres is generally accompanied by a high infant mortality; but this tendency, however, may be counteracted by the happy results of measures of assistance and propaganda for infant welfare adopted in the centres in question. In this way, in the Italian town of Sanpierdarena, with 65,000 inhabitants, child mortality up to twelve years of age has come down from 48 per cent. of the total death rate in 1901 to 22 per cent. in 1920, and for children below one year from 16.1 to 8.5 per cent. of births.

It is true that several enquiries, an English one of 1910 and an American one of 1922, raise some doubts as to, or even deny, the injurious effect of the industrial occupation of the mother on the children, and put in the first place the influence of other factors, such as the ignorance of mothers as regards infant feeding and deficiency in hygienic care. Robertson (1910) is of the opinion that the factor “social status”, i.e. the amount of poverty, is of more importance than the factor “work”. But the industrial working mother has recourse to paid wet nurses more often than the poor woman, and that is why the infantile mortality during the first year is considerably higher than that of infants of poor mothers (Finizio); the earnings of the industrial working woman are not generally sufficient to neutralise the harmful effects that arise from neglecting the welfare of infants — hence indeed, arises the importance of industrial crèches. Proof to the contrary is supplied by the infants of agricultural working women; they are breast fed and well cared for, and show much lower death rates.

**WORK AND GROWTH**

The normal progress of growth presents a true picture of the general state of the body. It is influenced by numerous factors: climate; season; mode of living; feeding; illnesses; sanitary conditions; work, either heavy or un healthy, or precocious, domestic or in the field; or economic conditions. It is merely intended to deal here with the factors, sanitary and economic conditions, and work.

The influence of hygienic and economic conditions on height and weight is proved by numerous researches, according to which the average height, and the weight of children of well-to-do parents at any given age are higher than those of poor children.

But, as regards height, the rhythm of growth is only influenced after the twelfth year, from which point the difference between the rich and the poor tends to increase.

The average weight of the children of the rich is always, at every age, greater than that of the children of the poor.

In conclusion, the poor grow more slowly and with more difficulty. Bad sanitation and low economic conditions place them definitely and permanently in an inferior position to that of the rich.

School medical officers are generally agreed that children from fourteen to fifteen years of age leave school for the factory too soon, and this is especially the case in industrial centres, where children are physically so below the average that they ought to attend for one or two years more before beginning any kind of work.
children and young persons

According to these experts only 42 per cent. of the schoolchildren examined in twenty German towns had a good physical constitution, 50 per cent. had an average constitution and 8 per cent. a bad one. Investigations made at Munich before the war showed that about half the schoolchildren had a good constitution.

Another enquiry, made at New York in 1924, dealing with 412 children, showed that: 18 had no physical defects; 99 had simple defects due to hygienic conditions; 179 had medium defects requiring slight medical attention and hygienic supervision; 93 showed serious defects causing a partial or temporary incapacity, capable of being overcome by adequate treatment; 16 showed bodily affections, or physical deformities which were capable of benefiting by treatment without medical supervision; 7 showed organic lesions requiring immediate medical intervention and probable cessation from work.

It is a common and just reproach that hygienic control of children and adolescents is not organised in every civilised country: far too much heavy work, for instance in ironworks, at transport, in the butchery trade, or at baking, is given to adolescents without their having been gradually accustomed to the work, and without their being placed under periodical medical supervision.

It is clear that puberty, which is a period of unstable and labile equilibrium in juvenile life, is affected by the harmful influence of any factor resulting from work: by sitting or standing; by close air or too much draught; by dust, steam, fatigue, strain, prolonged working hours, or night work. In such ways the body can at this time be shaped and moulded as wax by factors which act on it.

Several experts have studied the effect of physical work on growth and have compared the records obtained in the case of children at work with those obtained from children of the same age at school (Roberts, Cowel, Giordano, Bowditch, etc.).

The conclusion may be drawn that as regards height, weight, and chest measurement, increase of growth is less in girls in heavy work than in schoolchildren, and that, in consequence, the index obtained was an index of inferiority. The differences found between well-off and poor children, and between children at work and at school, are greater and more defined as the age rises and a period of adult life should characterise a race.

At the commencement of work, at twelve to thirteen years of age, height, according to Allaria, is said to be less for working girls than for young girls of rich parents; then it increases slowly, during puberty and stops much sooner than with the rich. The result is that in adult years the height of working women is less than the average height which under favourable conditions of life should characterise a race.

The weight of women workers is, at the beginning, lower than the average weight of rich young girls, and this constant difference is maintained subsequently. In working women the increase of weight during puberty is so retarded and difficult that the ultimate weight is very deficient compared with the requirements of ordinary physical development.

In the same way the average pulmonary capacity is always lower at the
same age in working women than in young girls of rich parents. At nineteen years the average value for the latter was 24 litres, for weavers it was 2 litre, and 1.6 litres for dressmakers in the case of whom occupational posture constitutes an obstacle to the normal development of the thorax.

At equal ages the muscular force of the working women was lower than that of girls in well-to-do families; in the case of the weavers it was deficient, even though they were of peasant origin, while the deficiency was greater in the case of the dressmakers. Premature and complete arrest in the growth of the body and in the development of the lung capacity has been found in working women at the age of seventeen years.

This deficient physique which is due to conditions before the young girls enter on factory life is aggravated during adolescence and during the working period, especially if they have a struggle to make a living.

The results of examinations made by English doctors of young persons of fourteen to sixteen years who applied for a certificate of fitness for work provide interesting points on the causes of final or conditional rejection. The number of young persons examined was 350,862 in 1923, 364,297 in 1924, 390,814 in 1923, and 267,964 in 1922. The percentage of young persons rejected for reasons of a medical kind (see below) was respectively 1.84, 1.78, 1.96, and 1.98. The percentage of rejections and of conditional certificates for the same reasons was 4.49, 4.14, 4.57, and 4.47.

The causes of rejection or for issuing conditional certificates for medical reasons may be classified as follows (the figures represent the total for the years 1922 to 1925 inclusive):

<table>

An English enquiry dealing with differences in height and weight of workmen of rural or town origin gave the results shown in the table at the top of page 414.

In accordance with the Royal Belgian Decree of 1 June 1920, which instituted a hygienic survey of adolescents at work, doctors selected and paid by the employers as well as factory medical officers, have carried out the following number of examinations during the years 1924-1925:

The number of firms that organised health surveys was 1,960 in 1924 and 2,020 in 1925. The number who did not was 666 and 257.

The factory medical officers examined 14,040 adolescents in 1924, of whom 8,822 were men. The certifying surgeons examined respectively 37,967 adolescents in 1924, of whom 22,604 were men, and 48,045 in 1925, of whom 27,423 were men, and 48,045 in 1925, of whom 27,423 were men and 48,045 in 1925, or a total of 51,907 examinations in 1924 and of 63,420 in 1925.

An additional half-yearly examination was considered necessary for 4,680 persons in 1924, and for 5,027 in 1925; one every three months for 1,564 persons in 1924 and for 1,907 in 1925; and every month for 211 persons in 1924 and 287 in 1925.

The percentage of adolescents found in good health in 1924 was 93.69, compared with 98.61 in 1925; the percentage for men was 93.15 compared with 89.12 in 1925; and for young girls it was 94.36 compared with 87.93 in 1925.

1 Recruits for the Army: Report upon Physical Examination of Men of Military Age, published by the National Service Medical Boards (Cmd. 504).

Note the slight superiority of height of the recruits from Chester and Lancaster compared with those from the most important and most particularly industrial towns. The figures given above refer to men of the first grade; the statistics relating to 1,000 other men of the second grade show a much worse physical condition. (Journ. of med. Hyg., Jan. 1921, p. 326.)

The anomalies noticed by the factory medical officers during these examinations may be summarised as follows: vertebral column, 39 (37 in 1925); pelvis, 2 (2); limbs, labour; skin, scalp, 40 (20); heart and vessels, 26 (37); respiratory passages, 142 (145); of which, tuberculosis, 45 (171), and bronchitis, 10 (3); alimentary canal, 14 (30); mouth, 797 (976), of which, dental caries, 622 (737); enlarged glands, 175 (17); nose, 54 (24), of which adenoid vegetations, 41 (26); hernias and diseases of the sexual organs, 127 (143); nervous system, 6 (10); ear, 33 (118); eyes, 353 (478); various, 24 (15), 3 of which were lead poisoning.

In Sweden the Act of 1912 on the protection of labour requires an annual medical examination in which height and chest measurement are taken for every boy and girl admitted to work until the age of eighteen years. By making use of the particulars supplied by each person's docket, the statistical department of the Administration for labour and social supervision has studied the development of 35,445 boys and 8,436 girls (out of 65,000 docket) who, in each occupational category, had worked at least for three years in the occupation concerned without having passed into any other occupation and had three medical examinations.

These 43,881 young persons are classified by age thus:

<table>

The boys were chiefly occupied in engineering works, saw mills, paper mills, textiles, boot factories and glassworks. The girls worked in the food industries, textiles, boot trade and lithographic printing.

The average weight, height and chest measurement are shown by age as follows:

**BOYS**

<table>
<thead>
<tr>
<th>Age</th>

</table>

These results lead to the same conclusions as for the boys. It is again found that for girls the period of active growth, properly so called, as well as the maximum increase in weight and in chest measurement, generally takes place at an earlier period than for boys. This peculiarity is due to the fact that the period of puberty, as we have seen, terminates generally in girls between the fourteenth and fifteenth year, from which results that, by maturing thus early, girls of fourteen are more developed, from the triple viewpoint of weight, height and chest measurement, than are boys of the same age. But during further development boys exceed girls first in height and, later, in chest measurement and weight.

The Swedish investigation has shown that children of less than thirteen years, as regards height, weight and chest measurement, form a group the data for which are somewhat asymmetrical, in the sense that individuals whose height is less than that of the normal type are relatively less well represented than individuals who are taller. Close analysis of the statistics leads to the conclusion that selection of individuals of less vigorous physique has attached to the figures for weight a greater importance than to those for height or chest measurement.

In addition the enquiry has confirmed that differences in physical development between thirteen and seventeen years correspond in a certain degree to initial differences of development existing at the age of thirteen years. According to a table based upon data derived from the special examination carried out, with a view to selecting individuals who have been under continuous observation between the thirteenth and seventeenth year, increases of weight and height among children belonging to the extreme categories when under thirteen years, develop less during the period in question than in individuals who had belonged to the middle category. This difference is less accentuated as regards the chest measurement.

A similar investigation carried out in the case of girls proved that development in weight, height and chest measurement, between ages fourteen and seventeen, is on the average more pronounced for the smallest of the girls at age fourteen than for those who were more advanced at the start. This slowing down of growth does not seem to have an equivalent in the case of boys, who are less developed at the start. This fact would seem to prove that the period under discussion is for girls less critical than for boys, for whom it coincides with puberty.

Several enquiries deal with children employed in the most varied occupations, which, it must be confessed, do not show the same standards of hygiene and healthiness. Reference may be made to the enquiries of Dementiev made in the Russian textile industry; of Erisman, also from Russia; of Frongia, in the Sardinian mines; of Allaria, made among spinners and dressmakers in Turin; of Giordano, among miners of Sicily; and of Roberts, of Great Britain, who has emphasised the beneficial effect of legal protection on the growth of English children. As a matter of fact, children who in 1833 from the age of eleven years passed half the day at school and the other half at the factory showed an average height of 136.4 cm. In 1900 the half-time system was prohibited for those younger than twelve years; and seven years later the average height of children of this age was 139 cm. The average weight also rose from 31.4 kg. to 34 kg.

The facts collected in 1926 by Kose and Itani on 1,683 children of Nagoya, Japan, employed on half-time in the textile or pottery industries, or on toys or machinery, have established that the age of admission to work has been for some seven years; for others, from eight to nine years; and for most ten
years. Admission to work at too early an age is found most often in the case of girls. The figures for height, weight, and chest measurement, compared with those for 45,000 scholars, show that, with the exception of children aged seven years, they are always lower for children employed on work.

Reference should be made to the article "Women's Work" for the effect of work on the pregnant woman, on the foetus and on the mother. It need only be remarked here that children born of tired women are particularly liable to be seriously affected as regards their development and their viability — a condition especially pronounced in the case of children of women employed on heavy or unhealthy work, or where poisons are handled which act on the sexual and maternal function.

There follows here a somewhat rapid sketch of examinations made of children and adolescents employed in industry. It completes what has been said above and helps to emphasise the injurious influence exerted on the normal progress of puberty or the aggravating influence exerted on pre-existing physical weaknesses.

Erisman found in some occupations that the development of chest expansion and weight is retarded, although height increases at its normal rate.

Hahn has found that, in the case of bakers' and gardeners' apprentices of Munich, the average values for height and weight, as well as the ratio H/W, are lower than in the case of students.

The bakers' apprentices showed defects of the skeleton, with pulmonary and cardiac lesions of a more serious degree than did the gardeners' apprentices.

Schlesinger has also pointed out decided differences between anthropometric data for boys at work and boys at school of the same age in Strasburg.

As a result of an enquiry made among apprentices at Munich, Kaup found among blacksmiths, butchers, locksmiths, tailors and bakers a large number of diseases and constitutional anomalies attributable to work. Kaup classifies the adolescents examined into three groups.

First, persons with deficient physical development and deficient chest measurement as the result of unfavourable external conditions. This poor nutrition is a cause of inferiority, which extends throughout the period of occupational work; it is due to work under unfavourable conditions, and to lack of functional stimulation. Type: tailors, clerks and shop assistants.

Second, persons with physical development above the average, but of less breadth, for lack of sufficient stimulus to development of breadth and of adequate nutrition. Type: clerks and students.

Third, persons with almost normal development, with development in correspondence, as regards height and chest expansion, as a result of normal conditions of nutrition and activity at the student period and of sufficient stimulus for the development of height and chest expansion in the occupational period, during puberty. Type: blacksmiths and butchers.

Height and chest measurement are in close relation to the development of other systems and organs. The curves of development for the heart and for weight are parallel. The expansion of the thorax influences to a certain extent the position of the abdominal organs. It is also considered that bad conditions of nutrition and various influences due to work (toxic substances in particular) may intervene, setting up reactions which interfere with various hormones.

In 1909-1910 Winter, on examining 3,436 apprentices of Vienna, found that 10 per cent. required medical supervision and that in 40 per cent. the general state of health was mediocre or bad. Among other things, he found in 20 per cent. anaemia, in 20 per cent. defects of sight, in 2.5 per cent. deafness, and in 20 per cent. dental trouble; 605 apprentices suffered from impairment, that was either congenital or acquired, of the various organs.

Berger found constitutional defects in a seventh of the students at training schools at Crefeld. Kaup found that of the apprentices of Munich, on an average 11.6 per cent. had infiltration at the apex of the lungs; 8.6 had cardiac defects; 36.48 had struma; 13.7, nervous disorders; 31.5, defects of vision; 21.4, rickets; 12.3, scoliosis; and 26.75, flat feet.

In Sweden, the medical examination of 45,000 adolescents, of whom 12,000 were girls of from thirteen to seventeen years of age, has established the facts that, in 1920, 15 per cent. had organic defects, of which 2.4 were of the skeleton, 1.6 of the heart, 0.4 had tuberculosis, and in 1.2 the lymphatic system was affected. Of these adolescents, 1.5 per cent. had been discharged from work and 23.6 had been admitted conditionally or had been employed in other occupations.

An Austrian enquiry in 1910 showed that, in the case of 22.6 per cent. of the schoolchildren examined, the state of health was not good, and that, whilst this state was found in only 17.3 per
Among these latter, the state of health was not good in the case of 50 per cent. of glassmakers; in 46.5 per cent. of boys employed in the manufacture of metal capsules; in 33.7 per cent. of textile operatives; in 45.8 per cent. of fringe makers; in 42.7 per cent. of makers of hair nets; in 38 per cent. of dressmakers; and in 57 per cent. of workers in glass beads.

Apprentices to the metal industry were examined by Epstein, who has placed on record the obstacles put by work in the way of normal development, especially as regards the chest and lungs.

Heart disease, which at Munich affected an average 8.6 per cent., was found to affect 11.3 of clerks, 11.6 of tailors and 15.1 of bakers. The degree of anaemia among young persons in the two last of these categories was in direct proportion to the duration of the period of work. As a matter of fact, Epstein found that the incidence rate was 1.6 per cent. for bakers and 8 per cent. for tailors on beginning work; but it reached 13.6 and 9 per cent. at the end of the first year, and 23 and 16 per cent. at the end of the second.

While scoliosis shows an incidence of 11.6 per cent. as an average for all occupations and only 6 per cent. for blacksmiths, it reaches 17.22 per cent. for tailors, varying from 10 per cent. in the first year to 20 per cent. in the third. Flat foot was found in that adolescents do not as a rule enter this occupation till sixteen years of age.

Mention may be made of deformities of the fingers as the result of accidents, of hernias and varicose veins. As regards hernias, Opitz noticed in apprentices an incidence of 5.8 per cent. against a general average of 1.4 per cent.; 15.5 per cent. among metal workers; 10.5 among wheelwrights; 8 to 10 per cent. among foundrymen, boilermakers and bakers; 0.8 to 2.2 per cent. among students, clerks, hairdressers and shoemakers.

Deformities of the skeleton show a rate of 22 per cent. for turners, mechanics, opticians, watch-makers and shoemakers. *Genu valgum* or *genu varum* has been found on an average in 7 per cent.; but it varies from 14.1 in bakers and 12 per cent. in turners, wheelwrights, blacksmiths, to only 4 per cent. among students and clerks.

It is the same in the case of dental lesions, due to sugar and flour. Whereas a bad set of teeth is generally found in 21 per cent. of persons examined, among pastrycooks the percentage is 51 per cent. (Rose).

Attention must be drawn to the fact that work exercises its injurious influence on the body of adolescents in a comparatively short space of time.

This fact has been proved by the investigation of Zinsli, carried out on the textile workers of Appenzell. Menishausen, on behalf of the State of Baden, and Winter, on behalf of Austria, have found that the height of men increases with the importance of their native village. Tallness may be accompanied by a degree of weakness which is due to the fact that most of these persons work in the sitting position in confined places and in a wrong posture. This condition is not reported from rural districts. During periodical medical examinations, it is certainly difficult to separate the influence of the factor "work" from that of other factors, such as family or social environment. However, an enquiry in 1921 by Mitchell, of Newark, dealing with 1,200 students at secondary schools for apprentices, showed that 6.5 per cent. of boys and 9.2 per cent. of young girls had received medical attention on account of poor nutrition. As regards weight, 22 per cent. of the young girls were considerably under weight from that cause.

Out of those classified as suffering from deficient nutrition 35 per cent. had orthopaedic defects as well, which were found in only 17 per cent. of well-nourished young girls. According to this author, these defects were due to work
CHILDREN AND YOUNG PERSONS — 448 —
carried on in a wrong attitude, predisposing to tuberculosis. This expert has no doubt of the existence of a connection between the industrial work of adolescents and tuberculosis. As a matter of fact, 12.5 per cent. of the boys had early forms of tuberculosis of the lungs, and 13.5 per cent. were under suspicion; 16 per cent. of the young girls had early pulmonary signs, and 16 per cent. of the young girls had early forms of tuberculosis of the lungs. Of the young girls, 12.8 per cent. of the boys had lesions and 13.5 per cent. were under suspicion; 16 per cent. of the young girls had early forms of tuberculosis of the lungs. The expert found these defects grew worse under the influence of work in 68.6 per cent. of the boys and 57 per cent. of the young girls. In the same way as regards teeth, which were examined six months after commencing work, the condition was bad in 58.9 per cent. of boys and 57.5 per cent. of young girls.

Another interesting enquiry into the health of 2,076 children at work is that made by Jago Galdston in 1925 at New York. These children were aged from fourteen to seventeen years and able to attend a secondary school on one morning or one afternoon each week. The statistics deal with 2,000 children, of whom 433 had been subjected to a second examination. Of these 2,000 children, 264 were aged fifteen years. 978 were sixteen years, and 758 were seventeen years. According to weight, height, appearance of the mucous membranes and the muscular tone, more than a third were regarded as being in a state of under-nutrition; 6 to 18 per cent. and even more, of the children showed a weight lower than the average; only 54 per cent. showed a weight above it. Defects of sight were present in 540 children; 60 had other eye diseases; 87 had diseases of the ear, including 4 cases of diminished hearing; about one-half, some 45 per cent., were affected with dental caries; 154 had cardiac lesions; more than half had large tonsils which required surgical treatment; 187 had polypi of the nose, or upper respiratory passages; numerous cases of dermatitis and of orthopaedic defects, were noticed. The examination of the respiratory apparatus showed 6 cases of active tuberculosis, 31 of suspected tuberculosis, and 10 of the chronic kind.

Of these 2,000 children, only 225 could be considered as in a good state of health; 620 had at least one defect; 645 had two; 374 three; 135 from four to six; one child showed ten.

Galdston concludes that in present-day conditions of work few children escape tuberculosis infection and that the number of children over fourteen years who are not infected is very small. It must, however, be borne in mind the natural powers of resistance and immunity which develops in persons exposed to the danger.

PATHOLOGY OF GROWTH

A number of facts show the unfavourable action of occupational work on the development of puberty. Of the morbid conditions are even known under the name of "diseases of adolescents".

Among diseases of growth — dysgenesis — the best known to-day are the following: heart disease of the young or "juvenile heart", which might also be called "irritable heart of adolescents"; syndromes of growth of the locomotor apparatus — the fibro-, osteo-, and chondropathies of growth — which include the important adolescent curvatures of the spine, and the algias — tarsalgia and metatarsalgia; and the deformity of Madelung; the functional albuminuria which occurs at puberty or in the condition of lordosis (ren juvenum); the neuropathies and psychopathies of growth, which are syndromes of disturbed equilibrium of the sympathetic nervous system; pathological conditions of the skeletal apparatus — such as chlorosis and chloro-anaemia; infantilism and bodily and sexual wrong developments; and pathological precocities. (For fuller details see the report of Pende.)

These conditions will now be reviewed in brief.

The skeleton. — Curvatures of the vertebral column, such as scoliosis and kyphosis, the foundations of which may have been laid in school days, are certainly aggravated by conditions of work. Schlesinger has reported them in 12 to 17 per cent. of adolescents aged fourteen years and in 14 to 24 per cent. between ages seventeen and twenty-four. According to Scheuermann, these curvatures are found among workers employed in heavy and agricultural work. Blanchard claims to have found rates as high as 66 per cent. among young persons working at home in the American clothing industry.

In the spring of 1925, Jankowsky and Wigilew examined 779 adolescents in the Podolsk district: 483 from the engineering industry (383 young men and 100 girls) and 274 textile workers (139 men and 135 women).

The proportion of anaemia, 18 per cent., and of tuberculosis, 27.5 per cent., was fairly high. Workers in the engineering industry showed higher
rates compared with the textile workers on account of heart affections, diseases of the ears, nose and throat, digestive disorders, and eye diseases with 8.6 per cent. against 2.5 for textile workers. The general state of health was poor and the development irregular (6.4 per cent. against 2.5 for textile workers). A little more than a third of all workers examined were in good health.

Medical examination of a group of 412 Russian children showed that 28 per cent. of the defects found had been aggravated by work and that this aggravation affected 40 per cent. of the children observed. The defects found were classified as follows:

<table>

It may be noticed that boys are more affected by prolonged standing than girls; but that the latter are more affected by prolonged sitting and by wrongly constructed seats.

Some illustrations of normal posture and of wrong postures, exaggerated by occupational work, will explain better than a long description the problem under consideration.

Among the deformities of the skeleton should be mentioned chiefly genu valgum, characterised by deviation of the legs outwards with projection of the knees inwards. It commences between thirteen and eighteen years of age and occurs chiefly in predisposed persons employed in occupations requiring prolonged standing. Genu varum is characterised by deviation of the limbs inwards with projection of the knees outwards; it is much rarer than the preceding and may be due to the same causes.

Tarsalgia, or painful flat feet, occur frequently in young persons and readily affect young persons of thirteen to eighteen years who are growing rapidly and are employed too early on an occupation requiring prolonged standing.

Carrying heavy loads undoubtedly tends to develop this lesion. It is characterised by weakening of the plantar arch, by turning outward of the sole of the foot, and by pain which precedes or accompanies the deformity.

An enquiry made in New York relative to 412 children (206 girls and 206 boys) under sixteen years of age and employed in any occupation for not less than six months has shown distinctly that a quarter of the children were only provided with seats which compelled them to assume such defective postures as would certainly result in deviations of the vertebral column.
GOOD ATTITUDE (A, B) AND BENT ATTITUDE (C, D)

Note in A and B the correct line of the back and the abdomen, and the position of the shoulders. A line drawn vertically passing by the ears falls towards the middle of the foot.

Note in C the pronounced kyphotic curve and the centre of gravity falling on the heels.

Note in D the pronounced kyphotic curve, the abdominal relaxation and the bent position of the head.

DEFECTIVE POSITION ACCENTUATED BY A STANDING POSITION OR EXCESSIVE WALKING

Relaxed abdomen and kyphosis. Office boy aged fifteen years ten months. Worked for four and a half months; 60 per cent. of day standing; and 40 per cent. walking.

Bent attitude; relaxed abdomen. Errand boy aged fifteen years nine months. Worked for six and a half months. Often carries heavy weights. 30 per cent. of day standing and 70 per cent. walking.

Kyphosis and relaxed abdomen. Saleswoman aged fifteen years nine months. Worked for six and a half months. Standing or walking 90 per cent. of the day.

Bad attitude generally. Thin girl and too tall aged fourteen years ten months. Worked six and three-quarter months. Messenger; walks 90 per cent. of the day.
The girls were more seriously affected by this defect than the boys.

Another enquiry carried out among 100 adolescent Russian dressmakers’ apprentices, aged from fifteen to eighteen years, led to Kaznelson finding deformities of the skeleton in 91 adolescents. Deformities of the thorax were present in 23 per cent., 34 per cent. of 54 per cent. who had deformities of the vertebral column were affected with scoliosis (32 per cent. to the left and 2 per cent. to the right); 12 per cent. with kypho-scoliosis; 7 per cent. with kyphosis, and 1 per cent. with lordosis.

When these results were compared with those of 9,000 schoolchildren examined by the surgical staff of the same clinic, it was found that the school-children were affected with scoliosis in a proportion of 19 per cent. and of deformities of the thorax in a proportion of 14 per cent. While in apprentices dressmakers the scoliosis is mostly with convexity to the left, in school children it is generally to the right, which is explained by the position of the body in dressmaking and at school.

If the time spent at work be taken into consideration, it will be found that scoliosis affects 28 per cent. of dressmakers who have worked two years, 40 per cent. of those who have worked two to three years, and 73 per cent. of those employed more than three years.

Variations in the shape of the thorax, difficult or stunted development, affectations which arise from these in the aeration of the lungs, and bad air in workplaces, all are factors which combined with external factors, favour the development of tuberculosis in these youthful bodies.

The muscular system does not escape the injurious action of the factors just mentioned. Work requiring excessive muscular force, or the use of certain groups of muscles or of certain muscles, whilst others remain inactive, may, in the long run, cause a great many disorders of nutrition in the muscular tissue, and more or less serious lesions in development, such as atrophy, hypertrophy and hernias of muscles, which are dealt with in the article “Occupational Diseases: Locomotor System.”

The whole circulatory system is also liable to be affected by the factors enumerated, which favour disturbance in the balance of the nervous system of young neuropathic workers. Such young persons suffer from general weakness from enlargement of the cardiac area, and from disorders which are associated with disorders of the circulation. An observer may notice the facial pallor of these youths; it is due to constitutional weakness of the circulation, described by Benjamin. In some cases at least an early arteriosclerosis either general or localised to the upper limbs is present due to heavy work, to strain and to poisons, whether occupational or not, such as lead, nicotine and alcohol.

Dealing with the senses, sight is certainly the one that is most affected. Work of all kinds which by its preciseness or the small size of the object handled necessitates visual effort, and also bad or insufficient lighting, provoke in children not only disorders of vision or aggravate a pre-existing myopia, but, in addition, give rise to general disorders, such as headaches and neuroses.

All the conditions which have just been dealt with cause serious injury to the physical constitution of the child, to his character, as well as to the normal development of his intelligence.

Adolescents who after a period of occupational work return to school are generally much less quick to learn than those who have not left their studies — those whose intellectual development has not been interrupted by too early employment.

An American enquiry carried out among children employed in growing sugar beet in Michigan and Colorado showed that 20 to 30 per cent. of them were backward at school, compared with those who did no work.

Another enquiry made in three States of U. S. A. showed that about 71 per cent. of children from eight to sixteen years of age working on farms were a year behind at school. A third enquiry made in rural districts on 11,000 children proved that 38 to 69 per cent. of white children and 71 to 89 per cent. of negro children working from one to six years behind at school.

From the moral point of view, observations made in seven large American towns on 9,278 delinquent boys showed that 56.5 per cent. were out at work. Out of 561 delinquent girls, 62.2 per cent. were also at work. These percentages, compared with those of children of the general population, tend to show that offences are more numerous among children put to work too young than among others.

The proportion of delinquents was especially marked among little newspaper boys, also among errand boys, and, as regards girls, among domestic servants.

Among young girls occupational work causes well-known disorders: pallor, anaemia, chlorosis, constipation, and, especially, disorders of sexual development, such as dysmenorrhea, meno-
and metro-rrhagia, abdominal pains, and hysterical nervous disorders.

The statistics of the Sickness Insurance Offices show the incidence of sickness among young persons. This incidence is fairly high; it does not appear immediately on the adolescent commencing work, but some years later, when the injurious causes have had time to act. This condition is seen for instance among tailors, shoemakers, boiler-makers, blacksmiths, printers, bakers, and painters. A fact admitted by most experts must not be forgotten, namely, that children and adolescents of feeble constitution enter by choice certain kinds of occupation, where they are more liable to become the victims of diseases, especially of tuberculosis, and to have their condition aggravated by such accompanying social factors as bad housing and insufficient nourishment, leading up to muscular weakness, and to have their condition aggravated by such accompanying social factors as bad housing and insufficient nourishment, leading up to muscular weakness, anaemia, and lowered resistance to infectious diseases.

The Sickness Insurance Office of Leipzig gives as the incidence of sickness, including accidents, for insured persons of fifteen to nineteen years of age, a rate of 37.3 for boys. The following age group, that is from fifteen to twenty years, but only 53.7 and 51.7 for the two following groups. This incidence of sickness is greater among young girls. As a matter of fact the Leipzig statistics give rates of 32.3 (without including accidents) for the age group fifteen to nineteen years against one of 25.7 for boys and a duration for each case of sickness of 21.7 days, against 17 for men.

In the industries which require a similar amount of exertion, when they are taken into account, it will be found that the sickness rate is almost always more unfavourable for young girls than for boys (Koelsch). In munition works young girls of sixteen to twenty years showed a sickness rate 30 to 40 per cent, higher than youths of the same age. Girls under nineteen years of age were affected with malaise, fatigue and weakness, two and a half times more frequently than men. Thus, for example, per 100 members of the Sickness Insurance Office aged from fifteen to nineteen, anaemia figured in the case of men with a percentage of 0.6 and in the case of women with a percentage of 7.9, or fifteen times more.

**Hygiene**

Physiology, on the one hand, and pathology connected with work, on the other, prove to us that children must not be admitted to work too young. At the age of twelve for example, nor at ages thirteen to fourteen, years be employed on heavy work at engineering or mining, if maturity is to be attained with good health and a vigorous body.

The protection of the child and adolescent is concerned with a number of questions of the first magnitude: a minimum age for employment; medical examination of physical fitness for employment; periodical examinations; hours of work; rest intervals; weekly rest; night work; and feeding.

For some years past there has been a definite tendency, especially in some countries, e.g. the United States, to raise the age of admission to work and to fix it at sixteen years. But having found that even at this age quite a large number of young persons entered the factories without having reached their full development, several American States have laid down laws for the protection of childhood which may usefully be mentioned.

Some States give to controllers or an inspector the power of subjecting boys to a medical examination when they find that these youths are not physically fit for the work on which they are occupied; others confer on the officer appointed to issue the certificate for work the right to examine any youngster that does not appear to be in good physical condition. Other States have laid down regulations for a compulsory medical examination for any youth who applies for a certificate to work. This examination must take into account the work which the youth wishes to take up and should be repeated each time that the occupation is changed.

Up till 1921 no American State provided for a periodical medical examination of adolescents, but since then twenty-two States have raised the school age and have organised a medical supervision of schoolchildren, thus making the work of the certifying doctor easier.

The reader may be referred to the resolution passed by the Special Commission for Child Labour at the meeting of the International Association for Labour Legislation, held at Basle in 1913. Here it suffices to repeat the standard proposed by the Children's Bureau of the Labour Department of the United States and by the Conferences on Standards of Child Welfare (1919-1923), which includes, on the one hand, medical examination by an official (a school medical officer or a
medical officer of the public health department) and, on the other hand, an examination for admission to work for children and adolescents up to eighteen years of age.

Among the general recommendations we find that the minimum age of admission is fixed at sixteen years. The Commission recognises that puberty may appear at an earlier or later age, and that, in the latter case, the youth should — the Commission is emphatic on the point — undergo a period of apprenticeship, during which the lad should not be employed on hard work.

No youth of from sixteen to eighteen years should be admitted to an occupation unless he shows a normal development for his age, good health and the fitness required for the work he has chosen. The medical examination should be made with the child stripped, should be repeated periodically up to the age of eighteen years, and every time the occupation is changed.

It is the duty of the local authorities to investigate the conditions of industry and occupation in their district, so that they can judge of the fitness of candidates, and the effects that conditions of work exert on the health and development of young persons.

As a minimum standard of physical fitness the average rates of normal development given below are adhered to, and any child who has not this minimum of weight and height is excluded:

<table>
<thead>
<tr>
<th>Age (in years)</th>
<th>Height (in cm)</th>
<th>Weight (in kg)</th>
</tr>
</thead>
<tbody>
<tr>
<td>14</td>
<td>153</td>
<td>36.287</td>
</tr>
<tr>
<td>15</td>
<td>158</td>
<td>38.555</td>
</tr>
<tr>
<td>16</td>
<td>163</td>
<td>40.823</td>
</tr>
</tbody>
</table>

1 If not clothed, not more than 2.2 kg. should be allowed for the clothes.

If a child has not this minimum he should only be admitted to work when two doctors certify him as fit. But exclusion should be absolute for any child that does not show external signs of puberty.

A certificate of fitness should be refused to any child affected with non-compensated disease of the heart; with tuberculosis or other serious disease of the respiratory organs; with active tuberculous glands; with active tuberculosis or syphilis of the bones or joints; with total blindness; with complete deafness, but admitting conditionally those who can be re-educated; with trachoma, chorea, syphilis, hyperthyroidism, acute or subacute nephritis, or ankylostomiasis. These children should be sent to institutions or to associations and polyclinics, which provide the assistance necessary for each being expressed in centimetres, the subject being seated.

For nurslings developing normally and normal adults the quotient $H$ expressed in centimetres will be approximately 100. For children in the growing state it is about 94.5. The extreme variations are from 89 to 109. A rate above 100 indicates hypernutrition, and one below 94.5 undernutrition.

A Swedish enquiry has also studied the question of a vital index showing the progress whether more or less satisfactory, of physical development, independent of the absolute rates of these measurements. It recalls the formula

$$T = \frac{100P}{H}$$

where $P$ represents the weight in grammes and $T$ the height in centimetres.

But this formula, proposed by Rohrer, has now only historical interest and is liable to numerous inaccuracies. Investigators are considering whether in the case where not only data for height and weight are dealt with, but for chest measurement as well, it would not be better to replace the formula of Rohrer by the following:

$$T=\frac{100p}{H}$$

where $pt$ represents the chest measurement. By the help of this formula, starting from the average data collected during an enquiry on juvenile workers of both sexes, the investigators obtained the following results:

<table>
<thead>
<tr>
<th>Boys...</th>
<th>5.11</th>
<th>5.10</th>
<th>5.05</th>
<th>5.06</th>
<th>4.96</th>
<th>4.88</th>
</tr>
</thead>
<tbody>
<tr>
<td>Girls...</td>
<td>5.29</td>
<td>5.25</td>
<td>5.21</td>
<td>5.21</td>
<td></td>
<td></td>
</tr>
</tbody>
</table>

In Switzerland the physical fitness of recruits is determined by means of the formula $F = H - (C + P)$ where $H$ is the height in centimetres, $C$ the circumference of the chest, and $P$ the
particular case. A certificate of admission should be refused unless the defects found are treated in a suitable manner. Thus visual defects require glasses; contagious diseases of the skin and teeth, appropriate treatment; dental defects call for dentistry and extractions; poor nutrition demands nourishment; while surgical attention is required for hernia, interference with nasal breathing, running from the ears, and orthopaedic defects; and suitable medication for intestinal parasites.

A provisional certificate, for a period of three months, may be issued if the treatment commenced is not yet complete, in the case of: poor nutrition, orthopaedic defects, diseases of the teeth, nose, ears, intestinal parasites, partial blindness or deafness.

Another interesting example is that of examinations arranged in Great Britain for young persons of from fourteen to sixteen years, which provides for a half-yearly examination for young persons of sixteen to eighteen years employed in certain industries. The results of these medical examinations have already been given above.

The essential object of this legislation is choice of work suited to the physical fitness of the candidate so that he has an average chance of continuing his occupation in years to come without exposing himself to risk of injuries affecting his normal development and his state of health. The certifying surgeon should always have in mind the aphorism that the child of to-day is the father and man of to-morrow. The certifying surgeon has a great responsibility towards workers, for he must avoid admitting as their fellow-workman anyone affected with contagious diseases, or with any kind of affection liable to cause any kind of harm to others.

In the case of the English factory surgeon, the object of the certificate of fitness is to declare that no physical disease and no kind of infirmity renders the candidate unfit for the employment in question and for the period of work laid down by law.

In the same way as the American legislation, British law provides for absolute or conditional rejection, admission or exclusion from certain work or certain operations; it requires that account be taken of the home surroundings of the candidate, of the general condition of hygiene in the factory where the candidate wishes to enter, of special conditions in certain operations which he will have to perform, and of the risk of accidents.

The certifying surgeons study the hygienic and sanitary conditions of the industries in their districts, so as to be always in a position to advise young candidates well.

Without entering into details which would lead too far, it will suffice to say that the definite opinion given by the surgeon, based on physical and psychic examinations, should also take into account the characteristics and the requirements of each occupation, the direct and indirect causes of injuries or dangers, as well as the influence which each occupation may exercise on the constitution and the personality of candidates.

Control of the employment of children working at home, and in seasonal operations in the country, is difficult. Welfare work for children in the period between leaving school and entering the factory is therefore important in order to avoid vagabondage.

**Legislation**

The absolute minimum age below which children's work is prohibited in industry, without any reserve, is as follows:

- 10 years: China (boys), Hongkong, Hungary, Portugal, Spain; 12 years: South Africa, Argentina, Austria, Brazil (Sao Paulo), China (girls), Czechoslovakia, France, India, Italy, Japan, Lithuania, Luxembourg, Norway, Peru, Hungary; 13 years: Germany, Chile, Finland, New Brunswick, New South Wales, New Zealand, Queensland, South Australia, Sweden (boys); 14 years: Belgium, Brazil (federal district), Bulgaria, Ceylon, Chile, Cuba, Denmark, Estonia, Great Britain, Greece, Holland,
Irish Free State, Latvia, Manitoba (boys), Nova Scotia, Ontario, Panama, Quebec, Saskatchewan (boys); Sweden (girls), Switzerland, Tasmania, Victoria, Western Australia (boys), Yugoslavia; 15 years: Alberta, British Columbia, Guer- tenstein, Martinawa (girls), Poland, Saska- thewan, Western Australia (girls).

As regards mines see article "Mines (Hygiene in")

In the United States each State has its own laws. It is therefore difficult to sum up the arrangements in a few lines. Suffice it to say that, with the exception of six States, the permission of admission into factories is fourteen years and six States have fixed fifteen years and even older still. (For details see Industrial and Labour Information (published weekly by the International Labour Office), 8 June 1925, p. 51.) As has been mentioned above, American legislation tends and, rightly, to go on raising the age of allowing juveniles to enter factories.

As regards the admission of juveniles into commerce, it can be said that, speaking generally, the question is very complicated and that it would be better to refer to the legislative texts.

With some legislatures the age of admission of children is made to depend on the occupational risk. Thus, for example, a law which admits children to industrial work at fourteen years of age, prohibits the employment of juveniles of less than fifteen years at a considerable number of unhealthy operations. All work in abatoirs, knackers' yards, and gut works, is prohibited to juveniles of less than sixteen years. All work near transmission machinery, and at machinery cleaning and repairs, is forbidden to adolescents of less than seventeen years; nor are adolescents of less than seventeen years admitted to work near machines in motion; while adolescents of less than eighteen years are excluded from factories and workshops where explosives are handled.

Another law excludes adolescents of less than sixteen years from work on Sundays and general holidays; those of less than seventeen years from any overtime work; those of less than eighteen years from night work and from any shift of workmen employed for more than four consecutive hours without a rest pause; from exhausting work, such as loading and unloading ships or working cranes; in quarries; as mechanics or chauffeurs; from oiling and cleaning machines in motion; from handling driving belts; from work with circular saws; from founding metals and glass-blowing; from carrying incandescent materials; and from selling distilled alcoholic drinks.

Young persons of less than fifteen years or, according to the country, of less than sixteen, seventeen or even eighteen years, are excluded from certain unhealthy, dangerous, or heavy processes. There may be mentioned, among others, the silvering of mirrors with mercury; work with chromium; vulcanisation by sulphide of carbon; the manipulation of lead compounds and lead derivatives; the pottery industry; brassfoundry work, and accumulator factories or very dusty operations; or operations which give off vapours, poisonous gases, fumes, or steam, entailing work in a humid atmosphere; or operations with exposure to high temperatures, or to a warm damp atmosphere, or to excessive fatigue from carrying weights and loads (see article "Women's Work"), or to dangers of poisoning by lead, arsenic, or phosphorus.

This exclusion also extends to all work or operations which involve any hazard from vapours or injurious dust, unless the dust or vapours are removed by mechanical means.

Night work is prohibited for children under fifteen years in: Italy, Japan, Rumania, and in special cases in Denmark and Germany; for those under sixteen years in: Argentina, Belgium, New Zealand, South Africa, Spain, United States; under seventeen years in: Holland, Poland, and, in special cases, Norway; under eighteen years in: Denmark, France, Great Britain, Norway, Sao Paulo (Brazil), Sweden and Switzerland.

In France, in certain cases the law allows the admission of children aged thirteen years in Germany and Spain those aged fourteen years.

As regards the conditions of admission for children and young persons to street stalls, see article "Women's Work".

The measures which have been dealt with up to the present have been made

---

1 The Act of 7 Dec. 1996 contains a clause which has a very general bearing, for it applies to "workmen and clerks employed in industrial or commercial concern of whatever kind". The Government has the power to prohibit by a public administrative order the employment of juveniles and women under eighteen years in any work in which their health or morals may be endangered.
the subject of International Conventions or Recommendations.

The Washington Convention (1919) fixed the admission of juveniles to industrial work at fourteen years, except in the case of businesses in which are employed only members of the same family. Some exceptions are made in the case of Japan and India (Articles 5 and 6).

By April 1928 this Convention had been ratified by the following States: Belgium, Bulgaria, Chile, Czechoslovakia, Denmark, Estonia, Great Britain, Greece, Ireland, Japan, Latvia, Poland, Rumania, Switzerland, and Yugoslavia.

The same Conference approved a Draft Convention prohibiting the employment during the night of children under eighteen years, with an exception for children over sixteen who are employed in certain industries, e.g., steel and iron works, gunpowder, paper-mills, sugar refineries, and the reduction of gold ore, on work which, by reason of its nature, must necessarily be continued day and night. The term "night" signifies a period of at least eleven consecutive hours, including the interval passed between 10 o'clock at night and 5 o'clock in the morning (for details see the Convention).

By April 1928, this Convention had been ratified by the following States: Austria, Belgium, Bulgaria, Chile, Denmark, Estonia, France, Great Britain, Greece, Holland, India, Ireland, Italy, Latvia, Poland, Rumania, Switzerland, and Yugoslavia.

A Conference at Genoa adopted a proposal which fixed the minimum age for the admission of juveniles to work at sea; that of Geneva in 1921 adopted a Convention fixing the age of admission of young persons to work as trimmers or stokers on board ships, as well as an agreement relating to compulsory medical examination of juveniles and young persons employed on board ships (see article "Seamen").

The 1921 Geneva Conference adopted a Convention relating to the age of admission of children to work in agriculture and a Recommendation relating to night work of children and young persons in agriculture (see article "Agricultural Labourers" and the texts of these Conventions).

Several laws require the examination, free of expense, of adolescents by a doctor nominated by the factory inspector, in order to decide that the work on which the adolescent is employed does not exceed his physical strength and is not injurious to his development.

In Belgium one of the chief duties of the factory medical service has been putting into practice the periodical medical supervision of adolescents at work.

This supervision includes essentially: a medical examination of the adolescent during the first month he is admitted to work; an annual re-examination; and extra re-examination for individuals of delicate health; an obligation placed on the employer to pay attention to measures considered necessary by the inspecting doctor with a view to safeguarding the physical development of those delicate in health; refusal to admit to work adolescents who decline to submit to health supervision; and the adjustment of each child to work for which he is physically fitted.

Supervision of the health of adolescents at work was laid down by the Royal Decree of 1 June 1920. A Ministerial Order determines the method of conducting this supervision (30 October 1920), and decides as to the sort of individuals to be examined and the kind of medical form to be used.

Among the medical investigations may be mentioned points relating to the skeleton — the vertebral column, thorax, pelvis, and limbs; to the mouth — malformations, teeth and glands; to the nose — malformations and adenoids; hernias; and nervous disorders. The forms used in the investigation contain also columns for annual records from thirteen to eighteen years, for acuteness of vision, acuteness of hearing, height, weight and chest measurement.

A memorandum drawn up by the English medical inspector of factories for certifying surgeons may be mentioned here. It is also interesting to mention the instructions drawn up by the Industrial Hygiene Service of the Factory Department of New York for young girls at work. These instructions include advice regarding food, beverages, clothing, spare time, personal cleanliness, sleep, care of the teeth, sexual hygiene (menstruations), constipation, colds and headaches. Similar instructions have also been prepared for young girls employed in particular industries, such as laundries.

Chlorates

Spanish: Cloratos.

Under this designation are grouped facts concerning chlorates of potassium, sodium, and ammonium, since injuries caused by these products differ only by a mild degree in intensity.

Chlorate of potassium, \( \text{KClO}_3 \), is obtained by bubbling an excess of chlorine through a solution of caustic potash, or by heating a solution of potassium hypochlorite. Up till recently it was prepared commercially by bubbling chlorine through milk of lime. The chloride of lime formed was decomposed, after filtration, by a measured quantity of potassium chloride. The potassium chloride, which is not easily soluble, was separated by evaporation and purified by recrystallisation. By this method much of the chlorine was lost. It is now produced by electrolysis of a warm concentrated alkaline solution of chloride of potassium, to which is added hydrate or bichromate of potassium. The purification of the chloride is done by dissolving it in warm water, adding a little barium chloride to precipitate the chromate, and then filtering it to remove the iron as well. The crystallised chloride is separated by cooling. The bichromate can be replaced with advantage by chloride of cerium. Chlorate of sodium is a secondary product in the manufacture of caustic soda by the electrolytic method.

Potassium chlorate is used in the manufacture of matches, especially in Swedish ones, fireworks, explosive capsules, and some explosive powders; in dyeing, in order to oxidise certain substances which produce aniline black—here the oxidising effect is accelerated by means of catalysts, such as salts of copper, and vanadium. Chlorate of sodium, which is less costly, is being used more and more to replace it.

Sodium chlorate, as well as the perchlorate, are products from the electrolytic process analogous to that used for salts of potassium (see that article).

Ammonium chlorate, \( \text{NH}_4\text{ClO}_3 \), is prepared by neutralising a solution of hydrochloric acid with ammonia or ammonium carbonate, or by precipitating a solution of calcium chloride by ammonium carbonate, or by mixing a solution of ammonium tartrate with potassium chlorate. The crystals melt at 102° C. with an explosion. Exposure to yellow light in time also causes an explosion. For perchlorates, see article "Explosives".

The chlorates, and potassium chlorate in particular, have caused quite a large number of accidental poisonings, but they are not very active substances. The sodium salt is still less active. In large quantity and by ingestion, which does not occur in industry, they exert a poisonous action due to their violent oxidising properties, and to their forming methaemoglobin in the blood with destruction of the red blood cells. In vitro blood to which potassium chlorate has been added gives in the spectroscopic bands characteristic of methaemoglobin. The clinical picture is characterised by serious jaundice, anaemia, and coma. The salts are rapidly eliminated in the urine and are found in the saliva, sweat, and milk.

When heated, chlorates set free oxygen; when exposed to blows or friction, they set fire to various combustible bodies, such as sulphur, phosphorus, sulphide of antimony; hence arises danger from explosion. Strong acids, and, in particular, concentrated sulphuric acid, cause with chlorates an explosion due to the formation of the explosive dioxide of chlorine.

Another danger, and perhaps the most important to bear in mind, is that, when working with chlorates, the clothing may become impregnated, and then burst into flames very easily; whence arises danger from burns. In powder factories the manipulation of chlorates certainly sets free dust in large quantities, but sickness definitely due to this substance has not been observed (Courtois-Suffit).

In the German factories the inhalation of dust containing chlorates appears to have caused disorders of nutrition and of the respiratory apparatus, which, however, seem rather to be due to impurities in the chlorates, inasmuch as these lesions, although arising from the product obtained

See also Bibliography of Industrial Hygiene, published quarterly by the International Labour Office.

Drs. Fuss (Geneva).

See The drawings on p. 426 are taken from Pamphlet No. 136, published by the Bureau of Women in Industry, New York.
electrolytically, were not caused when products were obtained by other methods.

Cases of irritation, erythema of the skin, and even of sores situated on the fingers, accompanied by oedema of the face, are fairly common. Oppenheim reports twenty-six cases of dermatitis due to chlorates made electrolytically. Egli mentions some cases of explosions in chemical laboratories due to experiments made according to inaccurate instructions given in chemistry textbooks.

Montesano reported some cases of eczema among munition factory workers. Ranelleti, in a factory for producing chlorate of soda by the electrolytic process, found that 56.5 per cent. of the workers had ulcerations, and 15.7 per cent. had perforation of the nasal septum caused by bichromate of potassium used in electrolytic operations. One case of ulceration by chlorate was compensated in Switzerland in 1924.

It may be noted that hydrogen comes off from electrolytic tanks into the air of workrooms and carries with it small quantities of potassium chloride; in time the roofs of the factory are covered with a thin white layer of this salt.

It is advisable to ventilate the workshops thoroughly; to make the floor impermeable; to close all openings on to public streets; to set up the departments for crystallisation, crushing and packing in separate rooms; not to use wooden receptacles; to isolate vats from the ground by means of porcelain bowls containing oil; to isolate the floor of the workshop so that the workmen can touch the vats and clean the electrodes and yet be protected against electric shock; to have the workmen medically examined on engagement and periodically thereafter if solutions of chlorides with bichromate are used; to distribute working clothing resistant to fire; to clean the clothing frequently; to ensure first-aid treatment for all cases of burns of the skin and mucous membranes; to discharge into the drains only liquids abundantly diluted with water.

Injuries caused by chlorates of sodium and potassium are compensated by Swiss, Japanese and Finnish laws (see also article "Occupational Diseases: Compensation").

Concerning hygienic measures, see article "Chemical Trades".

### Chlorates (Alkaline)

In this article the chlorides of sodium, potassium, ammonium, and calcium will be examined.

Potassium chloride, KCl, is found in very large quantities in the form of sylvinite in the deposits of Stassfurt, or mixed with magnesium chloride in carnallite. It is used in agriculture as a manure, in the preparation of other salts, in the electrolytic manufacture of caustic potash and of nitrate of potassium by the conversion method, etc.

Chloride of sodium, NaCl, well known under the name of "salt", used for the preparation of other artificial sodium salts, is found in the sea water (which contains only about 3 per cent.) or in the solid form in rocks (rock salt). It is extracted by evaporating sea water in saltpits by the heat of the sun. In cold countries sea water is frozen in winter, ice being thus obtained almost salt free: the process is repeated until a concentrated solution is obtained which is thus evaporated under direct fire in a large boiler or by a method analogous to that used at Stassfurt. In Germany the salt water is pumped up and sent in the form of fine spray on to piles of wood in bundles. Evaporation is favoured by the wind or sun; but this method loses too much salt (20-30 per cent. in the air).

Salt is used in the manufacture of the carbonate, sulphate and hydrate of sodium, hydrochloric acid; for the reduction of minerals; with hypochlorite of calcium for bleaching; in factories for cementation and for hardening files; in the manufacture of ice; in the freezing industry; for flavouring animal and vegetable products; for feeding cattle; in the manufacture of colouring matters; in pottery, textile manufacture, manufacture of paper, soap, refining of oils, etc.

Ammonium chloride, NH₄Cl, or sal ammoniac, is prepared to-day with the amnoniacal waters from gas lighting. Effort is made to obtain it by decomposing ammonium sulphate with potassium chlorate. Dissociation into ammonia and hydrochloric acid easily takes place in the presence of steam at a temperature below that of dissociation (350° C.). Ammonium chloride is used especially by solderers because, with this material, the hydrochloric acid which is set free dissolves the oxides on the surface of the metal; in colour factories, in textile printing, etc.
Calcium chloride is in nature united with magnesium chloride (tachydrite). It is obtained in great abundance as a residue in different industrial processes; for example, in the manufacture of ammoniacal soda. It is used as a dehydrator for drying gases (especially those of blast furnaces), but it cannot be used for ammoniacal gases because it combines with them; for dressing cloth; for preparing the brine (artificial ice factories), etc.

These substances have no great importance from the point of view of industrial hygiene. It should be borne in mind, however, that a source of danger may be present in the impurities they contain; hydrocyanic acid, arsenic, sulphuretted hydrogen gas, etc., and that electrolytic preparation of the chlorides may be the cause of mercurial poisoning when mercury is used in the baths. In this industry another danger is represented by the explosion of the mixture of hydrogen and chlorine if, owing to faulty supervision, these two gases come off in unduly large quantities. Work with salt is certainly very arduous, as is also that of concentrating the salt water; the hot and humid atmosphere represents a danger.

The toxic action of these chlorides depends essentially on the nature of the metal in combination; chloride of sodium is harmless (save in rare exceptional cases); that of potassium in large doses acts like a salt of potassium, that is, as a muscular poison.

The manufacture of Javel water (alkaline chlorides) presents the same risks as does that of chlorine (see that article) when the process of chlorine acting on a solution of caustic soda is employed.

Muller has examined 165 men employed in grinding and packing chloride of sodium, in 45 of whom he found nasal catarrh, in 45 perforation of the nasal septum, and in 9 recent ulceration. Further, he noted digestive disturbances and skin lesions attributable to the action of the hypochlorites.

An enquiry made in Russia in 1924 among 3,000 workers in the salt mines showed that a large number of cases of localised dermatitis occurred on the hands and feet.

The use of salt in the food industry (for flavouring) is also the cause of dermatitis, which occurs in those extracting and crushed the salt as well as in hemp spinners. An acne with redness and oedema of the face, the eyelids and borders of the ears has been found in table salt refiners (in workmen engaged in drying and stoving). Collis found pustular dermatitis in women employed in salting herrings. The lesion was situated at the internal surface of the forearm in those packing the herrings in barrels. Deep painful ulcers were also found at the end of the fingers, on the dorsal aspect of the fingers and hand and this form of ulcer affected mainly the young people gutting the fish. Catarrh of the respiratory tract is said to be frequent among workpeople engaged in concentrating the salt water.

The workrooms should be ventilated and local exhaust ventilation applied where dust arises (in crushing, packing, etc.).

Lesions due to chlorides (diseases of the skin) are compulsorily notifiable in Russia. Eczemas and dermatitis occurring in salt work, etc. are also notifiable in the Netherlands.

For legislation, see articles "Chemical Trades" and "Chorates".

---

**Chlorine**

French: Chloré. — German: Chlör. —
Italian and Spanish: Cloro.

**CHEMISTRY**

At ordinary temperature and pressure chlorine (symb. Cl) is a heavy gas (sp. gr. = 2.9), greenish-yellow in colour, with an irritating and suffocating smell, very soluble in various liquids (carbon tetrachloride, tetra and pentachlorethane, chlorine of sulphuryl), etc.

A litre of water at 15° C. dissolves about 2.5 litres of the gas; the maximum of solubility is obtained at 8° C. Wood charcoal readily absorbs it. Chlorine at ordinary temperature combines with the majority of the elements. It combines directly with the metalloids (except fluorine, oxygen, nitrogen and the inert gases) with evolution of heat and light. It reacts readily with metals; gold and platinum dissolve in chlorine water to form chlorides. Its great affinity for hydrogen is very characteristic. It destroys numerous organic matters in order to combine with the hydrogen in them, and in the presence of water it acts as an oxydiser — a fact which justifies its use as a disinfectant and deodoriser.

Chlorine similarly attacks certain metallic oxides. With alkalis, provided it is not in excess, it yields a mixture of hypochlorite and chloride (Eau de Javel); in the contrary case, a mixture of chloride and chlorite. Reacting on slaked lime it produces calcium chloride. (See also articles "Chlorides (Alkaline) and "Lime"). With ammonia it forms very readily white fumes of chloride of ammonium. By making chlorine act on hydro-car-
forms, substitution or chlorinated additive products are obtained, such as chloroform (CHCl₃), carbon tetrachloride (CCl₄), etc. With carbon monoxide in presence of wood charcoal oxychloride of carbon (CO Cl) or phosgene gas is formed.

- Chlorine can be liquefied at a temperature of 21°C and a pressure of 6 or 8 atm. (by means of steel pumps lubricated with strong sulphuric acid) or by cooling to -49°C at ordinary pressure by means of sulphuric acid refrigerating machines. Liquefied chlorine is a dull yellowish-green liquid having a specific gravity of 1.42 at 15°C, boiling at -33.6°C, and solidifying at -102.6°C in clear yellow crystals. It is put on the market in steel cylinders. The receptacles ought to be able to resist a pressure of 22 atm. (the pressure exercised by the liquefied chlorine is from 6 to 7 atm. at 20°C), and they ought not to contain more than 1 kg. of liquid per 0.8 litre of capacity.

**MANUFACTURE**

(1) Electrolytic Manufacture

This is to-day almost the sole method for the industrial preparation of chlorine, either aqueous solutions of alkaline chlorides or of the fused chlorides being electrolysed.

(a) In the electrolysis of aqueous solutions of alkaline chlorides, sodium or potassium chlorides are used, and the chlorine is recovered as a by-product in the electrolytic manufacture of caustic soda (or potash). In such electrolysis one of these substances and hydrogen is formed at the cathode and chlorine at the anode. These are prevented by appropriate devices from combining with one another, and they are recovered separately. Chlorine is put on the market after having been liquefied by pressure. The hydrogen is generally lost, although, in certain processes, it is combined with chlorine, yielding hydrochloric acid.

The processes used are classed under four categories — electrolytic cells with a porous partition or diaphragm, with mercury, with a bell (without diaphragm or mercury), and with a diaphragm and circulation.

In the first process the diaphragms are usually made of vegetable parchment, asbestos cloth, treated with silicate or coated with kaolin, or asbestos plaques dipped in a solution of gelatine to which bichromate of potash has been added, etc.

In the mercury process the cathode consists of mercury so placed that the sodium formed in the course of the electrolysis is immediately absorbed, forming an amalgam, while chlorine is given off freely at the anode. The amalgam of sodium thereafter decomposed by the water gives soda and hydrogen regenerating the mercury. The Castner apparatus consists essentially of a trough, the bottom of which is covered with a thin layer of mercury and divided into three compartments by partitions which do not reach to the bottom. The end compartments each contain the carbon anode and receive the solution to be electrolysed. The cathode is in the central compartment where the water circulates. As the trough is agitated, the mercury circulates between the compartments. The amalgam is formed with disengagement of chlorine in the end compartments, and then becomes decomposed in the central one, forming caustic soda, evolving hydrogen and regenerating the mercury. In another apparatus, the Kellner, the mercury is forced to move continuously from side to side by compressed air (monte-jus). Solvay effects the decomposition of the amalgam in a cell distinct from that of the electrolysis apparatus. In another type of apparatus, regeneration of the chloride of sodium is prevented by placing a concentrated solution between the brine at the anode and the mercury at the cathode.

In the bell process, the typical form is represented by a kind of bell containing the anode, mixture of the products issuing at the two poles being prevented owing to the superior specific gravity of layers of liquid rich in alkali.

The last procedure allows more concentrated solutions of form to caustic soda by utilising, as in the bell process, circulation of the brine towards the cathode.

(b) Electrolysis of the fused chlorides is a process of manufacture less employed than the former, and serves especially for obtaining metals, such as sodium, calcium and magnesium, chlorine being a by-product. Generally, chloride of sodium, mixed with chloride of potassium and chloride of calcium, is electrolysed in an apparatus of which several types are known (Grabau, Borchers, Graetzel, etc.).

The chlorine obtained in these different ways is aspirated into an apparatus where it is generally compressed before being placed on the market.

(2) Preparation by Decomposing Hydrochloric Acid

(a) The manganese dioxide process is only used on premises where relatively small quantities of chlorine are needed for use in the factory.
ganese dioxide being relatively costly, this method is becoming less and less important. The Weldon process permits utilisation of the residue of chloride of manganese. The mud remaining in the chlorine generating still is first treated by carbonate of lime, then led into towers, where it is submitted to the action of milk of lime, a current of air, and steam. Manganese of calcium is formed, which is used instead of manganese dioxide. The chloride of manganese formed is treated anew, as described, and the process is repeated.

b) The principle of the process utilising the oxygen of the air consists in passing a mixture of air and gaseous hydrochloric acid over a catalyst. The Deacon-Hurter process, generally employed, consists in purifying and drying the gases coming from the saltcake furnaces. This purification consists in deposition of the dust and elimination of matters such as arsenic and sulphuric acid, which rapidly destroy the power of the catalyst. Further, the sulphuric acid is reduced to sulphurous anhydride, which converts the chlorine into hydrochloric acid. The purified and dried gases pass then to a superheater (at a temperature up to 450° C.) and then into a decomposer—an apparatus of cylindrical form, where the gases arriving at the periphery traverse an annular layer of the catalyst, and pass away through a central tube. These gases, which then contain, besides chlorine, water vapour, hydrochloric acid, nitrogen, etc., next pass through a purifying apparatus made up of a series of towers and plate columns. The solid chloride of lime is prepared by drying the chlorine in towers through which sulphuric acid trickles.

3. The Preparation of Chlorine by Decomposition of the Chlorides takes place in Several Ways

(a) Chloride of soda mixed with iron sulphate and calcined in a current of air yields chlorine. This method is used especially in the treatment of copper ores by the wet method.

(b) Ammonium chloride and calcium chloride, residual products in the manufacture of soda by the Solvay process, contain chlorine which is extracted by different methods (Mons, Solvay, Lye, etc.). In the last named, starting with calcium chloride and by double decomposition with lead nitrate lead chloride is obtained, which, when electrolysed, yields chlorine. The nitrate of calcium and residual lead serve to regenerate the lead nitrate.

Chloride of magnesium, which exists in abundance in the Stassfurth mines, can also yield chlorine. The chloride is dried by progressive heating (which yields a mixture of chloride and of oxychloride) and heated in a current of air furnishes chlorine.

Sources of Intoxication

(a) In the course of manufacture. — The risk of inhalation of chlorine in the form of gas is greater in the Weldon process which gives a more concentrated gas than in the Deacon process with its feebleer concentration. The danger is still less in the electrolytic processes because the modern installations prevent any escape. In this method of manufacture the dangerous process is especially the emptying of the electrolytic cells. In compressing the gas there is danger from the bursting of the receptacles and reservoirs containing the gas, whether pressed or liquefied.

In the Weldon process manganese poisoning has been reported from the use of manganese dioxide, especially in the process of grinding (Embden) and from the regeneration of chloride of manganese (Jaksch). In addition to this form of poisoning cases of poisoning by hydrochloric acid, chlorine fumes, and arsine wetted hydrogen gas, have been reported (in a factory for making washing powder).

The electrolytic process utilising mercury has been known to cause mercury poisoning. Besides poisoning by chlorine and hydrochloric acid, the Deacon process has caused poisoning from sulphur dioxide. This hydrochloric acid, it should be remembered, contains, as impurities, arsenic, sulphuric acid and sometimes nitric acid.

In all the electrolytic processes with alkaline chlorides the workpeople are exposed to the action (generally local) of caustic alkalis.

(b) In the course of the use of liquid chlorine or of operations which liberate the gas. — Chlorine is used in a great number of industrial processes.

Chemical industry: manufacture of hydrochlorites (Javel Water, Labarraque's solution), chloride of calcium, chlorates (of potassium and sodium) and perchlorates; manufacture of inorganic chlorine compounds: tri-, penta- and oxy-chloride of phosphorus; chloride and tetrachloride of sulphur; chloride of zinc, and of nitrogen; of synthetic hydrochloric acid (liquid chlorine, etc.); manufacture of organic chlorine compounds: chloride of
methyl, methylene, ethyl, carbon tetrachloride, mono-chloro-acetic acid, chloral, chloroform, chlorobenzol and other chlorine derivatives of benzene, and its homologues, etc.; manufacture of ferrocyanide of potassium, of iodine and bromine, of caustic soda by the electrolytic process; manufacture of asphyxiating and lachrymatory gases: chloro- acetate of ethyl, chloracetone, chloride of benzyl, chlorofomiate of trichlor-methyl, phosgene, chloride of cyanogen, etc.

**Manufacture of colouring matters:**

A great number of initial substances and certain chlorinated colouring matters.

Use of chlorine (in gaseous or liquid form) and of chlorinated substances for *decolorising* (bleaching, decolorising paper and textile fabrics); manufacture of shoddy; obtaining patterns on cotton cloth.

**Metallurgy of gold (separation of gold from silver).**

*Tinning industry:* retinning (Goldschmidt process); use of *aqua regia* (formation of nascent chlorine), of chlorinated substances as disinfectants, deodorants (e.g. in the purification of water), etc.

Chlorine vapour is also detectable in submarines (see that article).

**Toxicity**

According to Lehmann and Binz, chlorine has an irritating action on the mucous membranes (ocular, nasal and respiratory) as well as on the skin (action on the albuminoid substances and the epithelium, which it breaks up, with formation of chlorine compounds) and a general narcotic action when introduced into the general circulation. This paralysing action is denied by some writers (Jaksch, Kobert). Whether it be so or not, the mechanism is also explained differently because, according to some authorities on inhalation, free chlorine is at once changed into hydrochloric acid on reaching the mucous membranes and acts as such; while others (Cameron, Binz) believe that the chlorine remains free, and others again are of opinion that it changes into oxygenated compounds on reaching the mucous membranes and exerts its action in that manner.

The channel of absorption is through the respiratory tract.

According to Lehmann, a proportion of 0.001 mg. per litre is injurious to man; one of 0.003 mg. has a definitely irritating action; one of 0.003 to 0.004 mg. can be borne for some time; 0.005 mg. represents a maximal dose which can only be borne for a brief period; and 0.006 mg. is rapidly fatal bringing about remarkable respiratory lesions. Lehmann has demonstrated that the very smallest quantities of chlorine in the air are completely absorbed in the respiratory tract. He has even been able to prove experimentally that acclimatisation takes place — a fact already proved in the case of workpeople, in regard to whom acclimatisation takes place in several days or several weeks. (Certain workers can stand a dose four times as powerful as that poisonous to individuals not acclimatised: Lehmann, Ronzani).

Finally, an atmosphere containing more than some millionth parts of chlorine cannot be borne, as even traces in the atmosphere render stay in the room impossible.

**Statistics**

Among the numerous cases of poisoning by chlorine, it will suffice to refer only to those reported by factory inspectors or reported as industrial maladies. Often, however, such cases are not distinguished from those set up by hydrochloric acid, or even sulphur chloride.

**Bavaria.** — In 1919 7 cases were reported, in 1920 6, several in 1921, and 4 in 1922.

**Great Britain.** — Cases due to chlorine and hydrochloric acid numbered 8 in 1914, 3 in 1917, 4 in 1918, 9 in 1919, 8 in 1920, 3 in 1921, 11 in 1922, 48 in 1923-1925 and 44 in 1926-1928.

**Switzerland.** — Cases numbered 4 in 1915 (receiving compensation as accidents), of which 1 proved fatal; 16 in 1916; 1 in 1918; 2 in 1919 (including cases due to sulphur chloride); in 1920, 8 cases of poisoning and 3 of ulceration; in 1921, 5 cases of poisoning.

**Symptoms**

(a) *Acute intoxication.* — This rarely occurs, because small quantities of chlorine giving rise to an intense feeling of suffocation compel resort to fresh air. A dilution of 1 per 1,000,000 sets up a feeling of burning of the mucous membranes of the eyes and nose — even though the smell of chlorine is not itself perceptible. The phenomenon admitted by some writers of a reflex occlusion of the glottis which, though it entails difficulty of breathing, at the same time hinders inhalation of large quantities of vapour, is denied by other experts. When massive intoxication occurs death supervenes rapidly — in a few minutes — by pulmonary involvement, suffocation, and rapid collapse.
Usually acute intoxication commences with local irritation of the eyes (ichthy- 
mation), of the nose and throat (coryza), and of the buccal mucous membrane 
(excessive salivation). If the action on the ocular mucous membrane lasts 
some time or is very intense, slight or 
severe conjunctivitis results, as well as 
irritation of the cornea. The respira-
tory troubles are itselfed in air hunger, 
oppression, spasmodic cough, intense 
dyspnoea, bronchial catarrh, and 
sometimes lobular pneumonia. When 
exposure has been rather prolonged, or 
when the vapour has been highly 
concentrated, the patient has an 
irresistible cough with expectoration, 
sometimes bloodstained, spasm of the 
glotts, dyspnœa, chest pains, pulmo-
nary oedema, nausea and vomiting. 
The complexion is at first pale and then 
congested. The symptoms rapidly 
disappear on reaching fresh air or 
continue for some time if the poison 
remains. Death is caused by pulmo-
nary inflammation and oedema, with 
cyanoesis, small pulse, etc. If death 
does not occur, bronchitis, pneumonia 
and haemoptysis often supervene. 

The skin is affected by a feeling of 
burning, tickling, the formation of 
nodules, of vesicles, and sometimes of 
onopen sores.

(b) Chronic intoxication shows itself 
in chronic catarrh of the bronchi. 
Leymann has found among workpeople 
in a chlorine and calcium chloride 
factory a morbidity rate from respira-
tory disease of 17.8 per cent. (as against 
8.8 per cent. for ordinary workpeople). 
On the ocular mucous membrane there 
is dryness of the conjunctiva and 
painful inflammation of the cornea, and 
hyperplasia or palpebral eczema. Accli-
matisation would seem to take place in 
the case of workpeople who have to 
spend much time in an atmosphere 
containing chlorine. Among the general 
symptoms of chronic poisoning gastric 
troubles are reported — anorexia, 
wasting, anaemia with pallor of the 
face, and even precocious senility. 
Headache, vertigo, and sleeplessness 
have also been reported.

Teeth: The dental lesions are said 
to be less due to the chlorine vapour 
than to the hydrochloric acid (formed 
by the combination of the chlorine gas 
with the saliva) the action of which 
dissolves the dental substance. The 
flannel rags which the workers place 
between their teeth in the effort to 
prevent inhalation of the vapour play 
an injurious part. (See what is said 
of this in article " Nitric Acid ".) 

The lesions consist in a gradual 
destruction of all the dental substance 
without the production of any real 
inflammatory process. Vogt considers 
that the dental necrosis is analogous 
in its development to phosphorous 
necrosis of the jaw. The tooth becomes 
yellow and, after having been softened 
and deprived of its smoothness, finally 
crumbles away. The affected teeth 
are very sensitive to changes of tem-
perature, to mastication, and are liable 
to be the seat of excruciating pain. 
The crown of the tooth breaks up 
gradually until the whole tooth dis-
appears. The incisors are the most 
seriously affected as they are the most 
exposed.

Chloracne was first observed and 
described by Herxheimer in 1899 among 
workpeople manufacturing chlorine 
electrolytically; it is a dermatitis 
affecting persons exposed to the action 
of chlorine and its compounds.

Essentially the lesion takes the form 
of inflammatory changes more or less 
serious in the sebaceous glands, result-
ning in the formation of abscesses, with 
ultimately scarring and disturbance of 
nutrition. The following seem to be the 
main forms assumed (in order of 
increasing severity):

1. The acne begins with an acute 
erythema and swelling of the skin, 
followed by a chronic inflammation of 
the sebaceous glands. These do not 
become inflamed so much as merely 
swollen and show white comedones 
with blackened points. The condition 
is a simple folliculitis showing a round 
papule, with a central vesicle and a 
blackhead. The skin looks as though 
it were sprinkled with gunpowder 
fired from a gun at close quarters.

2. If the sebaceous glands become 
inflamed acne pustules develop with 
ulceration and formation of prominent 
violet scar tissue causing the skin to 
look as though it were transparent. 
Later tubercles develop.

3. This stage shows atheromatous 
cysts from the enlarged and inflamed 
glands.

4. Sometimes a definite and obsti-
nate furunculosis develops, which heals 
with the formation of numerous scars 
after cessation from work and after 
going through a special treatment. 
The skin then shows a horny and 
markedly pigmented appearance. The 
general health is more or less affected 
and among the symptoms noted 
are pallor and oedema of the face, 
headache, and generally speaking those 
cited above for the chronic form. The 
malady, although serious, is not fatal.
Lehmann refers to one fatal case due to pyaemia.

The acne is situated on the uncovered parts of the body (especially about the ears) and chiefly where any irritation of the skin has resulted from friction with clothing. Where the injurious action has gone on for a long time, a more serious form has been described affecting the covered parts of the body (groin and genital organs) due to impregnation of the clothing with the toxic substances, micturition performed without washing the hands, working with the legs wide apart (thus favouring access of the gas to these parts of the body), etc. The workers are said to be more affected by acne during hot weather because the clothing then is light, open, and saturated with sweat (Holtzmann).

Conveyance of chloracne to the families of workers has frequently been observed (from the wearing of working clothes or contact with them).

The pathogenesis of chloracne is still very obscure despite the numerous researches into its cause. Several substances have been suspected; chlorine (first accused by Herxheimer who subsequently absolved it); oxide of chlorine (Herxheimer); chlorobenzol (the same observer has thought that the acne might be due to passage of chlorinated phenol into the blood); tarry substances (so that according to Russig the condition is one of tar or paraffin eczema); chlorinated tar products or organic chlorine compounds given off in the electrolytic manufacture of chlorine by the action of this element on the carbon anode. Cases of acne have been observed by Bettmann among workers unpacking a hydrochloric acid tower constructed with tarred plates. Disappearance of cases has been observed by factory inspectors on substitution of carbon electrodes by magnetite in two factories for the electrolytic manufacture of chlorine. On the other hand, cases were noted by the inspectors in Baden in a sulphate of soda factory worked on the Hargreaves principle, where salt blocks had been previously dried on a metallic belt painted with tar. This stuck to the salt and during distillation gave rise to chlorinated tar products.

Further, chlorinated phenols have been suspected: hexachlorobenzol, hexachlorethylene, paranitro chlorobenzol, etc. (Leymann, Lehmann); indefinite chlorinated substances (Holtzmann) thinks that in the course of the manufacture of chlorine there is formed a chlorinated product, still liquid at high temperature or which goes over with the other gases, and on cooling remains fixed to the anode or to the receptacles. He does not consider free chlorine itself can give rise to dermatitis.

Fumouze has suspected hypochlorite of soda. In the electrolytic manufacture of chlorine the hydrogen carries with it particles of caustic soda which combine with the chlorine to make hypochlorite of soda. This in the nascent state attacks the skin and also the respiratory tract.

The view of Bettmann; Hallopeau, Jacquet, Fumouze, therefore, is that the acne is a direct external effect, while others (Lehmann, Herxheimer, Jacobi, Roth, Robert, etc.) consider it to be a dermatitis due to the elimination of the poison by way of the sebaceous glands.

Demonstration

Qualitatively the gas is demonstrated by its characteristic smell. Among characteristic reactions the following may be cited: removal of the colour from paper impregnated with indigo sulphate, bluish colour given to paper treated with starch and potassium iodide.

For a quantitative determination a definite quantity of the air to be analysed must be drawn through a solution of potassium iodide and the iodine set free must be titrated with hyposulphite of soda (Bunsen method). One cc. of a decinormal solution of the hyposulphite corresponds to 3-5 mgr. of chlorine. This reaction should be carried out in the absence of any nitrous fumes which also liberate iodine (Lehmann method).

Prophylaxis

1. First aid, when large quantities of chlorine have been inhaled (massive and acute poisoning), consists in carrying the patient to fresh air with inhalation of oxygen in severe cases.

Tonic stimulants (black coffee, camphorated oil injected subcutaneously, inhalation of amyl nitrite) should be administered to guard against the paralysing action of chlorine on the heart. For the irritating cough injections of morphine hydrochlorate, inhalation of steam, pulverised soda, etc. (Leymann, Lehmann); indefinite chlorinated substances (Holtzmann) thinks that in the course of the manufacture of chlorine there is formed a chlorinated product, still liquid at high temperature or which goes over with the other gases, and on cooling remains fixed to the anode or to the receptacles. He does not consider free chlorine itself can give rise to dermatitis.

An atmosphere charged with chlorine, although very injurious, is practically colourless, as it requires a proportion of chlorine above 4-5 per cent. (in volume) for the mixture with air to have a density sufficient to show the colour.
very dilute ammonia, or antichlorine (hyposulphite of soda), alcohol vapour (according to the recommendations of the Association of German Chemical Industries) and ether vapour should be given.

2. In the manufacture and manipulation of chlorine the airtight condition of the apparatus, pipes, etc. should be ensured and they should be connected up with exhaust ventilation so that a slight negative pressure is maintained in them. At the end of the series of apparatus some device must be installed for absorbing the remainder of the chlorine (towers filled with quicklime).

In the workrooms good ventilation should be supplied and should be tested from time to time.

Absorption or condensation of chlorine in excess; purification and deoxidation of the acid, liquid and other residues should be effected. The piping for carrying them away should be corrosion proof. The residues, even if they have been purified, should never be allowed to discharge into water courses.

In the workroom there should always be a carboy of ammonia in order to neutralise the effect of chlorine in case of sudden escape of the gas.

The soundness of the reservoirs and cylinders containing compressed or liquid chlorine should be assured. In the United States, for example, the use of liquid chlorine is regulated by the Inter-State Commerce Commission. The capacity of the receptacles may be from 100-150, 2,000 or 30,000 lbs. All the receptacles used for transport must be provided with valves melting at 70° C., a temperature for which the pressure is only a half or a quarter of the pressure for which the receptacle is tested. The breakages observed were always due to the presence of foreign bodies reacting with the chlorine.

The electrolytic manufacture of chlorine lends itself best to the application of all preventive measures. In particular, before proceeding with the cleaning of the electrolytic cells, the acid remaining in them should be neutralised with water containing lime. Special precautions should be taken in the cleaning of the cells. Proper preventive measures have, as a matter of fact, brought about the disappearance of chloracne in the electrolytic manufacture (replacing carbon electrodes with other substances such as magnetite).

Cleaning the Hargreaves towers, which has caused cases of acne in the manufacture of hydrochloric acid, should not be carried out in summer and the towers should be previously washed with milk of lime. The persons employed should be protected by overalls and caps impermeable to paraffin; they should be supplied with gloves and the exposed parts of the face and neck should be protected with vaseline. The clothing should fit closely at every point. Respirators should be worn while at work and a bath taken after work. Cases of chloracne will, nevertheless, it should be remembered, occur at times, despite such precautions.

In the Weldon process the apparatus should be air-tight and should not be opened until the chlorine has been completely removed.

All processes giving off manganese dust should be carried on under locally-applied exhaust ventilation, and this should especially apply to the grinding of the pyrolusite (manganese ore) and to the drying of the residual manganese chloride.

As soon as chlorine gas is perceptible in the air of the workroom, it should be quitted and the manager informed. Obvious escapes should be reported and repaired as quickly as possible. Oxygen breathing apparatus ready for immediate use should be at hand where there is risk of toxic gas. These self-contained breathing apparatus should be periodically tested to see that they are in proper order.

As regards individual preventive measures, overalls and breathing apparatus (Pilzner masks, for instance) should be worn after many trials to find out which were the most efficacious substances against the action of chlorine when used in masks, Kohn Abrest has shown that when the proportion by volume of chlorine in the air was about one in 1,000, absorbent cotton wool (neutral) dry or moistened with distilled water is sufficient to absorb them. The relative value of other substances tested (sodium carbonate, hyposulphite of soda, potassium iodide or a mixture of these substances) is not appreciable unless the proportion of chlorine by volume is above 1 per cent. Below this strength the different substances in question, when only a single aspiration of poisonous gas is made, have all about the same activity as regards chlorine.

Cleanliness (douche baths) are of use against chloracne. Dental lesions
can be lessened by avoiding the habit of keeping a piece of flannel between the teeth, but often only change of employment will avail to arrest the lesions formed. Use of alcaline solutions does not seem to have given the relief expected. Stumps should be extracted. Acid foods or those liable to ferment should be avoided. Careful dental toilet should be practised.

The workers should be informed of the risks, and notification of the appearance of skin lesions made to a medical man. Workpeople showing special susceptibility to skin lesions should not be employed.

LEGISLATION

Statutory Rules and Regulations (as e.g. in Great Britain) deal with the evolution of chlorine in certain industries (paper factories, for example) and especially in the chemical industries (see article "Chemical Trades"). Employment of women is prohibited in Argentina and in France and Holland in the manufacture of chlorine, and in Japan wherever the nature of the work exposes them to the escape of chlorine vapour. Young persons under sixteen years of age are excluded from chlorine factories in Belgium, and under eighteen in the Netherlands and Switzerland; boys under fifteen in Italy, under sixteen in Spain and Greece; girls under eighteen in Greece, and under twenty-one in Spain and Italy. Intoxication and lesions set up by chlorine are treated as accidents and receive compensation as such in Japan, Switzerland, Finland and Great Britain.

(See also article "Chlorine").

Chloroform
(Trichloromethane)

Chloroform (CH Cl₃) is a clear liquid with a peculiar smell and a sweetish taste and very unstable (under the influence of light it becomes transformed into chlorine, hydrochloric acid and carbon oxychloride). It boils at 61 to 62° C. Its specific gravity (at 15° C.) is 1.498 to 1.502.

It is obtained either by distilling a mixture of ethyl alcohol or acetone, water, and chloride of lime, by decomposing chloral with caustic potassium, or by making nascent hydrogen react on carbon tetrachloride.

It is used in the preparation of formic acid and particularly in the manu-

facture of certain alkaloids. Under the action of electric discharges it gives rise to the formation of certain of the highly chlorinated hydrocarbons.

The following risks connected with its manufacture may be mentioned: chlorine fumes, fumes of acetone and alcohol; the action of intermediate products and impurities, such as: amyl alcohol, ethyl chloride, aldehyde, allyl chloride, tetrachloromethane, phosgene, and chlorinated derivatives of propylc, butylc, and amylic acids.

Chloroform constitutes a poison of the nervous system. It is also a poison of the blood (hemoglobinemia, hemoglobinuria). Simpson (1847) discovered that consciousness might be completely suspended by the action of chloroform, and this fact explains its wide use as an anaesthetic in surgical practice and also as a local anaesthetic. Clinically chloroform causes phenomena of excitement followed by depression, loss of consciousness, and finally paralysis (of the heart and of the respiratory system). It also irritates the skin and mucous membranes, on which it gives rise to redness, caustication, and phlyctenia.

Medical literature only records one case of occupational poisoning, reported by Hofbauer, affecting a chemist's apprentice who in decanting chloroform was suddenly attacked by vertigo and headache and was unable to stand upright.

Chloroform appears on the Swiss list of substances injury from which entitles the victim to compensation similar to that granted in the case of accidents.

Chloropicrine

Chloropicrine, or nitro chloroform or nitrated chloroform, the formula of which is C₆N₂O₂Cl₃, is obtained by the action of nitric acid on chloral or, more usually, by treating picric acid with chloride of lime. It was used during the war as tear gas and was known as "emetic gas". According to Minkowski, it is the cause of pulmonary oedema. In France its use has been proposed for killing the cocoons in the silkworm nurseries.
Chromium and Chromates

Chromium

Chromium (symbol, Cr; atomic weight, 52.5; density, 6.8) is a shining white metal which melts at 1,950° C. It can be filed and polished, but cannot be drawn out or rolled on account of its great hardness. It is non-magnetic. The metal does not oxidise when exposed to the air at ordinary temperatures; it is attacked in the cold state by hydrochloric acid, but not by other acids.

Chromium forms three series of compounds, derived respectively from the protoxide of chromium, CrO; the sesquioxide, Cr₂O₃, giving, as basic oxides, chromous and chromic salts; and chromic anhydride, CrO₃, giving chromates.

The chief mineral of chromium, chromite, or chrome iron ore (Cr₂O₃·FeO) is a combination of the sesquioxide of chromium with the protoxide of iron; it is extensively distributed, but the number of deposits worked is limited, because only ore containing more than 40 per cent. of Cr₂O₃ is utilised. This ore contains variable quantities of silica, alumina, lime, manganese, and sometimes of copper, nickel, and cobalt. Chromium is also found in the form of crocoite or Siberian red lead, which is a chromate of lead.

Chromium is prepared by reducing, with charcoal in the electric furnace, sesquioxide of chromium obtained by the reduction of sodium chromate by means of sulphur or starch. Sodium chromate itself is derived from chrome iron ore (see further on).

This process does not give pure chromium, but a strongly carburetted alloy, the carbon of which can only be eliminated by reduction under an oxide brasse. It is still more easily obtained pure by the alumino-thermic process, in which chrome oxide is reduced by powder aluminium.

By reducing sesquioxide of chromium in the electric furnace in the presence of silica (gin process), a silicide is obtained which, when submitted to an oxidising fusion in the presence of the sesquioxide of chromium and lime, gives chromium and iron chrome with a very small quantity of carbon. By reducing the sesquioxide by means of aluminium, chromium free from carbon is obtained. Chemically pure chromium is prepared by electrolysis.

Uses

Pure chromium is very little used. It is made use of to prepare alloys, such as nickel-chromium with 10-20 per cent. and iron chrome with 20-30 per cent., and chromium wire, used as anodes for depositing chromium on articles. For this purpose, only electrolytic chromium is used, which is hard, but malleable. The process of chromating or plating with chromium by electrolysis is now carried out with perfection. It protects metals under conditions wherein plating by nickel and other protective layers is not satisfactory. But this plating is no more resistant to hydrochloric acid than are the alloys.

This industry is continually developing, and it is perhaps necessary to supervise closely the health of workers employed on it. (See article "Electro-plating").

Iron chrome is used to make very hard and very tenacious chrome steel used for files, tools, heads of shells, armour plating, and ball-bearings.

Chromic alone or mixed with tar, lime, and bauxite is employed for making linings and refractory bricks used in the construction of metallurgical furnaces.

Chromium is not poisonous in itself. Its manufacture does not present special dangers, except in the case of the preparation of alkaline chromates. However, during such enriching operations as roasting, the workmen appear to be affected with disorders due to the carbon monoxide which is given off during the process.

Derivatives of chromium.—Chromic acid, CrO₃, or the trioxide of chromium, usually known in the trade as chromic acid (French, Acide chromatique; German, Chromsäure; Spanish and Italian, Acido cromico), is prepared commercially by treating the chromate of barium or lead with sulphuric acid. It is also obtained by electrolysis of chromic sulphate. The commercial acid takes the form of red crystalline masses, or powder, still containing sulphuric acid or chromates. It is very corrosive, and is a strong oxidising agent used in the dye industry. However, a mixture of potassium bichromate and sulphuric acid is generally used instead of it.

With the alkaline chromates, chromic anhydride is the only compound which is directly toxic.

Chromates

The most important chromates are as follows:

Neutral chromate of potassium, K₂CrO₄, is theoretically derived from...
chromic acid, \( \text{H}_2\text{CrO}_4 \), and occurs in the form of yellow crystals; it is rarely used (for dyeing and the manufacture of inks).

Neutral chromate of sodium, \( \text{Na}_2\text{CrO}_4 \), and neutral chromate of ammonium are used in making green oxide of chromium. Bichromate of ammonium is used sometimes in photogravure and in making explosives.

**Bichromate of potash**, \( K_2\text{Cr}_2\text{O}_7 \), occurs in the form of anhydrous, inodorous, red crystals tinged with orange, melting at \( 400^\circ \text{C.} \) and soluble in cold water. Immediately after melting, the bichromate becomes decomposed into oxide of chromium, neutral chromate of potassium, and oxygen. It is frequently used as an oxidising agent with sulphuric acid, forming chromic mixture; it then becomes reduced to chromic sulphate. In industry chromic acid is recovered from this solution by means of electrolysis in a vessel with a diaphragm. Chromic acid forms at the anode and hydrogen at the cathode.

**Bichromate of soda** is very dilliquescent when hydrated; but, when heated to \( 200^\circ \text{C.} \), it becomes dehydrated and is no longer dilliquescent. It can then be melted and cast into plates; to-day it replaces potassium bichromate in most of its uses, for it is more soluble and less costly.

**COMMERCIAL PREPARATION**

Chromite is first "étonnée", that is to say, heated and then suddenly cooled so that it breaks into small pieces; it is then crushed and sifted.

The powder obtained is mixed with carbonate of soda and quicklime; then it is heated to about \( 1,200^\circ \text{C.} \) on the hearth of a reverberatory furnace in a forced draught. In this way chromate of sodium, carbonate of lime, and oxide of iron are obtained, only the first of these being soluble. The mass, after cooling and crushing, is treated with water in an apparatus fitted with agitators. The solution is helped by jets of steam. The addition of an excess of alkali helps the formation of chromate calcium, which passes into the filtered liquid through the filter press. This liquid is concentrated and then treated by sulphuric acid which changes the sodium chromate into bichromate. The sulphuric acid must be quite free of arsenic and oxide of nitrogen. The solution is concentrated over an open fire, and the sulphate of sodium, which is only slightly soluble, is precipitated. The crystals are extracted, drained, washed, and dried. If the concentration is increased to \( 60^\circ \text{B.} \), crystals of hydrated sodium bichromate are deposited in their turn. They are transformed into potassium bichromate by double decomposition with hot potassium chloride. Potassium bichromate can be prepared by electrolyzing a solution of sesquioxide of chromium in excess of potash. The chromite becomes changed into chromate and then into bichromate. By new processes using residuary sulphate of soda and baryta in place of lime, bichromates and caustic baryta are prepared simultaneously.

The oxide of chromium obtained as a residue is then used in making alizarine dye or in electric batteries. Bichromates can be made by mixing it with slaked lime.

Neutral chromate of lead in the natural state is crocoisite or Siberian red lead; when obtained artificially it is chrome yellow. It is prepared by precipitating a solution of acetate or nitrate of lead with bichromate or chromate of potassium or sodium. It can also be obtained by digesting carbonate or basic chloride of lead with an alkaline bichromate. The extract of bichromate obtained by boiling is washed, filtered, dried, crushed, sifted, and packed.

Basic chromate of lead, or chrome red, or cinnabar of chromium, is prepared by treating neutral chromate with an alkali. By mixing the two chromates in different proportions chrome orange is obtained.

In commerce these two products are rarely pure. They are found under fancy names mixed with other substances, the chief of which are lead sulphate, chalk, kaolin, and gypsum.

**USES**

Chromates and bichromates are used in a great many industrial operations, among which may be mentioned: the manufacture of chromium and its compounds, such as oxides, salts, and chrome alum; chrome colours (see later), the manufacture of coloured crayons; paper, wall-paper and linoleum; the preparation of colouring materials which require an oxidising agent, such as aniline greens and reds, and for the oxidation of anthracene into anthraquinone; the manufacture of colours from logwood, catechu, and red wood; the manufacture of inks; of aldehydes and numerous oxygenated organic products; in scientific laboratories for the preservation of tissues; for bleaching oils, fats and beeswax; for...
purifying alcohol (e.g. the French national carburetant); the manufacture of fuses and explosives with pyroxiline and ammonal; Swedish matches; as colours in dyeing, for printing especially; for frosting, enamelling and colouring glass, porcelain, earthenware, and stone ware; for chromium plating; for staining and polishing wooden articles; for rendering gelatines insoluble under the influence of light, used in the graphic arts of photography, photogravure, carbon process, zincolithography, and photo-engraving; for rendering paper and tissues impermeable; in the rubber industry, for the preparation of mixtures and artificial rubber, and making tyres; in tanning with chromium; in the accumulator industry for bichromate batteries; and in laboratories for chemical analysis.

Chrome colours are generally those compounds of chromium which have been mentioned above, because these compounds are all coloured. Yellow colours, with shades varying from greenish to red, passing through orange, have a basis of lead chromates; others are prepared by combining chromic acid or the alkaline carbonates with various metallic salts.

Green oxide of chromium is obtained by calcining chromate of ammonium or a mixture of chromates of soda and sal ammoniac. Other greens are obtained by the oxidation of the bichromate, yielding residuary salts of chromium, which are treated with carbonate of soda, calcined and washed. English greens are a mixture of chrome yellow and Prussian blue.

The preparation and handling of these products is associated with the same dangers as the use of chromates.

Numerous brown, blue, and black colours have a chrome basis; but they are not generally used. Chrome alum appears in the form of deep violet crystals and is prepared by reducing potassium bichromate in sulphuric solution by sulphurous gas or alcohol. It is formed also as a by-product in the aniline dye industry and generally during the oxidation of organic bodies by potassium bichromate.

It is used as a mordant in dyeing, for preserving gelatine, and in tanning.

**Sources of Danger**

Chromic acid and the alkaline chromates have a local caustic action, which is more pronounced in the case of bichromates.

This action affects the skin and mucous membranes, especially in the case of hot solutions. It is more pronounced for women than for men (Gerbis).

The injurious cause shows itself sometimes in the form of finely divided droplets, sometimes in the form of somewhat fine dust or of small crystals. The evaporation and boiling of solutions of chromates give rise to vapours which carry minute particles of caustic materials into the surrounding atmosphere: drying, grinding, transport, and packing of the product, on the other hand, cause dust, varying in amount according to the technique used.

In various countries the quantity of chromates set free, in the course of operations, into the atmosphere of a workplace has been investigated. Thus for example at 50 cm. above evaporating pans, containing solutions of bichromate of soda, there was found in the steam 0.084 mg. of chromate per cubic metre; at 45 cm. above another pan, 0.736 mg.; on a square metre of surface at 37 cm. from an evaporating pan during one hour, the quantity of chromate deposited was 23.81 mg.; at a distance of a metre it was 128.20 mg., and on the wall near the pan 205.11 mg. At 35 cm. from another pan the quantity of bichromate was 786.09 mg., and near a third pan 825.26 mg.

In 1918 Legge found 3.3 mg. and even 6.6 mg. of bichromate dust per cubic metre of air taken at the level of the mouth of a workman employed in crushing; and 0.5 mg. per cubic metre under the same conditions in the packing department.

The preparation of alkaline chromates and the regeneration of lye-wash of chromium may set up ulcers, eczema, and dermatitis; and also lesions of the respiratory mucous membranes and conjunctiva, and perforation of the nasal septum.

The use of alkaline chromates in industry (see the list already given) favours the development of ulcers on the hands and feet, of conjunctivitis, eczema, and dermatitis. Thus, for example, ulcers on the hands and feet are very frequent in chrome tanning, and in work on wooden articles. Eczema of long duration occurs in making Swedish matches. Eczema and ulcers occur in the textile industry. On the other hand, perforation of the septum is not frequent in making Swedish matches, chrome tanning, work on wooden articles, or the textile industry. It is a little more frequent in explosive factories; although in all these occupations the incidence of perforation is much less frequent than in the manufacture of chromates.
Plating with chromium (see article "Electroplating"), which for reasons of economy is more and more replacing nickel-plating, exposes the workman to dangers of lead poisoning and to injuries from chromium.

In processes with the galvanic bath, chromate lesions of the hands and nasal septum may occur when chrome vapour, which forms during the electrolysis, escapes from the confines of the bath.

Lead poisoning arises because certain fittings and armatures are of lead which under the action of chromic acid becomes changed into chromate of lead, the solubility of which in hydrochloric acid of 1 in 10 has been demonstrated. The production and use of chrome colours expose workmen to risk of lead poisoning rather than to danger from chromium; here the cotton fibre is first soaked in a solution of salts of lead, then treated by a solution of a chromate, and, finally, in order to obtain certain colours, by lime water. The use of cinnabar of chromium in the boot industry explains the few cases that occur of lead poisoning; more frequently lead poisoning occurs from the inhalation of chromic acid of lead, which is often, but wrongly, considered as harmless. Perforation of the nasal septum is very rare in this occupational group; it is to be attributed to traces of alkaline chromates contained in the colours used.

Some experts hold that in an advanced phase it is possible for absorption of chromates to exercise a fairly intense action on the digestive organs, affecting chiefly the liver with parenchymatous degeneration, and on the urinary tract, causing nephritis. The diagnosis is up to the present only an experimental finding, according to which the lesion would be set up by the elimination of chromates.

Undoubtedly vapour from boiling solutions containing particles of chromates in suspension are partly absorbed by the respiratory passages; but it has yet to be proved that these particles reach beyond the upper respiratory passages. It is, however, certain that these vapours cause acute dermatitis, which is more common among young persons or those predisposed to diseases of the skin.

Urban, Colden, Hansen, and Forschbach had an opportunity of studying the effect of chromates during an acute outbreak of non-industrial poisoning, which enabled them to collect facts concerning the pathogeny, the clinical symptoms, and the pathological anatomy of this intoxication. Happily a similar instance is only seen in industries where a workman absorbs a solution of chromates unawares. Nevertheless, the incidence of respiratory and digestive diseases is a little higher than in industry in general.

The above-mentioned experts observed nothing new as regards skin lesions. They were able to show that these lesions only occur when the skin is already damaged. The absorption is very rapid (one to two days), and in acute poisoning the kidney symptoms are very serious, including oliguria and even anuria, with cyanosis, shivering, oedema, coma, and vomiting. But these renal lesions have never been found among operatives and deserve to be more closely studied.

Ulcer of the duodenum analogous to the gastric ulcer caused by lead, observed by Rossle, may be caused by the probable localisation of the poison to the coeliac plexus.

Lesions of the eye take the form of affections of the retinal vessels, paleness of the optic nerve, and anisocoria (unequal pupils).

Kossa obtained experimentally a glycosuria of renal origin.

As regards individual susceptibility, it is found that the facts furnished by industry, especially as regards perforation of the nasal septum, point to the absence of any immunity.

Lehmann has taken up the study of chronic poisoning by chromates. By experimenting with cats for five days, and for three hours each day, he found that the inhalation of 8 mg. of chromates per 1,000 litres of air is sufficient to cause a caustic effect on the mucous membrane of the nasal septum, bronchial lesions, and death from pulmonary lesions. The experiments showed that danger arises chiefly from absorption of chromates by the respiratory passages.

It should also be borne in mind that workmen employed in mordant work, using hot solutions of bichromate and dilute nitric acid, are exposed to the vapours of nitrous fumes. Hamilton mentions a fatal case of a workman at a colour factory, following the burning of a mixture of lead chromate, Prussian blue, and ferrocyanide of potassium in the preparation of chrome green.

Statistics

Lesions due to chromates are certainly more common than is usually admitted. On perusing medical literature it is easy to find that questioning and periodical examination of workers employed in making and handling alkaline chromates show a very large number.
It was Cumming, of Glasgow, who, in 1827, first described ulceration among workers at a bichromate factory. Perhaps without knowing of the work of Cumming, Becourt and Chevallier in 1851 observed the same lesion among workers in chromates at a factory near Paris, and, replying to a list of questions sent out by these doctors, Isaac Tyson, of Baltimore, in 1852 confirmed the observation of his French colleagues.

Several cases of ulcers and perforation have been reported in Austria; thus, for example, in 1942 out of 60 workmen 15 were affected. In 1923 the use of a solution of chromates in a map-making institution caused some serious cases of eczema and conjunctivitis.

In Germany, several cases were noted in a factory open at this date at Griesheim; other cases were noted in 1894; in 1900 Hermann found that 70 per cent of the workmen examined suffered from ulcers and 48 per cent from perforation of the nasal septum.

Some cases of dermatitis with itching, papular eruptions, and pustules have been found in the department of fulling sheets which contained traces of bichromates; out of 262 fullers at Forst, 35 were affected.

The most carefully prepared data are certainly those supplied by Fischer, who gives the results of observations made in seven chromate factories during several years 1898 to 1900.

For every 100 full-time workers, these factories showed annual labour turnovers of 121.1, 325.5, 14.4, 316.5, 57.3, 27.1, and 73.35. These differences are explained by differences in plant and in technical organisation. Out of 700 workmen employed at these factories during seven years, 2,282 cases of sickness occurred. For every 100 cases of sickness there were: 8.82 cases of chrome ulcers, caustic effects and burns caused by acids and alkalis; 24.39 cases of ulcers of the nose; 7.76 cases of perforation of the nasal septum; 6.95 cases of eczema, dermatitis, and boils; this group accounted for a total of 11.91 cases with 176.36 days of sickness. Diseases of the kidneys showed a rate of 0.07; nervous diseases, 1.77; diseases of the circulatory system, 0.42; respiratory diseases, 15.36; diseases of the digestive organs, 9.83; infectious diseases, 8.96; this group totalled 36.33 cases with 584.25 days of sickness.

Among 100 workmen there were 71.42 cases of perforation of the nasal septum; 16.56 had been affected before completing a year's work; 19.14 before one to five years' work; 18.28 before six to ten years' work; 13.42 before eleven to twenty years; 4 had a length of service of more than twenty years.

Out of 100 workmen dermatitis was due in 5.82 cases to burns by chromates; in 4.53 cases to caustic effects; in 7.77 cases to ulcers from chromates; and in 10.35 cases to ulcers not well defined, including, however, those groups under the preceding denominations; 29.71 were cases of dermatitis from chromates; 5.18 were eczema and itch; 1.62 were simple dermatitis; 5.50 were boils; and 0.65 were lesions of the nails. Workers at aniline and chromate factories show an incidence of dermatitis much higher than occurs among workers in other chemical industries, such as acids and alkalis. As a matter of fact while the rate for derma-
Ulcers due to chromates are common among workers in industries involving the use of these substances. The incidence varies depending on the specific type of work. Among workers in sulphate and sulphuric works, the rate is 7.44 per cent. Among those in caustic alkalis, it is 9.40 per cent. Those in chlorine derivatives and permanganate have a rate of 14.38 per cent. Workers in chlorine derivates and permanganate have a rate of 32.24 per cent., while chromate workers have a rate of 31.49 per cent.

In 1910, Wolff found among 64 workers, 51 with ulcers due to chromates, of which 33 had been employed in the works for one to ten years and 19 from ten to twenty-one years. One worker had an existing ulceration of the nasal mucous membrane or the incipient stage of perforation; on the contrary, fully developed perforation affected 47 workers (73.44 per cent.).

In Prussia in 1912, it was noted that 90 per cent. of the workers in chromate works were affected by ulcers. Medical examination and careful selection of candidates led to a reduction of the incidence of these morbid conditions to 13.3 per cent. after a period of 1 to 35 months. Although the length of time of contact with the injurious products is a factor, the formation of a thick scar on the mucous membrane, once formed, inevitably prepares the way for the final lesion.

In a paint works at Merseburg, perforation of the septum was found in 1922 among 6 out of 8 workmen employed in mordanting with bichromate. In the Dusseldorf district, the manufacture of ferro-chrome caused ulcers and perforation of the septum.

In a very close examination made by Lehmann, this authority found among 65 workmen, of whom 52 had worked from one to twenty years, 16 cases of ulceration of the nasal mucous membrane, 26 of perforation of the septum after working from one to six months, and 7 cases after six to twelve months. The total was

![Fig. 37. — Ulcerations of the nasal septum due to chrome (after RANGETTI).](image)

cent. In 1913, 19 cases of perforation of the nasal septum were noticed among 90 workmen; in 1917, 11 cases among 11 workers; in 1918, 5 cases among 50; in 1919, several cases of eczema; in 1920, 12 cases were excluded because they were due to other causes (caustic alkalis). In 1921, several factories were closed, and the cases diminished. Nevertheless, out of 89 workmen, 7.86 per cent. had fully developed lesions, and 12.36 per cent. cicatrices which showed the existence of former lesions.

In 1922, an investigation made at a chrome and chromate factory at Mersebourg, dealing with a period of sixteen years and with 210 workmen (30-40 workmen a year), showed no change in the nasal septum in 48 persons; in 17 slight change; in 56 a distinct change, and in 61 a very marked change. The perforation found in 28 workers (13.3 per cent.) after a period of 1 to 35 months did not depend so much on the length of time of contact with the injurious products, as on the formation of a thick scar on the mucous membrane which, once formed, inevitably prepares the way for the final lesion.
of the nasal septum; 13 cases occurred in workers employed in the rooms for the preparation of lyes; 7 of the workers were employed at melting furnaces; 3 in the concentration rooms and 1 was employed as a grinder; in 1923, some cases of eczema were recorded as situated on the hands of tanners working with chrome were probably due to chrome-alum; in 1924, in an alkaline chromate factory there were 33 cases of lesions among 140 workers, of which 21 occurred in the lye department, 12 at the furnaces, and 2 in the grinding department.

In Bavaria, in 1920, 27 cases of perforation of the septum were reported, 14 cases of erosions, and 12 of ulcers of the skin; in 1922, 114 workers were examined and 7 cases of perforation of the septum and 6 of ulcers of the skin were found. In Württemberg 4 cases of ulceration and perforation of the nasal septum were reported in a dyeworks in 1922; and in 1921 1 case was reported at Hamburg and 2 in Saxony.

In Great Britain, Legge reported in 1902 that out of 176 workers 71.6 per cent. had perforation of the septum and 11.3 per cent. had ulceration of the nasal mucous membrane without perforation. He noted that some workers were more resistant than others. Mitchell, in 1916, had examined during three years 886 workers at chromate factories and only found 175 cases of ulcers, or 20 per cent.

Some important figures collected by the Department for the Medical Inspection of Factories gives for the period 1920-1926 the following number of ulcerations by chromates and by industry:

In 1923 the cases amounted to 58 (occupation not specified); 3 cases were caused by fluoride of chromic acid used as a mordant. In 1924 Dr. Hamilton, of Manchester, examined 26 chrome workers and found ulceration of the nasal mucous membrane in 11 cases and perforation of the septum in ten. In 1925 a case of irritation of the upper respiratory passages was reported in a worker employed in electro-plating metal articles with chromium. The in- ventor of the process showed perforation of the septum; and one worker had dermatitis as well as irritation of the nasal mucous membrane. It is considered that these lesions were due to vapours of chloride of chromic acid given off from the electrolytic bath. In 1926 out of 13 workers at chrome colour works there were found 10 cases of dermatitis and 11 cases of lesions of the mucous membranes. The establishment of periodical medical examination stopped these troubles.

In 1926 a case of dermatitis was noticed in a worker who printed the "blues" on paper with chromates (Parkhurst).

In 1928 the total number of cases which occurred amounted to 70. The Factory Inspection Department in Great Britain (Home Office) published in 1925 a small propaganda pamphlet on the subject of dermatitis in polishers of wood. These workers and particularly cabinet makers are affected with very painful cutaneous lesions due to the manipulation of colours (Bismarck brown, Van Dyck brown) and potassium bichromate.

In Italy several cases of lesions by chromates have been reported. Thus, for example, Ranellutti in 1919 found among 69 workers at a chlorate factory, handling potassium bichromate, ulceration of the nasal mucous membrane in 38, or 56.5 per cent., 7 of whom, or 15.7 per cent., showed perforation of the septum.

In Japan, injuries caused by chromates have, until recently, been unknown; but in 1927 several cases were reported to the competent authority; in consequence steps are being taken to arrange measures necessary for protection. In one factory which used chromates nearly half the personnel were affected by lesions due to these substances.

In the Netherlands, the Department of the Medical Inspection of Factories had knowledge of 11 cases of lesions caused by chromates.

In Russia, Wilensky (1924) found in a chromate factory 197 workers out of 278 affected with lesions, of whom 49 had ulcers of the nasal septum, 92 had a small perforation, 70 had a large perforation, 21 had granular pharyngitis, 15 atrophic pharyngitis, and 80 chronic pharyngitis. According to this expert, cases of pharyngitis should be compensated in the same way as other lesions by chromates. In 1927 Hellmann in the black section of a dyeworks, reported among 18 workers 5 cases of ulceration of the hands and forearms caused by a bichromate bath used as a mordant. These ulcerations were of slow development, relapsed frequently and left deep cicatrices. Education of workers and prophylactic measures taken by the management have much reduced this danger.

In Switzerland 22 cases of lesions by chromates were reported between 1918 and 1925 to the National Insurance Office.
In the United States, Ducatel, of Maryland, mentions that Bäer, of Baltimore, had seen 20 cases of lesions caused by chromates present in vapours. Gilman Thompson has reported a case of general poisoning.

**Pathology**

Lesions caused by chromates particularly affect the skin and mucous membranes.

On the skin, chiefly on that of the fingers, hands, upper limbs, face, and even the feet, in fact everywhere where the skin comes occasionally in contact with the injurious products ulcerations appear, round and sometimes oval, with red and thickened edges, and a necrotic base; in size their diameter averages from 3 to 10 mm. Clinically the lesion is very varied; it begins with dryness, roughness, and fissures which are very often aggravated by maceration.

According to the constitution of the individual one may find dermatitis of a vesicular or papular type with itching; it is difficult to cure. Sometimes the lesion appears as an eczema of a different kind with oedema and pains, often with an acute onset, especially when the workman has come in contact with hot solutions of bichromate. Among the sequelae of irritation of the skin, cases of septic granuloma have been reported.

The ulceration of the skin commences in an insidious manner, without pain, with loss of substance and slight signs of infiltration, which, however, may appear rapidly and suddenly and cause a round hard ulcer sometimes under a scab; if the patient is not looked after the ulcer may become deeper and deeper and reach the bone or a joint. Cases are known where the joint and the adjacent bone were laid bare. According to the constitution of the individual one may find dermatitis of a typical; it appears within a year and the bad habit of picking the nose and the irritant dust has exercised its action before the development of the ulcer. Rhinitis characterised by coryza and epistaxis is often observed. On examining the patient one finds, generally by chance, ulceration or even perforation of the nasal septum. These lesions occur generally without any interference with the nasal function and without any discomfort to the individual, the perforating process being practically painless. The ulcer is situated at the lower part of the septum, usually on the central part, corresponding to the organ of Jacobson, which is rudimentary in man, and is in the form of a round white spot, greyish looking like mud, which becomes deeper and deeper, involving the mucosa of the cartilage, finally leading to a perforation in the lower middle part, circular or oval in form, of pale pink colour without any sign of reaction. When a rhinitis or coryza prepares the ground and when the irritant dust has exercised its action for a long time, haemorrhages also occur, which bring about a peculiar state of the mucosa which Zuekerkandl calls "xanthosis". The mucosa is then yellowish and this stage appears shortly before the development of the ulcer.

The lesion may appear after as few as eight days but generally after some weeks, from six to eight. It does not affect the shape or the function of the nose; it does not exercise any injurious action on the respiratory or digestive apparatus. The general condition remains good. Healing is effected by cicatrization of the edges of the perforation.
tion, fairly soon if the workman gives up his work, less rapidly, from one to two months. He has continuous gripes. In some rare cases necrosis of the nasal bone has been reported.

In the case of the mouth the chromates may cause irritations with small yellowish ulcerations, which heal slowly. On the tonsils ulcers may occur which in some cases have been diagnosed as syphilitic chancre; pharyngitis, regarded as characteristic, has also been reported by Wilensky.

Ulceration of the palate which heals fairly quickly has also been noted.

Multiple lesions of the eyes may be present involving the eyelids, conjunctiva, and cornea, but they are not usually serious or characteristic. Keratitis caused by chromic acid is a typical affection which does not irritate the conjunctiva, but on the contrary damages the epithelium and the superficial layers of the cornea, which are coloured brown on the part not protected by the eyelids. The brown coloration is due to the formation of the insoluble oxide of chromium under the action of light. This lesion is persistent and causes diminution of vision. Vapours containing chromic acid do not usually cause this coloration, which is almost always due to contact of the eye with the substance itself. As a matter of fact the case of keratitis reported by Koll in 1905 was due to carrying chromium to the eye by means of a handkerchief soiled with the irritating substance; the cases reported by Bayer in 1908 occurred among workmen employed in an aniline black factory. In (1903) permanent anaesthesia of the corneal conjunctiva was observed.

As regards the ear, a few ulcers situated in the external auditory meatus have been known; more rarely still irritation of the tympanum and of the middle ear, which, however, is not at all characteristic.

Most experts admit that chromates exercise a local effect and that a general effect is scarcely likely. Others, however, speak of an action by chromates either on the respiratory or digestive passages, or on the kidney tubuli.

Ulcerations found in the mouth, tonsils, and pharynx certainly prove that particles of chromates gain access to the upper respiratory and digestive passages. But it is somewhat difficult to attribute to chromates any bronchitis, asthma, albuminuria, or nephritis observed from time to time among these workmen. The suggestion cannot be excluded that particles of chromium may be introduced by food or dirty hands into the digestive organs and there cause troubles but they are in any case very slight. Kidney lesions are very doubtful. Even though chromium was found in 4 cases out of 17 examined, at a maximum of 0.68 mg. per litre of urine, albumen was only present as a trace or was absent.

Chrome colours and lead chromate often cause lead poisoning with its well-known symptoms. Cases of ulceration or perforation of the septum among workmen who handle these colours are unknown.

Detection

(a) In the air. — Air is aspirated by means of a receptacle containing about 75 litres of water, at the rate of about one litre per minute, and passed through a filter of cotton placed at the point where it is carried into a horizontal glass tube about 25 mm. in diameter, and finally drawn through a wash bottle filled with distilled water. The amount of chromate found is estimated in the form of bi-chromate of sodium. The cotton is carefully reduced to ashes in a platinum crucible. The ashes are melted with carbonate of soda and chlorate of potassium; the product so obtained, which contains all the chromium in the form of chromate, is extracted with water, rendered acid, and reduced; then the oxide of chromium is precipitated by ammonia or weighed after suitable treatment.

(b) In the urine. — Urine to which carbonate of soda has been added is evaporated and incinerated. The residue is extracted with water, evaporated, melted with carbonate of soda and chlorate of potassium, then dissolved in water, and after that in warm dilute sulphuric acid. The ash which had been submitted to extraction at the start is rendered acid and boiled with alcohol; it is then added to the acid solution. The chromium becomes changed into sulphate of chromium. The mixture is rendered alkaline with ammonia; it is then treated by sulphuric hydrogen for an hour. The precipitate is filtered and melted with carbonate of soda and chlorate of potash; the residue is extracted with water and rendered acid. The solution is then rendered alkaline by potash lye, oxidised by hydrogen peroxide and evaporated to dryness. It is extracted by water and filtered. Chromium is detected by colorimetry or titration.

Other different methods have given results which are not as good. In particular, it is inadvisable to isolate chromium in the form of hydroxide, after transformation of the chromate into sulphate of chromium. In the same way the use of coloration of chromate of silver, with a view of detecting small quantities of chromium, is practically impossible because of the great quantities of chlorides always present.
HYGIENE

As has been said above, risk of injuries caused by droplets and dust of chromates depends not only on the industrial operation, but chiefly on the technique adopted. As a matter of fact precautionary measures and an adequate installation can so reduce the danger to a minimum that one can scarcely imagine injury to the respiratory system of the workmen being possible; while risk of cutaneous ulceration should be at a vanishing point. Ulcers may be observed, but generally the lesions are of little importance and suitable treatment rapidly cures them.

Workplaces, yards, and covered passages must be kept as far as possible free from contamination with chromates; all necessary care must be taken as soon as possible to remove chromates which soil workplaces, floors, and walls, as the result of splashing from leaky vats or of leakage from pipes, which may dry in situ. Strict cleanliness of the floors, walls, apparatus, and tools must be ensured; and also thorough cleaning whenever necessary, and at least once a quarter.

The operations of fusing the raw materials, drying the melted mass before it is cooled, and concentration and evaporation to obtain crystals of bichromates set free vapours containing particles of chromium. Hence it is essential to prevent the escape of these vapours, not only by using a closed apparatus furnished with efficient exhaust ventilation, but by installing an automatic system which reduces to a minimum, or entirely eliminates, manual labour. Melted materials, except when close to the furnace, must only be deposited in a place which is specially set apart for this purpose. If the melted material is still hot, it can be moved in any kind of receptacle; but if it is cold, trolleys or closed receptacles only must be used.

Vats for lixiviation or for evaporation, as well as other receptacles containing solutions at a higher temperature than 50° C., and acidifying vats, must be provided with an exhaust ventilating-cowl to convey the vapours outside the workplace, or better still to convey them to a chimney. This operation can be made healthy by removing fumes by aspiration or by a very efficient exhaust, when the bichromate of soda produced is not in the dry state; receptacles containing corrosive liquids must be effectually closed if the sides do not ensure the workmen efficient protection against any overflow of the solutions. The circulation of saline solutions must be carried out by a watertight system of pipes or by other mechanical means.

Every precaution must be taken to prevent any production of dust in the workplace. This is why the operations of grinding, emptying, furnace cleaning, sifting, mixing, drying, pounding, and packing must be done in hermetically-sealed apparatus with efficient exhaust ventilation, and, if possible, by automatic means. It is advisable for these operations to take place in separate workplaces. If it is not possible to prevent chrome dust from rising, or to remove it at once and completely, the workmen should be supplied by the employer with respiratory system of ventilation to protect the nose and mouth. Such respirators must be washed at least once a day and kept in good order by a responsible person. But this measure is notoriously inefficient, and it is clearly necessary to replace manual labour by mechanical processes wherever possible.

Measures must be taken to remove waste materials and waste water. Waste materials may be deposited as a temporary measure either in tanks, or ad hoc in storehouses, provided that they are protected from rain and that they do not soil the ground. The waste water must only be discharged into sewers after neutralisation.

Care must also be taken to condense nitrous vapours or to discharge them into a very high chimney.

At all works for chrome plating a good system of ventilation must be arranged above the vats. Lead material must be replaced by aluminium. The plant set up should be technically irreproachable. The workmen should be provided with means for personal cleanliness, and the personnel should be compelled to observe the prescribed regulations.

Measures for individual hygiene are very important. The workmen should be instructed as to the dangers associated with chromates and the best means of protection, either verbally or in the form of written medical examinations or by pamphlets and posters.

All candidates for work should be medically examined to make sure they have no lesion of the skin or no disease. Daily examination should be made of the hands before or after work by persons trained to detect or prevent ulceration. Medical examinations periodically and also on resuming work after absence for any cause whatever should be instituted; they are required monthly in Germany and Great Britain. Inspection of the condition of the
mucous membranes is necessary, especially those of the nose and posterior part of the mouth. In a German factory this inspection is made twice a week. The inspection must be very strict for apprentices, so that those predisposed to skin eruptions, those who show sores, the weak, and the tuberculous may be promptly eliminated. In short, an instructed and permanent labour staff informed as to the risk incurred must be ensured.

When mechanical protection is impossible or insufficient, the mouth and nose should be protected as well as the eyes and the skin.

With this in view, not only the wearing of goggles is advised, but the application to the skin of special ointments and a suitable treatment for the nasal mucous membrane is necessary. Thus, for instance, Collis and Hunt suggest the use of a substance, insoluble in water and bichromate, which is very useful for tanners. It is composed of mineral vaseline (1,360 grm.), soft paraffin (150 grm.), and cyllin (85 grm.).

Others advise the introduction into the nostrils of plugs of cotton wool moistened with a substance, insoluble in water and bichromate, which is very useful for tanners. It is composed of mineral vaseline (1,360 grm.), soft paraffin (150 grm.), and cyllin (85 grm.).

Levi, of Milwaukee, recommends the application of a pomade with a ichthyol basis, balsam of Peru, and sal ammoniac: which is very useful for tanners. It is composed of paraffin (170 grm.), ançl cyllin (85 grm.).

For the nasal mucous membrane, as well as for parts of the skin which may be exposed or be invaded by particles of chromates, a suitable treatment is necessary. Thus, for instance, Collis and Hunt suggest the use of a substance, insoluble in water and bichromate, which is very useful for tanners. It is composed of mineral vaseline (1,360 grm.), soft paraffin (150 grm.), and cyllin (85 grm.).

Levi, of Milwaukee, recommends the application of a pomade with a ichthyol basis, balsam of Peru, and sal ammoniac: which is very useful for tanners. It is composed of paraffin (170 grm.), ançl cyllin (85 grm.).

Ample provision must be made for cloakrooms; for washing accommodation provided with nail-brushes and soap; for douche baths, to be taken twice a week; and for containers which should be situated so as not to be soiled by particles of chromates either from dust or fumes. (See also article "Leather and Skins").

**LEGISLATION**

The absolute exclusion of women from operations which necessitate contact with chromates is provided for in Argentina, Germany, Great Britain, Holland, Japan, and Russia; of young persons under sixteen years in Belgium and Germany; of young persons of less than eighteen years in Great Britain, Holland, Poland, and Russia; of boys of under fifteen years and women under twenty-one years in Italy; and of boys under sixteen years and women under twenty-one years in Spain.

Special legislation for alkaline chromate factories exists only in Germany (16 May 1919) and Great Britain (9 August 1913). Regulations of 21 January 1907 made in Great Britain for paints and colours and also the Belgian Royal Decree of 5 November 1910 contain provisions for dealing with colours with a basis of chromate of lead.

A British Welfare Order of 22 March 1918 provides for hygienic measures for workmen employed in tanning with bi-chromates; another of the same date provides for the protection of workmen in factories where bichromates are used for dyeing. An Order of 11 July 1922 for the chemical industry covers the manufacture of chromates, bichromates of potassium and sodium, the handling, transport, or any other work on these substances connected with their manufacture (see sections 22 et seq.).

In Russia, an Order of 1923 (no date), concerning measures of precaution to be
taken in the manufacture of chromium salts, deals with the work of adolescents and women, with the duration of work, the arrangement of the workplaces, lighting, heating, ventilation, and prophylactic measures.

For the instruction of workers leaflets have been provided by the British, German (1927), and Netherlands inspection departments. These instructions must be posted in workplaces and medical examination rooms.

Lesions caused by chromic acid and alkaline chromates are compulsorily notifiable in France, Great Britain, the Netherlands, and Russia. They are compensated as industrial accidents in the following countries: Australia (Western Australia, Queensland), Austria, Chile, Great Britain, Japan, New Zealand, Ontario, Switzerland, Venezuela and U.S.A. (Minnesota, New Jersey, New York).

These lesions are also included for compensation in other countries by a covering definition. (See article "Occupational Diseases: Compensation").

Clerks and Office Employees

(Professional and Commercial)

As might be expected, varying degrees of risk from a health point of view attach to the varied categories of employment indicated above, including such occupations as those of commercial, railway, shipping, insurance, stockbrokers' and lawyers' clerks, Civil Service clerks, bookkeepers, stenographers, typists, travelling salesmen, porters, and messengers. Medical statistics prove that the average health of office workers is far from being satisfactory — particularly that of commercial clerks, which occupation is ranked as one of the most unhealthy in the Registrar-General's annual reports (Great Britain).

In a graded list comprising 180 occupational groups, that of clerks in general occupied the eighty-seventh position in 1911. Insurance clerks, however, rank twelfth on the list. For the period 1921-1923, in a list comprising 178 occupational groups, clerks are classed as occupying the eighty-eighth place and insurance employees (forming a single group with bank clerks) the fifty-ninth place. Insurance agents forming one group with solicitors rank ninety-seventh, whilst insurance officials occupy the third place. The reason for the low mortality among insurance officials is certainly the medical entrance examination, the encouragement and opportunity given for athletics, together with good objective conditions in general, and the same applies to Civil Service clerks, mostly recruited from a social class enjoying greater opportunity for physical development and care of health. In a list of 178 occupations given in the Registrar-General's statistics for the period 1921 to 1923, Civil Service employees and clerks occupied the seventeenth place.

The position of clerks, and especially that of commercial employees, who appear fairly low in the list, is less satisfactory from a health point of view. The reason is to be sought in various unfavourable objective conditions: struggle for existence, etc. Lawyers' clerks maintain an average position between commercial clerks and employees and Civil Service clerks.

Two sets of factors are mainly responsible for sickness and general lowered vitality found amongst these workers: first, working surroundings, and secondly, external influences indirectly dependent on work which is poorly remunerated. The first of these covers deficient air space, bad ventilation, temperature, poor lighting, and unsatisfactory sanitary conditions, as well as work in basements, at outside stalls, insecurity of employment, low salaries and high prices, excessive hours (in certain services, and at certain periods), lack of organisation, unduly early commencement of career, inferior mealtime arrangements, sedentary work, and mental and physical strain; while the second series may be said to include crowded travelling to and from business, lack of open air and physical exercise, lack of initiative and suppression of personality, inferior housing conditions, insufficient medical attention, insufficient rest and nourishment, suburban neglect of local community interests, strain of work and continuation classes after office hours, public holidays and trying conditions (travelling on public holidays), poverty, and adverse family circumstances.
An American enquiry into lost time due to sickness, covering the year ending January 1921 and relating to 1,382 office employees, revealed an annual average of 8.15 days per person, and a similar average over 8 days was arrived at by the Committee on Industrial Waste of the Federated American Engineering Societies, reporting on 42,000 male and female employees. In the first estimate the majority of employees were women, and an average of 2 days per head due to an influenza epidemic was included, but the average age of employees was only 23.7, and health was under careful supervision.

According to Emmons, during a month in the year 1920 (22 working days), the medical service of a commercial establishment was requisitioned 310 times, that is to say, benefits were accorded to 44.5 per cent. of the employees. In another commercial establishment employing 3,000 persons, medical visits amounted to 1.2 per head.

A German insurance society for clerks accorded, in the course of twelve years, benefits to 50,000 members, 16,000 of which were granted in respect of pulmonary tuberculosis.

An enquiry effected in New York relating to seventy-two firms (insurance companies, banks, wholesale manufacturers, engineering, advertising, and publication offices) showed that few firms had definite rules for payment of salary during illness, but in general payment over a "reasonable period" was reported and usually full pay for a time at least. A few firms deducted sick leave from annual leave.

Pathology

Tuberculosis is the most prevalent disease amongst law and commercial clerks. Besides pulmonary and respiratory diseases, the other effects of occupation most commonly noted amongst clerks in general are particularly neurasthenia, nervous diseases, anxiety, neurosis, eyestrain and shortsightedness, malnutrition inducing physical and mental deterioration, mental fatigue, depression, arrested growth, digestive and metabolic derangement, low vitality, mental atrophy, headaches, exhaustion, irritability, hypersensitiveness, obsessions, sleeplessness. Nervous fatigue and lowered vitality very often affect eyesight, which in turn reacts on the nerves, since the effort required for the act of concentration uses up the reserve of nerve energy and increases neurasthenia. Clerks fear nervous breakdown and ocular neurasthenia on account of dismissal, and anxiety adds to nervous fatigue. Often they cannot afford good treatment to prevent errors of refraction and only visit unskilled opticians who give incorrect advice. Apart from these general

Statistics

**British** mortality statistics (1911) for commercial clerks, by far the largest clerical group numerically — are as follows (per 1,000): phthisis and tubercular diseases, 239; diseases of the heart and circulatory system, 141; diseases of the nervous system, 128; cancer, 116; diseases of the respiratory system, 115; diseases of the digestive system, 67; and of the urinary system, 63.

For the period 1921 to 1923 these figures are: tuberculosis, 272.4; heart affections, 127.2; diseases of the circulatory system, 127.2; diseases of the nervous system, 122; cancer, 116; diseases of the respiratory system, 115; diseases of the digestive system, 67; and of the urinary system, 63.
