First and foremost hernia must be avoided. It is obvious that this form of lesion forbids the lifting and carrying of heavy objects, standing for any length of time, work at sewing machines, blow-pipe work and using wind instruments. People suffering from hernia are often hampered in their movements; in this case operation is advisable, especially as it is a simple and safe procedure which has, as a rule, satisfactory results. Whilst there is no risk in advising an operation in a case of hernia, especially as the best truss obtainable is inadequate if the man is to do heavy work, an operation in the case of other diseases of the abdominal organs must not be undertaken lightly.

In cases of repeated attacks of appendicitis there should be no hesitation in recommending an operation in the interest of capacity for work; for in these cases the purely medical indications are identical. The doctor's responsibility is far heavier when he recommends an operation chiefly on economic grounds with a view to maintaining the capacity for work. This, for instance, applies to a case of ulcer of the pylorus or duodenum, or to a case of biliary or renal calculus. Here has to be faced the question of an unhealthy constitutional condition which cannot be avoided. But even in these conditions an operation should be decided on if repeated attacks keep on impairing to a noticeable extent the capacity for work. By means of the operation the patient recovers for a time at least, and sometimes for quite a long period, his full capacity for work.

These problems are not firmly enough fixed in the medical mind as yet, and their solution involves not only extensive medical knowledge, but also a very complete acquaintance with the individual's economic conditions, and of his means of holding his own in the labour market.

Yet another point arises with regard to diseases of the abdominal organs; that of deciding how long sick men can remain capable of work. Perhaps prognosis may be fairly easy to make
in a case of carcinoma; but it is far more difficult when it is concerned, for instance, with a question of organic disease of the pylorus, with resulting dilatation of the stomach; and it is still more complicated when one is face to face with the onset of cirrhosis of the liver. The doctor, in this case, has to weigh up accurately the relation between the capacity of reserve energy and the possible industrial injury. He must have a high standard of medical knowledge; he must be able to consider each case from a strictly individual point of view, and also be able to draw upon his own knowledge and experience; for at the present time there is no fixed rule of action in this field of medical work.

The scientific development of industrial medicine in this direction should, in the interest of the workers, be hastened as much as possible, for with it is connected the solution of other difficult problems, such, for instance, as those of nervous diseases.

**Dr. J. Lowy**

(Prague)

**Nervous System**

The incessant progress of industrialisation in civilised countries, which has even extended since the war to countries up till then relatively uncivilised, has necessarily increased the demand made on the nervous system. Under the conditions created by the war and during the first phase of industrialisation, unemployment, worry, scanty nourishment — in brief, all the forms of social wretchedness — have made their pernicious action felt on the sanitary condition of the population. It was, however, possible to determine the causes of this damage and to minimise them to some extent.

A review of industrial diseases as surgery as this must be does not allow of a complete account of all the harm that industrialism may exert on the health of the workpeople, such as the development of fatigue, the increase in the spread of venereal disease, especially of syphilis, alcoholism, etc., which have been found among the workers of all industrial communities, with the exception perhaps of very few countries. As a consequence, there has been a parallel increase in nervous and mental diseases.

A brief description only will have to be given of the nervous and psychic diseases which may be regarded as an immediate effect of the occupation, as such meriting the appropriate title of occupational diseases.

Mention only is made of such maladies as are outside the central nervous lesions due to toxic agents or infections as, for example, those due to the growth of parasites (cysticer cus, echinococcus, distoma, actinomycosis).

1. **Spinal Cord**

Occupational diseases of the spinal cord may be due to poisons: these cause especially myelitis and are mainly due, apart from alcohol, to lead, arsenic, carbon disulphide, chloroform and carbon monoxide; the last-named poison can even, as the result of multiple haemorrhages, bring about the signs of sclerosis. Lesions due to temperature (rheumatism and rheumatoid myelitis, sclerosis following chill) are met with among persons exposed to bad weather conditions (peasants, foresters, farm labourers, workpeople, soldiers, etc.).

Traumatism, severe effort and fatigue result similarly in myelitis, haemorrhage into the cord (especially as the result of carrying heavy loads), sometimes sclerotic patches, myelomalacia (among workmen employed in caissons, and divers), syringomyelia (the temperature anaesthesia of chauffeurs, erectors, blacksmiths, etc.).

Locomotor ataxy (tabes dorsalis) is a post-syphilitic disease and cannot be classed as of industrial origin except in so far as the circumstances of the employment may hasten its evolution.

In studying the outside factors influencing tabes, L. Rosanes has tried to fix what is the part they play in determining or aggravating it. Alcoholism with its tendency to provoke nervous troubles clinically close to those of tabes, perhaps plays an important role in para-syphilis by impeding the power of regeneration of the nerve cell.

In the case of saturnism sometimes met with, it is difficult to rely on a like explanation, the clinical picture differing so much from that of tabes.

Sudden chill may assist in the development of tabes. Physical fatigue, the result of the war, has provoked a very clear recrudescence of tabes in women.

Injury has in many cases exercised a very definite part, but the part which coincidence may play ought not to be forgotten. Industrial fatigue may play a part in the localisation of tabes: amaurosis has shown itself especially in subjects whose life work is exacting and close (mechanics, seamstresses, shoemakers); the symptom known as perforating ulcer affecting subjects who are subjected to constant standing.
2. NEUROSES

It is not the intention here to study how far industrial neuroses constitute especially a symptom of general nervous exhaustion, and to review the consequences of chronic fatigue or a manifestation allied to general neurasthenia; or again to go into questions belonging to the vast field of injuries or fatigue.

With the progress of knowledge of general nervous maladies it is now possible, thanks to the researches on fatigue, to make distinction in different cases as to whether the cause is industrial or not. Whatever be the truth at the present time, it is desirable to review the field of occupations which bring about occupational neuroses.

Industrial work, the utilisation as readily as possible of the forces of labour, the mechanisation of numerous industrial jobs, the monotony of the operations which convert the workman more and more into a machine, all have a decidedly injurious psychical effect. In spite of the different efforts made to interest the workman in his task (sharing in benefits, social work of all kinds), the fact remains that the majority of industrial workers have lost joy in their work. The wage question is the one and only interest and the principal object; the fear of unemployment, of inability to work, increases the nervous condition and adds naturally to discontentment, to strikes and measures of reprisal on the part of the employers.

All these matters affect even more intellectual workers. In many countries the war has destroyed many values, thousands of men wounded; during its course are more or less affected in their capacity to work or have become incapable of work. Effort has been made to parry these injurious consequences, but it has even led to an increase in the unemployment of the intellectual workers, technical experts, chemists, medical men, lawyers, etc.

These circumstances, together with the political instability which still prevails in the world in spite of all the efforts of peace organisations, render the struggle for existence still harder. Functional neuroses are sufficiently frequent; it will suffice to mention their many causes: infections, intoxication, over-pressure, injuries; and outside the factory the role played by food, housing, etc.

Workpeople are also to-day a prey to neurasthenia, a functional neurosis implanting itself on a pre-existing state of loss of nervous energy, and due principally to anxiety arising from the feeling of instability and insecurity. It is found among all classes of society.

The feeling of responsibility is another cause of neurasthenia and explains what is met with among medical men, locomotive-drivers, chauffeurs, railway workers, telegraph and telephone operators, managers, police agents, transport workers in large cities, etc.

Very often injuries set up a hyster neurasthenia which shows itself in symptoms such as those commonly met with: cerebral, spinal and visceral affections.

Hysteria is not a malady peculiar to women; it attacks men also. The emotions, injuries, intoxication and nervous contagion facilitate its appearance. Traumatic hysteria bears a close resemblance to common hysteria.

The anxious state of mind of a person who has met with an accident and is expecting to receive compensation is also a very important etiological factor.

Forms of neuroses were studied among the victims of the first railway accidents. This morbid condition was described by English surgeons under the name of "railway brain" and "railway spine" because cerebral and spinal symptoms dominated the clinical picture.

While traumatic neurosis was denied at first it is now fully accepted following on the numerous observations made.

Certainly traumatic neurosis among healthy people is rarer than was believed because generally it only affects individuals with a personal or family neurotic susceptibility. For a long time much was talked of "malingering" in these forms. Charcot said that the idea of malingering was very often based on the ignorance of the physician. And as a matter of fact these cases only vary within the very wide limits of 1.5 to 36 per cent.

Social legislation, especially compensation for accidents, has caused an increase in these cases of so-called malingering; but they should not be exaggerated because authorities believe that they are not the principal nor the most important cause of this increase.

Certain instantaneous cures after payment of compensation have been looked on as proof of malingering whereas, on the contrary, they are due to auto-suggestion which is as real as a complaint although of purely psychological origin (Cevidalli).

These cases, which are classed under the name of malingering, are really very rare. One in 5,000 cases of accidents in Austria; 12 in 24,000 accidents on the Italian railways; 3 observed by
Bernacchi during twelve years among 23,000 accidents (Allevi).

Traumatic neuroses are then generally the expression of the predominance of a lack of will power in face of certain circumstances as the result of an emotional state bound up with some economical interest or other. According to this view aided by analysis of phenomena, in accordance with present knowledge of neuroses generally, the picture of a traumatic neurosis has the character of an anxiety neurosis or "sinistrosis". Hence the diminished importance, as a predisposing factor, to be attached to it in poisoning.

Injuries of the head or other parts of the body are often the cause of a psychosis which may occur suddenly (rare), but more frequently does so after the lapse of some time. The psychical effects are rarely immediate; they come on as a secondary phenomenon and may be accompanied by malaise, headache, paralysis, etc. Sand is of opinion that psychosis appearing five years after an injury can have no relation to it.

Individual or family predisposition is not absolutely necessary nor has the seriousness of the accident an absolute value. The injury sets up all the clinical symptoms of mental disease: psychosis, hysteria, epilepsy, etc. The victims of accidents who have difficulty in obtaining compensation when affected by traumatic neurosis show the symptoms of paranoia, agitation or persecution mania. Further, as a result of trauma cases of mania, melancholia, mental confusion, progressive paralysis and delirium tremens are described.

Lastly, the neurosis of telephonists (see that article) and tetany which can, although rarely, be set up by lead, phosphorus, chloroform and atropine should be cited. Frankl-Hochwart found among 399 cases of tetany, 174 shoemakers, 95 tailors, 26 cabinet makers, 20 locksmiths and 19 lathe workers. This malady has also been described as shoemakers' cramp.

3. CRAMPS

The neuroses of most importance from a practical point of view are those affecting co-ordination of movement, such as occupational or professional cramps, which are characterised by tonic and clonic spasms, by tremors or paralytic affections. They occur only in connection with a functional or customary professional act and are localised in certain muscles habitually accustomed to perform harmoniously this regular act (Macé de Lépinay). These affections are incorrectly described as cramps, spasms, and loss of power. They would be better described by the term "dyskinesias" (Jaccoud) or "professional neuroses of the co-ordinating centres" (Benedict). They ought not, according to these authorities, to be described under the name of neuralgias or occupational palsies.

These accidents with their selective qualities only occur under two conditions: hereditary predisposition of the subject and frequent repetition of the same functional act. These conditions are necessary, but one of them alone is not sufficient.

In some they originate peripherally, in others centrally, but whatever be the origin, it is necessary for the condition to take on its peculiar features — that the mental factor should always enter. In not a few of the cases some definite anatomical lesion is present in the affected member — arteritis, myositis, synovitis, neuritis, but in the majority of cases no local lesion can be found.

The prognosis in every professional form of cramp should be given with reserve and should be based on the cause which has given rise to the affection; on the existence or pre-existence of other neuroses; on the mental state of the patient; on the length of time the malady has been present.

The professions concerned are very various. Without giving a complete list, it may be recalled that Oppenheim has described in his book a cramp occurring among pianists, violinists, flautists, violoncelliists, harpists, organ players, drummers and orchestra conductors. A professional cramp has been described as affecting seamstresses, telegraphists, shoemakers, cigar makers, watchmakers, hairdressers, folders of newspapers, locksmiths, tinsmiths, nailmakers, workers in wool, silk ironers, florists (making bouquets), fencers, motorists, milkers, etc. Oppenheim considers that the cramp observed in sawyers and similar manifestations in quite a number of other trades such as turners, saddlers, cabinet makers,Waiters, ought all to be classed among professional palsies of neurotic origin.

The typical neurosis of this kind is the well-known writers' cramp (graphospasm, metathorgraphia) which is distinguished according to its main symptoms as a form of contraction either paralytic, or a tremor or a neuralgia. Writers' cramp may occur as an occupational malady in all the professions where it is necessary to write much and rapidly, that is, among
those employed in commerce, in offices, among shorthand writers, officials, etc.

As a result of the introduction of typewriting machines this neurosis has become rare; but it is still met with sufficiently frequently among typists, who are often badly paid and obliged to work overtime. Long continued shorthand-writing fatigues the hands, and the nervous system is injured by a state of general fatigue, especially when work is done at night.

Oppenheim has himself observed a form of cramp in a hairdresser in the act of shaving (cheirosparasm or xyrosparasm which he distinguishes from cheirophobia). Professional neuroses have been described among diamond cutters and money changers. Here it is a combination of neuroses and difficulty in co-ordinating movements of the upper limbs.

This lesion similarly although more rarely affects the lower limbs in dancers, soldiers, tradesmen's tri-cyclists, seamstresses, sewing machine workers, knife and scissor sharpeners, harp players (muscles of the calf), etc.

Identical cramps of the muscles of the head are still rarer. Cramp of the tongue in clarionette players and of the lips in trumpet players have been described by Oppenheim, who cites also certain cases of neuroses due to continued microscopical work (spasm of the muscle of accommodation), in watchmakers (spasm of the orbiculoris), and nystagmus analogous to that of miners in a cathedra. Statements as to traumatic lesions of the peripheral nerves as a consequence of injuries which can, under certain conditions, be regarded as industrial accidents, it will suffice to bear in mind that they also involve medical considerations in the domain of industrial medicine, especially when these lesions arise from small repeated multiple injuries in the course of work (pricks, bruises, wrenches, cuts and, more particularly, pulling strain and pressure) which are important in that they may give rise to paralysis.

Under the name of professional neurites, Oppenheim includes injury caused by continuous pressure of a tool on certain nerves bringing on inflammation.

In the upper limbs neuritis of the ulnar has been described, with paralysis and paraesthesia, among other symptoms in bicyclists, metal turners, watchmakers, hat finishers, glasscutters, tanners, bilhors, cabinet makers, shoemakers, glassblowers, typists, engravers, telephone and telegraph workers, diamond and crystal cutters, violincellists, ice-sawyers, waiters, poker workers, bakers, healers, workers in incandescent lamp factories, etc.

Neuritis of the median nerve has been observed in finishers, cabinet makers, locksmiths, carpet beaters, dentists, blacksmiths, etc., and in a cutter in consequence of continuous use of a pair of scissors.

Neuritis of the brachial plexus has been found in watchmakers, cabinet makers, gymnasts, boiler makers, soldiers, shoemakers, carriers of heavy loads (Oppenheim and Salomonson), etc.

Professional neuritis of the muscles of the hands has also been described in sedentary professions (professors occupied at their desk, office workers, book-keepers, seamstresses, shoemakers, etc.).

The distinction between neuroses and professional neuritis may sometimes be very difficult — especially when the two are combined — and may even be impossible if the classical symptoms of neuritis (muscular atrophy, reaction of degeneration) are not present. On the other hand, the signs of muscular atrophy may be the prodromal indication of a progressive muscular dystrophy, disease of the spinal cord, so much so that every care must be taken as to prognosis in each case.

Even when the diagnosis of neuritis is certain, it is not always easy to say, in every case, whether it is a neuritis due to the occupation or not (infection, alcoholism).

Without wishing to lay down ex cathedra statements as to traumatic lesions of the peripheral nerves as a consequence of injuries which can, under certain conditions, be regarded as industrial accidents, it will suffice to bear in mind that they also involve medical considerations in the domain of industrial medicine, especially when these lesions arise from small repeated multiple injuries in the course of work (pricks, bruises, wrenches, cuts and, more particularly, pulling strain and pressure) which are important in that they may give rise to paralysis.

Under the name of professional neurites, Oppenheim includes injury caused by continuous pressure of a tool on certain nerves bringing on inflammation.

In the upper limbs neuritis of the ulnar has been described, with paralysis and paraesthesia, among other symptoms in bicyclists, metal turners, watchmakers, hat finishers, glasscutters, tanners, bilhors, cabinet makers, shoemakers, glassblowers, typists, engravers, telephone and telegraph workers, diamond and crystal cutters, violincellists, ice-sawyers, waiters, poker workers, bakers, healers, workers in incandescent lamp factories, etc.

Neuritis of the brachial plexus has been found in watchmakers, cabinet makers, gymnasts, boiler makers, soldiers, shoemakers, carriers of heavy loads (Oppenheim and Salomonson), etc.

Professional neuritis of the muscles of the hands has also been described in sedentary professions (professors occupied at their desk, office workers, book-keepers, seamstresses, shoemakers, etc.).

The distinction between neuroses and professional neuritis may sometimes be very difficult — especially when the two are combined — and may even be impossible if the classical symptoms of neuritis (muscular atrophy, reaction of degeneration) are not present. On the other hand, the signs of muscular atrophy may be the prodromal indication of a progressive muscular dystrophy, disease of the spinal cord, so much so that every care must be taken as to prognosis in each case.

Even when the diagnosis of neuritis is certain, it is not always easy to say, in every case, whether it is a neuritis due to the occupation or not (infection, alcoholism).

Without wishing to lay down ex cathedra statements as to traumatic lesions of the peripheral nerves as a consequence of injuries which can, under certain conditions, be regarded as industrial accidents, it will suffice to bear in mind that they also involve medical considerations in the domain of industrial medicine, especially when these lesions arise from small repeated multiple injuries in the course of work (pricks, bruises, wrenches, cuts and, more particularly, pulling strain and pressure) which are important in that they may give rise to paralysis.

Under the name of professional neurites, Oppenheim includes injury caused by continuous pressure of a tool on certain nerves bringing on inflammation.

In the upper limbs neuritis of the ulnar has been described, with paralysis and paraesthesia, among other symptoms in bicyclists, metal turners, watchmakers, hat finishers, glasscutters, tanners, bilhors, cabinet makers, shoemakers, glassblowers, typists, engravers, telephone and telegraph workers, diamond and crystal cutters, violincellists, ice-sawyers, waiters, poker workers, bakers, healers, workers in incandescent lamp factories, etc.

Neuritis of the median nerve has been observed in finishers, cabinet makers, locksmiths, carpet beaters, dentists, blacksmiths, etc., and in a cutter in consequence of continuous use of a pair of scissors.

Neuritis of the brachial plexus has been found in watchmakers, cabinet makers, gymnasts, boiler makers, soldiers, shoemakers, carriers of heavy loads (Oppenheim and Salomonson), etc.

Professional neuritis of the muscles of the hands has also been described.
among coachmen (Raynaud, Constelmont), as well as an occupational palsy among lithographers (Vogt). Under the name of occupational paralyses, Oppenheim has described in accordance with observations of Bergen, Remak, Leudel, Bernhardt, Baraks-Dvidlicky, Hunt, and of his own, an atrophy of the first interosseous muscle and of the opponem pollicis in a file cutter, muscular atrophy in file cutters, paper folders. Some of these are workers indeed in whom the possibility of lead poisoning is not excluded.

Neuritis of the lower limbs is less frequent: it affects the cranial, nerves of the leg, especially of the fibula in the case of turners, sewing machine workers, workpeople in a bent position, employed in weeding or digging potatoes or peat, asphalters or street pavers, or persons employed in laying drains. Neuritis of the tibial has also been observed.

Fatigue is further often the cause of neuritis which complicates the occupational neuritis among cigar rollers (Coester), among sandworkers and letter sorters (Steiner).

5. CRANIAL NERVES

Lesions of the cranial nerves are rarer and due to poisons, particularly to lead (loss of the sense of smell, paralysis of the recurrent nerve, of the hypoglossal and eye muscles). Lesions of the auditory nerve are due especially to explosions; lesions of the optic nerve to the injurious action of luminous rays, toxic substances (methyl alcohol: polishing furniture), or are met with in processes involving fatigue of the eyes (engravers).

Mention ought to be made of the fact that toxic and infectious paralyses may be associated with occupational neurites (toxico-professional palsies of Oppenheim), as, for example, atrophy of the small muscles of the hand such as occurred to a woman during her convalescence from influenza, after working at sewing.

Poisons of the Nervous System

Cases under this heading constitute forms merging into real toxæmias of the nervous system, which may be produced in the course of general occupational intoxications, but sometimes (polysymptomatic saturnine neuritis) in the arms and legs often constituting a syndrome of arsenical pseudo-taebes, because involved in it are difficulty of speech, optic neuritis, and epileptiform seizures. Diagnosis per se can be established when the case history brings out the possibility of arsenical poisoning, but
especially from the examination for arsenic (in the urine, hair, etc.).

Diagnosis of manganese poisoning is more difficult, involving as it does psychical changes (laughing, crying), loss of sensation of paralyses, and notably difficulty in walking and speech, which sometimes lead to mistaking this form of poisoning for a disease of the spinal cord. If the mangano-phobia among workers in manganese described by Jaksch is borne in mind, special care is necessary before making the diagnosis of true manganese poisoning.

Industrial maladies from phosphorus, chrome, antimony, zinc and silver do not lead to special nervous changes—at least not when uncomplicated by lead as is the case with certain chromé colours.

On the other hand hydrogen sulphide, carbon disulphide and chronic poisoning through carbon compounds do bring about nervous changes. Those due to hydrogen sulphide include headache, vertigo, delirium, somnolence, and sometimes attacks of fury or a condition of stupor. In those with chronic poisoning have been described of inco-ordination of movement, paralyses, mental affections amounting even to dementia—symptoms well known in chronic poisoning from sewer gas or emanations from cesspools.

In poisoning from carbon disulphide the nervous symptoms are still more prominent. Following prodromal symptoms of headache, paralyses of the extremities, then a condition of maniacal excitement, which may last for weeks or months, followed lastly by psychical depression and sometimes by psychoses and forms of neuritis. The diagnosis is at times difficult, especially if knowledge of the exposure to carbon disulphide is missing. Erben recommends the following reaction: pass expired air into a colourless alcoholic or ethereal solution of triethylphosphine. The red colour produced by the carbon disulphide is very useful in deciding the diagnosis.

Non-fatal poisoning by cyamogen compounds produces paralyses of the extremities, hallucinations and, in chronic cases, insomnia, delirium, and paralysis of the pupil have been described.

Chronic poisoning from carbon monoxide is the most important from a practical point of view because it occurs far oftener than all the forms of poisoning previously mentioned. The nervous manifestations consist principally in paralysis, cramps, affections of sight, and psychical disturbance varying from simple amnesia (loss of memory) to states of the most violent excitement psychosis analogous to the psychosis of Korsakow, pseudo paralyses, and multiple scleroses. Diagnosis may be difficult in certain circumstances when the action of carbon monoxide is not borne in mind. On the other hand, other forms of intoxication may be mistaken for that of carbon monoxide. Moreover, it is the chronic poisoning which presents the greatest difficulty in diagnosis.

Functional affections of the nerves have been described: pseudo-tabes, pseudo-paralyses, multiple scleroses.

Neither phosgene nor nickel carbonyl, substances very similar to carbon monoxide, appear to cause nervous symptoms as there is no reference to this in medical literature.

Poisoning by carbon dioxide produces symptoms of asphyxia, but not any special nervous affections.

Organic toxic substances give rise to a host of nervous affections, as the result of the industrial poisoning they set up. Their number is very great and mention only of the most important will have to suffice here.

Petroleum benzine induces relatively often industrial poisoning by inhalation. In the chronic form it causes sensations of tension in the head, loss of the power of thought, nystagmus, fibrillary tremor of the tongue and hands, and loss of sensation to pressure in the nerves.

Crude petrol containing lower hydrocarbons brings about symptoms analogous to those of the pure substance.

Ethyl alcohol, which may be considered the most widely spread of all nerve poisons, causes in drunkards very well known lesions: alcoholic psychoses, poly-neurites, affections of sight. Little known are the professional lesions of brewers, hotel keepers, waiters, barmen, commercial travellers in wine, draymen—in short, all professions having to do with the manufacture or sale of wine or spirits. Among the higher alcohols amyl alcohol alone need be mentioned, inhalation of the vapour of which causes agrypina and chromatopsy.

Professional ether intoxication is rarely met with, and with the exception of occurrence of the Korsakow syndrome no mention of lesions of the nervous system is to be found in literature.

It is not possible to say whether persons who have indulged in ether (medical men, chemists, and their assistants, nurses), suffer ill-effects from it. In the cachexia due to ether, psychical disturbance may occupy a prominent place, as in all toxic manias as is well known; but what is least known is that children may derive the habit of ether drinking when, for example, their bread when taking their petits déjeuners is dipped in this substance (Erben).

A pernicious effect from the use of chloroform, as in the case of ether, has been observed in invalids when chloroform has been administered in the form of frictions, but also among chemists, druggists, medical men, and their wives, nurses, etc. Professional poisoning from chloroform has been observed in rare instances among surgeons and their assistants after its long use for operative purposes. One case has been reported in a chemist from pouring it from one vessel to another.

Ethyl chloroform which is used as a local anaesthetic and also for inducing narcosis
of short duration rarely induces poisoning and nervous affections.

On the contrary, hypnotics, like chloral hydrate, veronal, trional and other similar substances, in consequence of dosing in persons having the care of the sick, may cause serious nervous lesions.

Benzene, in consequence of its extremely wide technical use, causes acute and chronic poisoning. Inhalation of benzene vapour sets up headache and vertigo, buzzing in the ears, intoxication, and if inhaled for long convulsions and finally narcosis. In chronic poisoning delirium, apoplexy, hemiplegia and cramps are described.

Similar manifestations can be produced by toluene (Koelsch) and xyylene (Erben). According to Lehmann this latter substance is one-fifth more and toluene two-fifths more poisonous than benzene; they induce a more rapid narcosis and require a longer convalescence.

Among the poisons of the aromatic series, particular mention should be made of the nitro derivatives, of which nitrobenzene, in addition to blood changes, causes paraesthesia, troubles of co-ordination, convulsions, anaesthesia, and trinitrobenzene, trinitro-naphthaline and trinitrotoluene cause very serious nervous lesions. That, at any rate, is the view of Koelsch when dealing with the cases of poisoning from these substances which occurred in Great Britain and Germany. He describes the manifestations produced as follows: loss of consciousness, vertigo, numbness, insomnims, depression, mental weakness, affections of the sight, delirium, cramps.

Industrial poisoning from picric acid, as observed in one case, gave rise to pains in the legs, drunken gait, paraesthesia, loss of reflexes, pains in the nerves of the thigh, and neuritis (Koelsch).

Antimony, which is a special blood poison, causes sometimes symptoms of excitement and paralysis of the central nervous system. In serious cases generally delirium of the pupil, somnolence, coma, convulsions and occasionally difficulty of walking simulating drunkenness, or maniacal excitement are observed. In chronic poisoning, besides the tumours of the bladder, there are nervous symptoms: unsteady gait, vertigo, inco-ordination of movement and loss of sensation.

Among the toxic effects of aniline colours, not infrequently arising from impurities in them, mention should be made of paralyses caused by certain nitro and amido compounds.

Among the vegetable poisons rich in effects on the nervous system (such as curare, strychnine, physostigmine, pilocarpine, nicotine, caffeine, emetine, atropine, cocaine, opium, with its innumerable alkaloids especially morphine, and strychnine, many 'opium, morphine, nicotine, and, in later times, cocaine) have assumed great importance from the point of view of toxicology, but in regard to these it is not possible to speak of professional poisoning except in the rare event of their affecting workmen in chemical and pharmaceutical factories, or persons who handle them (doctors, chemists, druggists and nurses). The serious psychical and nervous effects of morphine and cocaine in drug addicts are so well known as to make it necessary to describe them here.

Nervous effects from tobacco which are met with usually in those who chew or cut off the ends of the rolls of tobacco with their teeth (Tabakwitzel) are shown in ambylopia, neuritis, even of the auditory nerve, and sometimes, psychoses. The effects of tobacco on the workmen in tobacco factories have been much discussed (see that article).

Poisoning among those who gather mushrooms is recognised (poisoning by the false amanita for example), as well as among persons who have charge of poisonous animals (snakes charmers, custodians of zoological gardens, laboratory research students and their assistants).

All these poisons may affect the nervous system and especially the upper limbs. Where there is a question of compensation these cases may cause symptoms suggesting malingering.

There has thus been rapidly passed in review those lesions of the nervous system which have their more or less evident cause, and even at times their material causes easily distinguishable as such in work; lesions of the nervous system produced by alcohol, syphilis, excessive use of certain muscles and nerves, and toxic substances, causing nervous lesions.

All these facts are closely connected with the pernicious effects of alcoholism, syphilis, influenza and other infectious diseases favouring or causing nervous and psychical maladies. At the present time, however, signs of a better understanding of these conditions are visible. For some time past, especially in America, great attention has been bestowed on mental hygiene. National committees have been founded in several Continental countries. This movement is in its earliest days; unfortunately it is too little known to the majority of medical men, and to the mass of workers and their trade unions.

LEGISLATION

Legislation in the Netherlands requires the notification of optic neuritis affecting coke furnace workers, gas workers, photo-engravers, autogenous cutters and welders; reporting of peripheral paralyses among asphalt workers, dock labourers, milkmen, washerwomen, labourers, pavers, those employed as chemists, ironers, potato-diggers, weavers; reporting of occupational cramps in cigar workers, seamstresses, dancers, those engaged in writing, metallurgists, musicians, pianists, knitting machinists, and watchmakers.

Compulsory notification is required in France of lead encephalopathy (Decree of 4 May 1921) and in Poland of optic neuritis.

The list of scheduled diseases under the Workmen's Compensation Acts include occupational diseases of the nervous sys-
Locomotor System

What is known as the "locomotor apparatus" will be dealt with in the first place on account of its accepted pre-eminent importance. By this apparatus is meant the combination of parts represented by the muscles, bones, cartilages, articular capsules and ligaments which constitute the lower limbs, with their three principal segments, the thigh, the leg and the foot, which are joined together and on to the trunk by three large articulations: the hip joint, the knee and the tibio-tarsal joint. The muscles are active force-exerting organs; they act through the bones, which are passive structures into which they are inserted. The bones are mobile levers moving on fulcrum points or joints. The movements originate from the central nervous system, sometimes by voluntary action, sometimes by reflex action, with a diphasic rhythm of contraction and relaxation. The mobility of the human body during locomotion depends upon this balanced rhythm, and upon the mobility of different segments of the body, kept in check by partial movements.

Locomotion is almost exclusively a function of the lower limbs, for it is only under special circumstances that the upper limbs are called upon to assist, as, for example, in swimming, crawling and climbing.

Since it must be recognised that the lower limbs serve another very important function in regard to the posture of standing, which cannot be dealt with as entirely distinct from walking, the upright posture position will be studied in its various attitudes of standing, sitting, riding and kneeling.

The occupational factors which cause anatomical and functional changes in the parts and tissues constituting the locomotor apparatus are numerous; this is more particularly the case as regards the various positions the human machine is forced to assume in order to effect certain kinds of work. In addition, the lower limbs collaborate with the upper limbs, acting as complementary structures; by this association are set going those actions and reactions which are necessary under various contingencies in order to bring about human activity in the complicated field of numerous industries. They may thus be influenced harmfully either through the working environment or the material and tools used, or the position required and maintained by technical needs, or yet by fatigue due to work of long duration or calling for short but intense, action of large groups of muscles.

As regards industrial accidents, the lower limbs rank close behind the upper limbs from the point of view of the frequency of injuries due to violent causes; on the other hand, as regards occupational diseases, they come some way after the upper limbs, owing to the fact that they escape the harmful effect of numerous injurious factors, associated with tools or working material with which the hands — the special organs of human activity — must necessarily either come in contact or be closely associated. Nevertheless, the organs of locomotion are at least equally affected by the changes effected by the influence of certain harmful occupational factors.

1. — Locomotor Apparatus

Attention will here be confined merely to a simple enumeration of occupational injuries of the locomotor apparatus. As most of these conditions are described in other articles, such as "Agricultural Labourers", "Bakery Industry", "Pottery Industry", "Rope Works", "Boots and Shoes (Manufacture of)" and "Iron, Pig Iron and Steel Industry".

(a) Affections due to conditions under which the work is carried on, and exclusively situated on, or having symptoms chiefly affecting, the locomotor limbs, are not numerous, and in general are due to injurious influences which act simultaneously on the whole body, such as high and low temperatures, or humidity.

Whereas high temperatures rarely cause localised affections, yet they may make their effects felt, especially on the feet, by causing excessive secretion of sweat ("hyperhydrosis"), e.g. blast-furnacemen, metal workers employed at rolling mills, glassworkers, stokers and engineers on board ship, even those without stockings and with wooden shoes), and soldiers after long marches. Constitutional predisposition generally favours this excessive secretion, which is localised by preference to the sole of the feet and to the interdigital spaces.
The sweat has a nauseating odour due to the ready decomposition of the fatty substances which it contains; it frequently causes a swelling, with softening and maceration of the skin, which takes on a whitish or dirty grey colour with eruptions and rhagades. This dermatitis may spread and lead to the formation of ulcerations and actual sores with all such recognised complications of infected wounds, as lymphangitis and distal adenitis.

In the same way, low temperatures in working places, in addition to their effect on the whole body, attack particularly certain parts least protected from the cold, such as the ears, nose and feet.

As regards the feet, cold acts on the peripheral circulation and nerve endings, causing a series of changes which range from the most simple and well-known erythema pernio to the most severe form of frost-bite and even to gangrene. In cold water, the extremities of the toes, may extend to the feet and encroach on the legs; it may even lead to death, chiefly as the result of general septicaemia.

The local effect of cold causes, in the first place, vaso-constriction — follows by vaso-dilation, characterised by a sensation of heat and a peculiar scarlet-red coloration, with cutaneous oedema, accompanied sometimes by phlyctenules containing sero-sanguineous fluid. If the condition does not stop there, vascular thrombosis occurs with arrest of the circulation, complete anaesthesia and dry gangrene of the tissues, which may extend along the limb with a margin of delimitation well defined from the normal tissues. The local action of cold may be further modified by conditions individual to the patient, and by such other factors as immobility, humidity, and tight shoes.

In addition to workers who are employed in cold, damp surroundings, mountain guides, soldiers and those who are employed on refrigerating apparatus are also liable to be affected by low temperatures.

The injurious effects of heat and cold may be associated with and increased by that of moist surroundings, in which the worker is compelled to work with bare feet. As an instance may be mentioned work in ricefields, where, during the weeding season, the temperature of the water varies between 20° and 45° C. After prolonged immersion of the legs, at the end of a day's work, the women workers present a condition of cutaneous hyperaemia, with lowering of the tone of the vessels and of all the soft tissues, so that in some cases— the skin has a macerated and somewhat oedematous appearance. (See article "Rice").

When a worker has to work with bare feet in cold water, as for instance in rivers, he is liable to a form of vasomotor neurosis. A condition of oedema of the extremities is then found; the toes can only be moved with difficulty and are pale and cold; a sensation of tingling is followed after a few hours by a sensation of heat and pain; the toes become red and sometimes a violet colour. This attack, which resembles Raynaud's disease, leaves forms of easily cured erythema pernio on the toes for some hours; it is due to the action of cold water on the sensory nerves of the skin; it causes a reflex vasomotor spasm with consequent paralysis of the vasomotors. Men employed in retting hemp and flax who work with their legs mostly immersed in water suffer from it; they are often affected with erythema pernio, which, from the extremities of the toes, may extend to the feet and encroach on the legs; it may even lead to death, chiefly as the result of general septicaemia.

The continued effect of cold on the feet is a source of frequent illness, without the occurrence of any local affection of the lower limbs (Branchle).

Work with bare feet in muddy places, such as excavations, and in the preparation and transport of clay, deserves special mention. Where ankylostoma is present in such ground, the legs may become the portal of entry for the parasite into the human system (Loos). Miners and gardeners are liable to contract ankylostomiases in this way.

All those who work with bare feet may be affected by such other forms of disease as dermatoses, eczemas, excoriations and ulcerations. The wounds, which may give rise to serious complications, and notably to tetanus, are numerous. Bites from leeches are quite common among those who work in the water of rivers and rice fields, and among peasants employed in hay-making and working in bare feet snake bites are not very rare.

Then again, certain forms of neuritis are due to rheumatic causes, e.g. ischialgia, met with amongst miners, stevedores, carriers, stokers and engineers, and certain forms of myalgias common among the same groups of workers and localised to the internal muscles of the thigh and calf.

The statistics of the English Ministry of Health emphasise the frequency of
cases of chronic rheumatism, especially in the forms of lumbago, muscular rheumatism and brachial neuritis. Llewellyn has called attention to the fact that cases of rheumatism are also common among women, and that almost one-sixth of the payments for sickness insurance are for cases of rheumatism among insured workers.

Among gardeners forms of rheumatism attain as high a figure as 25 per cent. of all cases of sickness (Hoffmann).

Etienne Martin and Juvin consider that a severe injury to a vertebral column, affected with old rheumatic lesions in a latent state, may cause the fracture of rheumatic neoformations and lead to a chronic vertebral arthritis with constant or intermittent pains.

(b) Affections arising from materials used do not often concern the lower limbs, because the physical action, or, as in most of the cases, the chemical action of any irritating substances — powders and liquids — used in the industries, seldom comes in direct contact with the lower limbs. The lower limbs, however, do not escape the general effect of the principal industrial poisons, e.g. lead, mercury and arsenic.

It is well known that lead paralysis almost always attacks the upper limbs and by preference the right; but it may sometimes occur, even primarily, in the lower limbs. In this case paralysis affects the external popliteal branch of the sciatic and chiefly the lateral peroneal muscles, the common extensor of the toes and the extensor of the great toe, the anterior tibial muscles not being as a rule affected. Sometimes, also, the posterior muscles of the leg, the adductors of the great toe, the foot muscles, the lumbricales and even the triceps cruris may be affected, either separately or as a localisation of a generalised condition.

In mercurial poisoning the lower limbs do not escape. Workmen affected by it complain of a feeling of weakness in the legs; they easily become tired and have a staggering walk. Sometimes, the disordered gait is due to a polyclonus rather than to weakness.

In arsenical poisoning paralysis caused by neuritis may be also found. In connexion to plumbism, occupational arsenical poisoning chiefly attacks the lower limbs and particularly the extensor muscles — through the external popliteal branch of the sciatic nerve — at their distal parts, the toes, and usually on both sides. Muscular atrophy quickly develops in the paralysed muscles, and there are constant disorders of sensation, these being prevalent in the paralysed areas in the form of violent and lancinating pains. The electrical reactions and tendon reflexes are the same as in lead poisoning.

Powdered mother-of-pearl (see that article) causes a specific disease of the bones, multiple recurring osteitis, which is seen in mother-of-pearl turners, more particularly among young workers. It affects the bones in general, and especially the long bones of the upper and lower limbs. Klein has described a form of osteomyelitis localised to the bones of the leg occurring among the jute spinners of Vienna, which is attributed by other experts to the effect of different factors (see article "Jute").

(c) Since working tools are rarely worked by the lower limbs, occupational diseases of these limbs from the use of tools are few.

There is not found on the lower limbs what corresponds to the occupational callosities of the upper limbs, caused by the reaction of the skin to irritating stimuli; but there is however noted the result of reactions to the influence of tools which cause irritation on some particular area of the limbs, either in the subcutaneous cellular tissue, or in the muscular tissue, or even in the skeleton. Here may be instanced the cobblers' callosity, situated at the upper edge of the rotula, circular in shape, in segments of a sphere; it is due to hyperplasia and hypertrophy of the cellular tissue of the zone against which the cobbler places his last and upon which he hammers the sole or the shoe. A small tumour, almost similar, situated at the middle third of the thigh, is found in workers who use pneumatic hammers. It is caused by the hammer, as it rests on the thigh, subjecting it to numerous minute vibratory shocks.

Reference must also be made to (i) a bony tumour due to thickening of the periosteum of the crest of the tibia, in its middle third, which occurs among miners in the Elbe district; these men are in the habit of resting on the crest of the tibia a kind of basket, into which the mineral falls when it is loosened (Mori); (ii) exostosis of the first metatarso-phalangeal joint of potters who use the Talo or pedal-driven wheel; it is caused by the continual blows which the potter gives with the internal surface of the foot, especially with the metatarsophalangeal joint of the great toe, to the pedal of the wheel to make it revolve (Pieraccini); (iii) thickening of the first metatarsal by osteo-periostitis occurs among the potters of Sardinia; it may be caused by the
action of the wheel, but even more likely by kneading the clay, which is done sometimes with the heels and sometimes with the sole of the foot, especially with the first metatarsal (Marcello).

Exostoses have been noted at the level of the digital tendons (joints of the back of the hand, especially at the base of the fingers, or on the palmar surface) in violinists.

Thickening of the convex part of the left collar bone has been noted amongst these artists. The collar bone also shows a ridge or depression due to the lower edge of the instrument (violin).

Violinists and leaders of orchestras also suffer from flat foot, and a convex deformition on the right side of the spine (scoliotic), which in time develops definitely into scoliosis.

All these affections originate in the same way. Innumerable minute consecutive shocks set up in the tissues a reaction to the irritation, which varies according to their histology; thus a tumour made up of connective and fatty tissues results if the reaction occurs in subcutaneous cellular tissue; while an osteo-periosttic formation develops if the reaction occurs in the periosteum or bone (Mori).

Mori, in an investigation into minute injuries to bones and anti-algic contractions, found that a direct or indirect contusion on an articular region may be followed by an osseous lesion either immediately or subsequently. The hypothesis of a lesion to the skeleton must not be excluded on account of the slightness of the injury, the absence of clinical signs, or of a favourable development; a radiological examination should be made in all cases of a para-articular injury at the commencement of the trouble.

(d) Affections caused by constrained attitudes and positions may occur in a workman who, during or on account of his work, is compelled to adopt a particular position of the trunk, and is often compelled to place his lower limbs in a position to correspond to the said position of the trunk.

Whatever these working postures may be, when they are maintained day after day and for long hours at a time, even those differing in but a slight degree from the natural static positions of the body, in the end lead to anatomical changes, and, in consequence, morphological and functional changes of the locomotor apparatus, especially when such other factors come into play as the nature of the work, sex, age, loads and special movements, all of which favour the development of such changes.

Arthrosis of the knee, of mechanical origin, following upon excessive industrial activity exacted from the static and dynamic elasticity of the segment in question, have been reported by Henschen (1929) among restaurant waitresses, bakers, waiters and soldiers.

The standing position is that required for most work. It is also the most natural and least injurious to the parts of the body called into play for maintaining that position, especially when it is interrupted by restful attitudes, which enable each limb alternately to relax from bearing the weight of the body, and more especially when some walking about occurs. But, if the rest period is insufficient, and if the upright position is accompanied by almost complete immobility, then the constrained upright position leads to conditions which favour the development of circulatory disorders and morphological changes in the extremities. These disorders become manifested as varicose conditions (see article "Occupational Diseases: Circulatory System", Varicose Veins).

The upright position also has an effect on the skeleton where there are other factors at work. "Bakers' sore leg", formed by a genu valgum on one side and a genu varum on the other, is well known; this last and other similar deformities are now however very rare, and are generally only historic souvenirs.

In the Prague clinic, out of 76 cases of genu valgum, or "bakers' sore leg", that were operated on in 1910, not one of the patients had a sedentary occupation. Among neighbours and heavy work Manz and Hofmeister have reported a deviation of the femur known as coxa vara. From the fact that it is met with frequently among agricultural labourers — 41 cases out of 79 — this condition has been called "peasants' leg".

Flatfoot originates from two principal factors — adolescence and occupation. Adolescent apprentices, employed on fatiguing work which requires the upright position for prolonged periods, easily incline to flatfoot; and the condition is found to occur with even greater frequency where the work is done in bare feet or in low-heeled shoes. Flatfoot is found among porters, barmen, sailors, potters working the wheel, guides, and soldiers.

Tillaux considers that flatfoot is due to fatigue of the peroneus longus, which in the upright position contributes to the resistance and solidarity of the plantar arch. When the weight
of the body on the plantar arch is prolonged to an exaggerated extent it
causes lowering of the anatomical constituents of the foot — osseous, lig-
amentous and muscular — and the lateral peroneus longus, which defi-
nitely holds up the plantar arch, becomes fatigued, the ligaments of the leg of the tarsus relax, the bones themselves slip one upon another; and, by the wearing down of the articular cartilages, a definite flattening of the plantar arch is established. The essential origin of flatfoot is then disproportion between the weight and the resistance (Hoffa).

Kaup has stated that the frequency of flatfoot among the young workers of Munich reaches the high percentage of 26.75, including slight cases, whereas the examination of recruits in the same town showed only a percentage of 0.6. Among the pupil teachers of the secondary schools, the number of cases of flatfoot increased during the three years of teaching and practical work; among barmen it varied from 18.95 to 69.23 per cent., and among bakers from 15.38 to 48. Among apprentice erectors of machinery, on the other hand, the frequency of flatfoot somewhat diminished.

Opitz, at Brunswick, found in the army 12.1 per cent. of flatfoot, whilst among barmen and bakers the percentages were respectively 25.6 and 22.

Talgia (painful heel) and tarsalgia are also to be attributed to prolonged standing.

Talgia, caused by compression and injury to the heel, in the upright position and on the march, affects the subcutaneous cellular tissue. It may appear in an acute form, but most often it has a chronic course and leads to atrophy of the adipose tissue of the cushion situated at the tuberosity of the calcaneum, with a preference for the right foot (Rivalta).

Tarsalgia (also called Morton's disease), or active contraction of the walking muscles, is common among porters, barmen and chiefly among adolescents, especially those growing quickly. It starts with a sharp pain at the middle of the sole, this being felt at the commencement of the step, when the anterior metatarsus rests on the ground to bring the body to the forward position; the pain then becomes continuous during the whole phase of weight-carrying; next it spreads; but it always remains most acute at the highest part of the arch. The painful phase is followed by a marked flattening of the plantar arch, and little by little a reflex contraction of the muscles occurs which prevents walking; and in the end there is the permanent formation of flatfoot. The disease has three stages: pain, spastic contraction, and definite morphological changes. It has been variously described as an alteration either of the articulations, or of the intermetatarsal segments, or of the bones (Bonomo).

With persons who remain for long periods on horseback, such as riding masters, jockeys and men who look after herds, the thighs and legs assume the well-known bow shape, which is also found among workmen who adopt during work the position of a cavalry man, e.g., knife-grinders who use electricity for driving the wheel and work sitting astride a seat with thighs and legs apart (Berlucci); saddlers, who work while keeping the same position astride a small model horse; and basket makers seated astride a stool.

Riders also suffer from a callosity on the heel, due to injury by blows from the saddle, myositis of the adductors, described by Ramazzini; a serous bursitis of the bursa on the internal side of the knee, upon which falls most of the friction between the knee and the saddle; myositis of the adductors, described by Billroth, among old light cavalry soldiers and cavalry recruits and represented by a typical osseous neoformation, which develops on all the adductors of the thigh, especially on the middle adductors; this condition arises from numerous minute contusions.

This neoformation has been regarded either as an ossification of the interfibrillar connective tissue of the periosteum (periostogenous theory), or as a degeneration of the muscle fibres with infiltration of young cells and transformation into cartilaginous tissue, which later becomes osseous (Havemann). Osseous neoformations may be met with among cavalrymen, as the result of the same mechanical minute contusions, in the vastus externus of the left thigh, due to injury by blows from the sword while the horse is galloping (Ludwig), on the pectineus (Josephsohn) and on the iliacus externus (Sangalli; Rivalta). Among riders is likewise found an insufficient functioning of the adductors due to contraction of the thighs.

In some trades the worker is compelled to adopt a kneeling position, crouched or with the body bent. The kneeling position adopted by domestic servants, parquet floor cleaners, floor layers, nuns and monks frequently causes, in addition to a cutaneous...
thickening of the front of the knee, a 
hygroma of the prepatellar bursa with 
the risk of suppuration supervening 
(see also "Miners' (Coalminers') Dis-

cases", Beat Knee).
The bent position of the body causes 
very important affections among women 
working in the ricefields during weed-
ing, reapers and mowers using the 
scythe, transplanters of turnips, potato 
gatherers, asphalters, parquet floor 
cleaners, and workmen who lift metal 
pipes. Thus, for instance, varicose 
veins are often caused either by any 
position which forms an obstruction to 
the return of the venous blood, or 
from the absence of movements of con-
traction and relaxation of the muscles 
which assist the return circulation.

Peripheral nerve affections, both 
pareses and paralyses, have been de-
scribed in the case of these workers, 
which have been attributed to compres-
sion of the nerves on hard surfaces, 
or to stretching of the nerves. They 
are found in the peroneal and pos-
terior tibial areas (Govers, Pieraccini) 
as a consequence of the stretching and 
compression to which the nerve is sub-
jected between the tendon of the biceps 
and the head of the fibula, e.g. among 
buckroo gatherers.

(e) Affections due to excess of work 
may be caused either by long hours, 
causing fatigue and exhaustion, or by 
putting the reserve muscular energies 
into play for a short period in order to 
expend unusual force so as to over-
come an abnormal resistance.

Excessive muscular work may lead 
to tumefaction of the muscle fibre, to 
fatty degeneration, to the disappear-
ance of striae, and to atrophy.

Excess of muscular work performed 
by the lower limbs is found equally 
among persons who are a great deal on 
horseback and among those who 
make long marches on foot; it also 
occurs among workmen who are 
obliged to use the feet and legs in order 
to work an instrument or a machine, 
for instance, knife grinders, organ 
players, tailors using pedal sewing 
machines, potters and turners.

Such excess of work may manifest 
itself in affections of the muscles, 
tendons, bones, joints and nerves; 
these will now be rapidly reviewed.

Myositis, caused by exhaustion, con-
fined to a muscular group which has 
undergone a long period of work, is 
characterised clinically by pain and a 
slight swelling of the muscles, which is 
sometimes accompanied by slight rises 
of temperature. According to some 
experts, it is due to simple exhaustion 
in consequence of a series of numerous 
contractions; according to others, it is 
due to insufficient elimination of the 
local products of organic combustion.

This strictly occupational affec-
tion is not common; it has been met with 
in an organ player who was obliged 
to contract his muscles to use the 
pedals from six to eight hours a day 
(Strumpell). It is quite often localised 
to the muscles of the calf in the case 
of recruits accustomed to long marches 
(Hayem, Strümpe1, Silva), and to the muscles of the thighs in 
the case of riders. It occurs in an 
acute form, accompanied almost al-
ways by fairly severe pain which dis-
appears completely in some days. 
There sometimes remains, however, a 
fibro-sclerotic induration of the muscle 
affected.

The occupational forms with slow 
development are much less painful; 
they develop slowly and usually lead 
to a hyperplasia of the connective 
tissue, causing in turn permanent 
functional damage which limits the 
movement of the muscles. Simple 
atrophy of muscular fibres may also be 
found.

The rheumatic factor often con-
tributes to cause, or at least to favour, 
this morbid condition.

Tenosynovitis or tenovaginitis from 
over-exertion, also called crepitating 
tenosynovitis from one of its charac-
teristic symptoms, is well known in its 
clinical aspect; it is due to an inflam-
atory process confined to the tendon 
and its sheath, which usually gives rise 
to the production of fluid.

The development may be slow, but 
mostly the condition develops in a few 
hours. It is the result of irritation 
caused by rapid and numerous move-
ments of the tendon in its sheath, and 
occurs generally following long 
marches and rapid or prolonged mani-
pulation of working tools.

The tendons in the lower limbs 
affected in consequence of muscular 
movements are numerous; the 
tendo Achilles is the most commonly affected, 
from above its point of attachment up 
to the area of muscle insertion, in the 
case of persons who walk much, women 
who work pedal sewing machines, 
knife grinders, turners, potters, cyclists 
and mountain guides. At other times 
the tendon is damaged exactly at its 
point of insertion — Albert's achillo-
dynia, which is different from trau-
matic achillodynia, this last being 
caused during walking as the result of 
the boot rubbing on the heel. Finally, 
inflammation of the serous bursa (burs-
itis) may occur at the heel under the 
point of attachment of the tendon 
(Rössler).
The tendon sheaths round the ankle, those of the lateral peroneal muscles, and the common extensor and the anterior tibial, may also be affected by prolonged marches and in persons unaccustomed to walk long distances and rapidly.  

Circumscribed inflammatory processes in the form of periostitis and osteoperiostitis have been described among soldiers, following upon exhausting marches, and have been attributed to fatigue (Laub). The lesion is generally situated at the upper third of the tibia, where it occurs as a painful swelling (Casarini); but it is also situated, although more rarely, at the lower third of the tibia, at the malleoli and the bones of the foot (Toussaint, Schwartz, Manceaux). The affection develops in a slow, dull manner causing pains and giving rise to the formation of fluid; it is reabsorbed leaving plaques of hyperostosis corresponding to the insertion of the muscles, especially of the solear muscle (Leistendorfen), of the common flexor of the toes (Hérol), and of the popliteus. This form is usually found in young persons at the period of the formation of bone tissue (Rivalta).

Stretched foot (in Italian "piede gonfio", in German "Füssgeschwulst") consists of oedema of the front of the foot and is peculiar to infantry soldiers and especially to recruits.

Osteoperiostitis of the metatarsals, which has been studied by Weissbach, Pauzat and Poulet, and radioscopically by Thalwitzer particularly, is characterised by fusiform bony prominences from 4 to 5 cm., extending from the base of the metatarsals along the insertion of the interosseus muscles. An intense uniform shadow without formation of fluid; it is reabsorbed leaving plaques of hyperostosis corresponding to the insertion of the muscles, especially of the solear muscle (Leistendorfen), of the common flexor of the toes (Hérol), and of the popliteus. This form is usually found in young persons at the period of the formation of bone tissue (Rivalta).

The lesions caused by quick, unforeseen, effective, but unco-ordinated contractions which exercise a pull on the antagonistic muscles in a state of passive contraction or of posture are more common.

This mechanism starts simple muscular distension, characterised by intense pain (simple myalgia) which heals readily, or a laceration of the muscle which is easily diagnosed by characteristic clinical signs; the adductor muscles may be affected in riders, commonly those on the front of the right thigh, or the calf muscles, giving rise to "coup de poing" (whip-lash) or pain from sudden contraction of the leg muscles. Sometimes the effect of the muscular pull does not spend itself in the muscle, but affects the skeleton at the point of attachment of the muscle, from which may arise

fatigue (Ferrier). During marching there is a broadening of the foot to reduce the vibrations and increase the stability of the body; at the same time the reflex contraction of the muscles is opposed to an excessive extension of the foot. But when, in consequence of excessive burdens and reduction in the energy of the foot muscles, caused by fatigue, these muscles do not respond adequately to their functions, extension occurs, and fracture may occur on a point of the arch, where the maximum of thrust and the minimum of resistance is concentrated. This fracture is usually found at the second metatarsal of the right foot; it is more likely to occur when running, jumping, or walking on uneven ground, or going uphill.

Among other painful conditions also attributed to fatigue are occupational cramps, which are, however, much less common than in the upper limbs, but may occur amongst dancers, knife-grinders and cyclists.

Fracture of the metatarsals is also attributed to arduous marches aggravated by burdens (Weber) and by

1The statistics of the Swiss National Accident Insurance Fund show that of 522 cases of bursitis, 52 per cent. were situated at the knee (on the right side more often than on the left); 42 at the ankhles — on the left side more than the right; and 8 per cent. were distributed over other parts (Wehrli).
transverse fracture of the patella, or even detachment of a bony layer from the calcaneum at the point of the insertions of the plantar ligaments.

Finally, always as the result of an effort with unco-ordinated movements, hermia of the muscle may occur either of the large adductor in the case of riders (Larrey, Dauve, Baudin), or of the gemell. The enveloping aponeurosis is torn violently and the underlying muscle makes the hernia; it becomes manifest either as a tearing of the sheath of the muscle, or as a swelling, depending on the period of contraction or relaxation of the muscle concerned.

2. — UPPER LIMBS

As regards the upper limbs it must be recalled that the influence of the occupation may manifest itself by an aggregate of changes. Thus Brezina and Lebzelter, relying upon an examination of 1,200 persons, found that manual labour exercised an influence on the breadth and thickness of the hand; the root of the hand is little affected, and, in the same way, the length of the hand does not seem to show any change. Quarelli (1889) has described luxation of the phalanx of the thumb among the dairymen of Piedmont employed in milking cows; Poncet, the hooked hand of glass-makers; Vernes, a contraction of the fingers in a state of flexion among nail-makers; Teleky, a similar deformity among basket-makers; A subluxation of the wrist, known under the name of "Madelung's deformity" may be met with in young laundry maids and grinders; Dupuytren's contraction, or contraction of the palmar fascia, has been described among English machine-lace makers (Collis) and is met with among other workers whose palms are exposed to frequently repeated injuries.

As regards bony lesions, Düttmann reports seven cases of necrosis of the lunar bone in workmen employed on difficult work; on the other hand, a new formation similar to osteomas of cavalrymen has been described in soldiers in consequence of the recoil of the rifle, the position of the injury being the deltoid. Another common occupational lesion is fracture of the lower end of the radius among chauffeurs, due to back-fire when starting the motor with the crank-handle.

Among muscular lesions may be mentioned atrophy of the muscles of the thenar area in workmen obliged to execute frequent repetition movements (Teleky); muscular atrophy of the shoulder and arms among tram-drivers (Schwarz); rupture of the muscle fibres of the right deltoid in blacksmiths (Layet); that of the tendon of the short portion of the biceps in laundry maids (Weber); rupture of the long flexor of the thumb at the point of its muscular insertion, in a workman employed in coupling railway carriages (Gontermann); muscular atrophy from the use of pneumatic tools (Beiniker).

Tenosynovitis of the wrist and crepitating tenovaginitis have been observed in workers at various occupations requiring a permanent effort from the wrist, e.g. coal-miners, laundry maids, stonecutters, pianists, carpenters, brick-makers and agricultural labourers.

Contractions of the tendons have been observed in cases of chronic lead paralysis. Further, ischaemic muscular contraction of the forearm has been reported following upon confusions.

3. — THORAX

In connection with the thorax, rickets has been described, especially in young workers. In some trades the effects of this disease pass off in the course of the occupation; thus, for example, among machine erectors, the frequency of the rachitic symptoms decreases from 30 to 8.7 per cent.; among barmen, from 49 to 14; and among tailors from 42 to 3.1 (Kaup).

Thoracic deformities, constituting what may be called occupational stigmata, have been observed in some occupations wherein the workmen maintain injurious positions, such as shoemakers, tailors, turners and boatmen, with very exaggerated right subclavicular fossa.

In the case of turners the right half of the thorax is reduced in its transverse diameter and forced backwards as compared with the left side. The muscles on the same side, especially the serratus magnus, are on the contrary unusually well developed.

Asymmetry of the thorax has been found in glass blowers and miners (Mazzi).

4. — VERTEBRAL COLUMN

Deformities of the vertebral column as a consequence of occupation have been described in apprentices by Elsener; scoliosis among stone-carriers, localised in the dorsal region and showing a convexity to the left by Golebiewski, and by Mazzi among agricultural workers employed in sulphuring vines. This deformity ceases to be noticeable...
As regards the treatment of flatfoot, the choice of suitable boots is of first
importance (Conn, Bradford, Bettman). The German Sickness Insurance Offices make frequent use of supports (Einlage) which help to maintain the plantar arch. This treatment cannot be of benefit in certain cases where the application of the support encounters opposition: with patients who do not wish to be cured for fear of losing their pensions; with patients who, after a preliminary failure, refuse to persevere in the treatment, being persuaded that it is useless (Blencoe).

LEGISLATION

In the Netherlands, there is compulsory notification of inflammation of joints, of musculo-tendinous sheaths, of the skin and subcutaneous cellular tissues for each of the following occupational classes: brickmakers, woodcutters, coal-miners, peat-diggers, boiler-makers, incandescent lamp makers, printers, flax workers, herring gutters, iron founders, glass-makers, carpenters, mat-weavers, laundry workers, hide-sorters, gut-cleaners, ironmongery factory workers, workers in building yards, shipbuilding yards, blacksmiths, shops, and sugar refineries, horticulturists, makers of clogs, oyster pickers, fishermen and packers of herring in barrels.

Synovial effusion is compulsorily notifiable for each of the following categories: at the knee: masons, thatchers, paviors, makers of rush mats, coal-miners, workers in shipbuilding yards, agriculturists and horticulturists, layers of stone flags and domesticities; at the elbow: coal-miners and glass-polishers.

Occupational lesions of bones, muscles and joints receive in some countries the compensation benefit which is given for accidents: subcutaneous cellulitis of the hand, subcutaneous cellulitis or acute bursitis of the knee or elbow in workmen employed on mining, in Canada (Alberta, British Columbia and Nova Scotia), Chile, Great Britain and Northern Ireland, the States of Minnesota and New York, Queensland, Venezuela and Western Australia; tenosynovitis and prepatellar bursitis, primary tenosynovitis characterised by a passive effusion or crepitation in the tendon sheaths of the flexors or extensors of the hand in workmen whose work involves movements or vibrations frequently repeated or continuous pressure, in the State of Ohio; inflammation of the tendon sheaths, arthritis caused by work, in Japan; chronic inflammation of the synovial membrane of the knee and elbow in stoneworkers, slaters, pontoon men and miners; chronic inflammation of the tendon sheaths among women ironers and women packers of parcels; flat-foot, "bakers' leg", etc. (overloading the joints), among leaders, weavers, messengers, dentists and sellers in the U.S.S.R.; occupational diseases of the tendons and muscles, in Chile; of bones, muscles and joints due to work with pneumatic tools, in Germany; diseases of the joints and muscles due to poisons (lead, etc.), in France and in countries which adopt the Anglo-Saxon formula (first column) or that of the Convention of 1925; for diseases of the bones caused by radio-active substances see that article.

Urogenital System

All the uro-genital organs are exposed to occupational injuries, and account should be taken of the fact that repercussions from them affect not only the individual but also the race. The uropeiotic and genital systems are easily affected and, although the diseases affecting them can be easily diagnosed, their etiology is difficult to
explain, because of the complications brought about by the role played by injurious bacteria.

Among affections of the kidney, of which all kinds occur, distinction must be made between primary and secondary effects. Among the primary occur simple albuminurias, temporary elimination of albumen which Strauss describes as "aneuphritic albuminuria." Such albuminurias, which are found after physical effort, especially among sportsmen and soldiers, have no particular importance, although Leube has been able to find them in 10 per cent. of the cases examined.

More importance is to be attached to haemoglobinurias resulting from marching, which O. Klein considers to be due, as well as haemoglobinurias from cold and orthostatic albuminurias, to the same cause, namely, circulatory disturbance of the kidneys, set up as reactions by walking and an upright position in persons affected with lorderosis as by chilling of the skin.

Some kidneys are predisposed to haemoglobinuria as in paroxysmal haemoglobinuria; under the influence of a cold spell there is a clear clinical picture characterized by haemoglobinuria and fever, which, in the absence of a positive Wassermann reaction, presents certain cytological and chemical modifications of the blood (increase in the resistance of the red blood corpuscules to hypo-tonic saline solutions, increase in the number of red and white blood cells of the haemoglobin and in the sugar content, etc.).

These cases are rare, but there ought to be other less precise intermediate cases, the study of which would be desirable as they might throw light on the relation between the influence of cold or humidity and nephritis. In the pathogenesis of nephritis from cold dependence has to be placed on hypothetical probabilities and no proof is available. Thanks to the researches of Eppinger and O. Möller, it seems to be established that the capillaries constitute a single system and that glomerular nephritis, for example, is only a partial manifestation of a malady affecting the whole of the capillary system. At the point where it acts, cold causes a vaso-constrictive effect with subsequent vaso-dilatation, and can thus set up reactions in other parts of the system.

It is well known how sensitive the kidneys are, especially when a predisposition to circulatory affections exists, and how, in certain well-known conditions of exposed parts, cold may bring about the grave clinical symp-
toms of paroxysmal haemoglobinuria. Thus it will be readily recognized that permanent functional damage to the kidneys may result from the prolonged and repeated influence of cold and humidity. While admitting this, it must not be forgotten that, from the point of view of infection, a certain predisposition plays an important part.

It is interesting to note that persons who are engaged in occupations most exposed to inclement weather conditions, such as agricultural labourers, builders, etc., are less subject to maladies caused by cold than are those who carry on work under sheltered conditions, as for example, tailors, who are particularly sensitive to cold.

The relation of cause and effect is thus less precise in these cases, and the same can be said of the relation between sore throat of occupational origin and nephritic foci. It is an established fact that such nephritis can be brought about by an angina in the throat, although no statistics exist to prove it from the point of view of industrial pathology.

The inhalation of toxic dusts must be particularly considered because they may set up serious irritation of the buccal mucous membrane and consequently severe sore throat. Among these dusts the most important are those of certain wools (alpaca, goat-hair, camel-hair, and common Asiatic wools, etc.); sharp particles of horn and ivory; hemp dust and organic fungi (from contact with the fungus Boletus ignarius); wood dust (mahogany, maple, logwood, sandalwood, etc.); dust arising from gathering the hop harvest; carpet dust, dust from hair (for cleaning brushes); leather, tortoiseshell, siliceous dust (stone cutters, glaziers, often polishers of precious stones like amethyst, agate); marble dust; dust produced in the manufacture of glass paper and emery paper and upholstery work; dust from metals, verdigris, tobacco, etc.

In these cases there is the possibility of nephritis secondary to an angina of the throat of this kind, and this is worthy of close study.

A secondary nephritis may constitute a syndrome accompanying industrial infectious diseases, as, for example, erysipeloid conditions, generalised or anthrax septicemia. A little more is known as regards the relation between traumaism and kidney diseases, because the latter are usually the result of external violence, such as a direct contusion in the region of the kidneys or an impact of the kidney
against processes of the vertebral column or lower ribs. The injury may cause disturbance or destruction of the kidney substance, rupture of the capsule or the pelvis, of the ureter or the vessels. The clinical symptoms show themselves in collapse, rapidly progressive anaemia accompanied by haematuria.

Beside these grave lesions, the kidney can be displaced and the floating kidney thus created, with its often complicated symptomatology, presents problems of certain practical importance. It should be mentioned here that, especially in women whose work involves intra-abdominal pressure, the abdominal walls may extrude with enteroptosis and a floating kidney.

Estimation of the degree of incapacity for work caused by a floating kidney is often very difficult, because there is no criterion by which to determine it. Before evaluating troubles of this kind it must be remembered that a floating kidney may not only be accompanied by nervous trouble but also that already existent hysteria or neurasthenia may be aggravated by it.

It is a well-known fact that a floating kidney occurs more often in women than in men. According to Stern, it is not a question, in the majority of cases, of a normally well-adherent kidney but dislocation of an organ already movable or non-adherent. Such an insufficient fixation is met with more often in women than in men, often as one of the symptoms of a general enteroptosis.

Other kidney affections of a traumatic nature are, according to Stern, haematonephrosis, hydronephrosis, peri-renal haemotoma, pseudo-hydronephrosis, cicatricial stenosis of the ureter or pelvis. The French authors Castaigneawl and Rethory report also the occurrence of diffuse inflammatory processes of the kidney of a chronic character. In German literature acute and chronic traumatic cases of nephritis have been described, as well as very varied infectious diseases of the kidney such as diffuse, pyonephritis, pyelitis, pyleonephritis, etc. Finally, it is known that kidney diseases of this kind may be aggravated by injury, but it is not possible here to discuss more fully the relation between traumatism and the kidneys.

Kidney lesions due to the most diverse types of poisoning are very important and better-known. It should be remembered specially in regard to such forms of poisoning that they may be simple functional troubles without disease of the kidney properly so called, especially when some mechanical obstruction of the renal canaliculi is present, set up by blocks of haemoglobin formed under the haemolytic action of certain poisons. The obstruction may reach such a degree as to produce complete anuria, ending in death, with a picture of renal uraemia.

The number of poisons causing methaemoglobinuria, jaundice, anuria, etc., is very considerable. The following are the most important:

(a) Inorganic poisons: chronic acid, nitrous fumes, nitrates, potassium chloride, arsine, hydrogen, etc.;

(b) Poisons of the aliphatic series: hydrazines (diamines), nitroglycerine, amylnitrite;

(c) Poisons of the aromatic series: chlorobenzene, nitro-dinitro-, and tri-nitro-chlorbenzene, nitrobenzene, amido-benzene (aniline), phenaacetin, phenyl-hydrazine, trinitrotoluene, toluidine, nitrophenol, etc.

It is not yet certain whether these cause functional disturbances of a mechanical nature or if the haemoglobin, dissolved in the blood, acts also as a foreign albumen body, thus causing epithelial alterations in the renal canaliculi, and in this way alterations which are of longer duration.

The principal poisons which directly cause renal disease, often of a very serious type, are lead and mercury. Others, like cantharides, arsenic, turpentine and different tar derivatives, produce, in addition to epithelial degeneration, exudative processes and above all cellular infiltration into the connective tissues. On this matter Munk has stated that "extensive necrosis of the epithelium in the principal pyramidal tracts and fatty degeneration (infiltration?) of the epithelial cells of the right tubules is always found. These ulcerations I have also found in the kidneys of some munition workers, who, in consequence of some insufficiently-known cause, had died with symptoms of poisoning or pneumonia." The reader is referred to different articles in the Encyclopaedia for data concerning the toxic action of different products, and mention will here be restricted to indicating the general lines of the problem.

Fatty degeneration of the kidney is recognised as occurring as the result of the action of phosphorus (acute non-occupational poisoning), arsenic (acute and chronic poisoning), and carbon monoxide, as are likewise renal troubles due to the action of acids (su-
phuric, nitric, oxalic, salicylic, phenic, etc.), of which the majority, however, are of non-occupational character. It is the same in regard to chromic acid, which in cases of acute poisoning can set up very severe nephritis, while important statistics show that the industrial use of chrome has produced nephritis very rarely if at all.

Generally speaking, acids and alkanes do not play a very large part in the pathology of the uropoietic system. Grun, however, has stated that in a soap factory where strong perfumes, and chemical colouring matter and alkanes were used, he had observed some cases of chronic nephritis which he had attributed to the use of these colouring matters and the inhalation of alkali fumes. Other kidney irritants are tar, cantharidine, naphthamine, carbon bisulphide, turpentine, etc. The latter has special importance from the point of view of industrial pathology, as experiments have shown that 3 to 4 mg. of turpentine vapour per litre of air cause symptoms of poisoning in animals and renal irritation and, further, that important nervous troubles and other organic affections in man may result therefrom (see article “Turpentine”).

Arsenic trichloride, which is used in the explosive industry, and tetrachloroethane, used as a solvent — both of which may cause fatty degeneration of the kidneys — are of less general importance.

Alcohol should be mentioned in passing, as it cannot be considered as an industrial poison but rather as a dangerous product absorbed with food — unfortunately in excess — in the most diverse industries, because it has the power of apparently dispersing sensations of fatigue. It is, therefore, only to be regarded as an indirect industrial poison able to produce renal lesions.

The most serious lesions are caused by mercury and lead.

Mercury used in a large number of industries causes in severe cases nephrosis (necrosing nephritis) of the kidney and in slighter cases a picture of a nephrosis. The symptoms are revealed by the presence of a large quantity of albumen in the urine with all manner of cylindrical casts and fatty degeneration of the renal epithelium.

The sufferer has a rather ruddy complexion, slight swelling of the face and possibly a difference in his voice accompanied by high blood pressure or cardiac hypertrophy, but with oliguria or anuria with sequelae as the principal symptoms.

The other renal poison is even more frequent, namely lead — and, likewise, oxide of zinc, the similar action of which on the kidneys is less known — which sets up two forms of lead nephritis, namely, interstitial nephritis and the small arterio-sclerotic kidney.

On a basis of a thousand autopsies, Ophuels has tried to establish the relationship between saturnism and gout on the one hand and arteriosclerosis and arteriosclerotic nephrosis on the other. He found that among 30 cases of gout, 3 were probably caused by lead poisoning, and that all the gouty kidneys produced arteriosclerotic changes which were more or less marked. The opinion that saturnine gout is the sequel of saturnine kidney, as the result of which the damaged kidney is unable to eliminate uric acid, has been often combated, and so much the more so since the two affections are often met with together, without, however, being necessarily connected.

The small arteriosclerotic kidney is met with not only among lead workers, but also as an industrial injury more or less direct in all cases where physical and intellectual over-pressure is accompanied by excessive drinking, as is so frequently the case among business men, artists, officials, etc. Occupations carried on in the open air are subject to this which is found especially, on the other hand, among those engaged on work in cold rooms or in a cold and humid atmosphere when accompanied by heavy eating and drinking as in the case of butchers, brewers, underground workers (mines) and agricultural workers.

According to the British statistics in the Decennial Supplement of the Registrar-General for the years 1921-1923, the mortality from acute kidney disease does not show any definite relationship with the social position of workpeople. The Registrar-General’s tables of the minimum and maximum figures of chronic nephritis, distributed according to profession, are reproduced in the table on page 491.

Among the parasitic maladies the most important are those due to Taenia echynocosus and Schistosoma haematothium. This latter has very great local importance, because something like 80 per cent. of the fellaheen in the Lower Nile Valley employed in agriculture and gardening, or as fishers or workpeople, are unaccompanied by this malady which is found especially, on the other hand, among those engaged on work in cold rooms or in a cold and humid atmosphere when accompanied by heavy eating and drinking as in the case of butchers, brewers, underground workers (mines) and agricultural workers.

on lesions such as cystitis, enteritis, urethritis, pyelonephritis, inflammation of the ureter, vesical tumours and stones. A classical description is that given by Goebel:

"Benign tumours in bilharziosis are in most cases tumours with granules arising from cystic cystitis, the origin of which is to be found in a proliferation of sub-epithelial connective tissue followed by epithelial proliferation. They may be compared to the small vegetative growths present in vegetative (proliferating) cystitis with this difference, that the epithelial proliferation in the large tumours never disappears.

"This participation of the epithelium to which the conservation of the tumours is perhaps due has its origin in prolonged mechanical irritation exercised by the eggs of bilharzia, without however excluding the possibility of an action of microbial origin. Perhaps the obstruction of the lymphatic passages and blood vessels by the massive accumulation of eggs in the sub-mucous membrane and muscles plays a part therein. The benign tumours are the direct consequence of infarcts in the vesical mucous membrane due to the eggs of bilharzia. The influence of decomposed urine or gallstones cannot be admitted in this connection."

"Besides granular tumours there is also met with a true neoplasia of benign type, a polyposis combined with bilharzian cystitis. It has not been possible to determine to what extent this neo-formation is due to an irritant inflammation of congenital predisposition. The historical details reveal close relationship between benign epithelial proliferation and an etiological action due to bilharzian cystitis.

"Malignant tumours constitute at least 50 per cent. of the proliferations observed in bilharziosis. They are in general and almost exclusively carcinomas and especially of a carcinoid nature. The genetic relationship between bilharzian cystitis and the development of carcinoma cannot be contested and is proved by statistics. Bilharzian carcinoma can be compared to the tumours occurring among paraffin and pitch workers, those engaged in the manufacture of aniline colours, smokers, etc. They do not, however, support the contention in favour of a parasitic origin of cancer. The epidermoidal (leucoplastic) or endodermal metaplasia of the vesical epithelium which occurs concomitantly with the tumours plays a decisive role in the formation of the carcinoid and of a mucous cancer of the bladder. Except over a few areas the carcinomatous epithelium is quite distinct from the pavement epithelium of the bladder. The cancer develops in the mucous membrane as a definitely isolated entity. In passing through the submucous and mucous, or more rarely the muscular tissues, the cancerous growth only englobes secondarily the eggs of bilharzia which are found in the peripheral layers of both striata and alveoli."

In the above description of Goebel the origin of the cancer is presented in such a clear way that it can be described as of an occupational nature.

The most important of the industrial diseases of the bladder are the tumours occurring among aniline workers. While referring the reader to the article "Tumours" for fuller details, it should be recalled here that since the observations of Rehn (1895) the number recorded up to the present time is pretty considerable. Thus, in the German chemical industry, up to 1926 some 250 cases of bladder tumours (Koelsch) have been recorded characterised by modifications of the vesical mucous membrane, accompanied by symptoms of irritation, dysuria, strangury and haematuria. The neoplasm may be either a papilloma or a malignant tumour which latter, in its turn, may be a secondary degeneration of the benign growth. Among the suspected causes are aniline, toluidine, xylidine, anisidine, p- and o-toluidine, benzidine, tolidine, etc. Other substances, such as Congo red, safranine, benz-purpurine, the
blue colours of rosaniline, have been held capable of causing proliferation of the vesical mucous membrane (see these articles).

Absorption of the toxic substance is considered to be by way of the respiratory tract and through the skin; the digestive tract playing an altogether secondary role. According to Nassauer, the chemical nucleus capable of engendering the harmful effect may be amino-benzine (aniline). The malady is met with especially among workmen employed inside the sheds of chemical factories. Cases, however, have occurred among persons living in the immediate neighbourhood of these factories (porters, canteen attendants, clerks, members of workers' families, etc.). The disease is fairly slow in its development and its appearance, on an average, takes place after fifteen years' duration of employment. Individual predisposition plays a part which ought to be borne in mind.

Besides aniline, arsenic has been thought to be a cause of neoplasms of the bladder. This view has been maintained by A. Hamilton as a result of observations made by Wignall, of Manchester. This last-named author has recently published (1929) some notes on cases of bladder affections, some accompanied by new growth, and others not, among workmen employed in the manufacture of a-naphthylamine (see that article) and other colouring matters of this group, which necessitated the use of arsenic. His cases numbered 20, of which 8 occurred between 1880 and 1910: 1 in 1914, 4 in 1918; 2 in 1924; 2 in 1926-1927: 2 in 1927 and 1 in 1928. Finally, Posner has described the case of a workman in the tar industry suffering from scrotal cancer (see articles "Tar", "Cotton", "Petrol" and "Tumours"). Posner, however, describes cases of atrophy of the testicle following chronic lead poisoning; on the other hand, men poisoned by this metal may beget children somatically and mentally weak. Thus Rennert has noted amongst the families of Hessian pottery workers, in addition to rickets, children with hydrocephalus and tonic and atonic convulsions ending fatally. Moreover, instances are given of parents, the victims of lead poisoning, having children who were idiots or epileptics or who suffered from hydrocephalus or convulsions, etc. This is comprehensible when it is recalled that lead acts injuriously not only on the male and female germ cells, but can also pass into the placental circulation and through the mother's milk.

In dealing with occupational injuries of the genital organs very clear distinction must be drawn between the two sexes. In man the only malady in general is that of scrotal cancer (see articles "Tar", "Cotton", "Petrol" and "Tumours"). Posner, however, describes cases of atrophy of the testicle following chronic lead poisoning; on the other hand, men poisoned by this metal may beget children somatically and mentally weak. Thus Rennert has noted amongst the families of Hessian pottery workers, in addition to rickets, children with hydrocephalus and tonic and atonic convulsions ending fatally. Moreover, instances are given of parents, the victims of lead poisoning, having children who were idiots or epileptics or who suffered from hydrocephalus or convulsions, etc. This is comprehensible when it is recalled that lead acts injuriously not only on the male and female germ cells, but can also pass into the placental circulation and through the mother's milk.

The female sexual organs are exposed to occupational risks in far greater degree than the male. Already from purely physiological causes, such as menstruation, pregnancy and suckling, the woman's resistance is diminished and rendered more receptive to injurious influences. Apart from the extremely probable alteration in the basic psychical functions of a subject which would repay closer study of it than has so far been made — the morbidity and mortality figures of the working woman show very high figures. The number of cases of sickness among working women according to Thiele is five to eight times more than that of the leisured class. Among these numerous maladies are those which
The occupational affections of the female generative organs are analysed in the article "Women's Work", to which the reader is referred.

The creation of what Hirsch might call a system of occupational gynaecology is altogether desirable and is required in the interest of the ever-increasing movement for the protection of women.

There remains to be studied a group of maladies often closely connected with occupational life, but which cannot be considered as industrial diseases: these are venereal diseases properly so called. The lessened mental and physiological resistance during puberty already mentioned, the common life of the two sexes, especially in factories, the absence of pleasure in the work done, which is often unduly mechanical, engender nowadays a tendency to alcoholism and accentuated sexual life. These conditions are still further increased by the employment of the mothers, employed as they are in industry, neglect the necessary supervision of inexperienced young persons. This state of affairs leads not only to an increase in sexual neurasthenia, but also to an increase in the risk of contracting venereal disease.

To the disease of the generative, digestive and other organs all contribute on the other hand to create such a state of things.

Apart from these considerations certain occupations predispose to a considerable degree to venereal disease. These are notably transport services (sailors, barges, etc.), night employment (post offices, hotels, transport, bakers, etc.) — occupations in which exposure to this risk is greatest. Certain authorities incline to the view that venereal disease affecting prostitutes should be given recognition as an occupational disease.

While cases of venereal disease may merely be regarded, as has been stated, as indirectly occupational, many cases of extra-genital syphilis are occupational in origin, e.g. syphilis contracted by medical men, nurses, midwives, laundresses or rag sorters who have handled infected material (see article "Syphilis"). In the past the most frequent instances of this character have been met with among musicians playing wind instruments and glass blowers. But contact with other articles, such as blowpipe pipettes, shuttle kissing, the habit of holding between the teeth nails which are kept in a common box (by bootmakers, carpet layers, etc.) have also given rise to buccal infections. The same is likewise the case even in regard to the use of brushes, chalk and feathers among painters, seamstresses, and office workers.

Acquired extra-genital syphilis is particularly common among medical men who, as a terminal action of the specific poison, are most liable to become the victims of locomotor ataxia and general paralysis of the insane. According to Trueb, the reasons for an unfavourable prognosis among medical men are: longevity and the conditions under which they have to carry on their profession which are a priori harder than in other occupations; the
injuries engenders a psychical and debilitating nervous change; and in cases where there is a neurotic tendency, as a result of overwork and exhaustion due to the hard work the medical profession entails, medical men suffer more than other classes both mentally and physically. Their powers of organic resistance are diminished and this fact together with impairment of force as regards healing and recovery may, as a terminal effect, bring on more or less rapid failure of the nervous functions.

On the other hand, there are countries (e.g. Algeria, Abyssinia, tropical Africa, rural districts in Central and Eastern Russia) which seem to be practically free from progressive general paralysis. The zone of the spread of this malady then is an index of the extent of the damage arising from intellectual life and a high degree of civilisation, for what has been said holds good equally of the occurrence of syphilis among all intellectual workers. The frequency of tabes and general paralysis in this professional class is not only favoured by the infecting agent, but also by the numerous occupational types of injury to which the central nervous system of intellectual workers are exposed.

From the foregoing it would appear that, in considering the origin of occupational maladies, account must be taken not only of the specific action of the professional damage, but also, at the same time, of the influence of environment in relation to diseases of the genital system, of the so-called secondary effects which are of importance as well as the primary injury. Those suffering from diseases of the uro-genital system may receive compensation where the substances giving rise to them presumably are scheduled under the Workmen's Compensation Act in force in the individual countries (see the article "Occupational Diseases: Definition and Compensation"). Certain lesions, however, figure in the list of scheduled conditions. Thus, for example, tumours of the bladder caused by amido-derivatives of the aromatic series are scheduled under the German Compensation Act. On the other hand, the British Schedule does not yet entitle victims to compensation. They are, however, statutorily notifiable in the U.S.R.R. Nephritis is compensatable in Bolivia, in France when due to lead poisoning, and in countries which have adopted the British formula and that of the Convention of 1925 (see also article "Infections").

**EYES**

**SOURCES OF INJURIES**

The causation of occupational injuries of the eye can be laid at the door either of environmental conditions, industrial processes or materials manipulated or liberated during work. Nevertheless, it is considered essential that the important part played by the constitution of the sufferer should not be ignored.

**Environmental conditions.** — First of all there must be taken into consideration atmospheric conditions, bad weather, sudden changes of temperature, humidity, and luminous radiations, the injurious effects of which are obvious in the case of such categories of workers as agricultural labourers, sailors, boatmen and drivers of vehicles.

Ordinary light, and especially direct sunlight, may be injurious under certain occupational conditions, as when, at high altitudes, through dazzle from snow and glaciers, it causes ophthalmia, or when the skin of the eyelids has become sensitive to the effect of luminous rays through the action of such products as pitch, tar or anthracene.
Sources of artificial light are especially injurious when they are rich in ultra-violet or infra-red rays (Vogt and his pupils); when their luminous intensity is insufficient or excessive; when the lights are inadequately placed or are too bright; or when the contrasts are too pronounced (see article "Industrial Lighting"). Similarly, it is necessary to take into consideration in many occupations the effect of heat rays, either isolated or associated with the preceding, and also of X-rays, radium and radio-active bodies.

Low temperature may likewise exercise an injurious effect on the eyes.

**Conditions of work.** — It is merely necessary to mention that excessive and prolonged work, especially when it is fine and the lighting is inadequate, is the cause of eyestrain and of several ocular affections. Even though such work does not usually cause definite anatomical lesions, it does in every case lead to functional disturbances — sometimes very severe — of accommodation, of refraction, and of the extrinsic muscles of the eye.

**Materials manipulated or liberated.** — This group represents the chief source of eye injuries.

From a practical point of view, materials manipulated or liberated may be said to injure the eye in solid, liquid or gaseous forms. But under any of these forms, the materials may exercise a mechanical, thermal, chemical or infectious effect, or more often a mixed effect.

In fact, the workman may be exposed to the effect of dust, liquids or fumes at a very high temperature, or to the effect of particles, especially metallic, at high temperatures, and at the same time to the effect of irritant or toxic gases.

First, there should be mentioned inorganic dusts from metals, glass, cements or stones, which are well known to be quite a common cause of ocular lesions: vegetable and animal dusts from flax, cotton, hemp, wood, tobacco, wool, animal or caterpillar hairs which act on the mucous membrane of the eye, either mechanically, or, more particularly, by chemical action through irritation, dehydration of the tissues, coagulation, or burning. The effect of dust obviously depends on the one hand on its composition (hardness, shape and surface of the particles, their solubility in the lachrymal secretion) and, on the other hand, on the quantity. But there are also materials which may cause a local toxic action or infection due to the microbes which they may contain, e.g. clothes and rags, and finally there is the very numerous group of dusts which exert a chemical action. The effect of all these dusts is aggravated by the habit of rubbing the eyes with dirty hands; a mechanical action which runs counter to its object.

**Chemical substances** may act on the eye by causing a temporary or serious lesion, quite independent sometimes of the duration of their action. No distinction can be made between the effect of these substances according to the form under which they act; either fumes, liquids or solid products may cause injuries of equal severity, according to their composition and the special conditions of action. Injuries to the eyes may be caused by phosphorus fumes, hydrocyanic acid, lachrymatory gas, phosgene, sulphuric acid, hydrogen, by nitrous fumes, by fumes of nitric acid, chlorine, acroleine or naphthalin. Droplets, liquids or solids may act by being projected on to the conjunctival mucus membrane, sometimes with very serious consequences; these comprise such substances as ethyl or denatured alcohol, the essential oils, benzene, its homologues and their nitro-amido derivatives; tar pitch, chemical manures, and basic slag. In the articles dealing with these different products full details are given of the eye lesions reported by experts.

Acids rank first in importance among the products which may cause burning or deep destruction of the tissues, next come the alkalids, and chief amongst these are lime and ammonia, the latter of which is perhaps the most dangerous of all bodies liable to attack the eye.

Disease of the eye may also occur as a symptom, isolated or not, associated with both general poisoning due to lead, mercury, arsenic, methyl alcohol, methyl bromide, sulphide of carbon, benzene derivatives or tobacco, and with such general conditions of the body as rheumatism or nutritional diseases. There may be also primary or secondary lesions of infectious or parasitic diseases, such as actinomycosis, an epizootic aphthous disease, ankylostomiasis, anthrax, glands, yphils, tetanus or palpebral vibrio gangrene. Among caisson workers and divers, tunefaction and emphysema of the eyelids and conjunctivae are sometimes observed, as well as changes in the fundus of the eye due to congestion of the optic disc, and paresis of the abductor muscle (Allan).

Some authorities have described eye affections among oyster-openers from
the dust generated, or from the projec-
tion of small splinters; lesions caused by
eel's blood owing to its haemolys-
ing action; and recently accidents of
severe nature due to scattering vaccina-
tion lymph.
Changes in the fundus oculi occur in
the case of serious burns on the body.
Thies has described two such cases,
which he attributed to toxins formed
on the surface of ulceraUons follow-
bring burns. In one well-known case,
that of a young chemist, blindness oc-
dered in one eye for twelve days and
in the other for nineteen days,
with, however, complete return to the
normal. Ocular lesions have been re-
ported following upon the effects of
pressure, such as work in compressed
air, of violent physical efforts with
detachment of, or haemorrhage into,
the retina of wounded and crushed
of the thrap, of contusions and serious
injuries of the body and especially of
fracture of the skull which are accom-
panied by changes in the eye giving
rise to haematoma in the lids, conjun-
tuUa, and optic nerve sheath.
Most of traumatic lesions — accidents —
to the eye must be given first place in
the occupational pathology of this
organ. Sudden violent lesions, caused
by flames, liquids or products at high
temperature, or products of which the
chemical action is serious, must be con-
sidered as industrial accidents from
the medico-legal point of view; as must
also all the numerous lesions caused
by foreign bodies, which too often lead
to perforation of the eyeball and to
loss of sight.
In certain occupations the eye is
much more exposed to accidents than
in others (see article "Metalisation ").
Metal workers are affected by metallic
splashes and particles of metal,
which are either in the molten state or at a
high temperature. Nevertheless in
the case of certain metals with a low
melting point, the particles may reach
the cornea almost cold, and cause less
severe injuries. Glassworkers are
exposed to burns from flames, gases,
liquids and hot solid bodies. Agri-
cultural workers are exposed to in-
juries from lightning, blows from
agricultural implements, and blows
from the tails or horns of animals,
which may produce rupture of the
sclerotic and subconjunctival disloca-
tion of the lens.
Foreign bodies may be superficial —
on the conjunctiva or cornea — or may
penetrate and be intraocular or intra-
orbital; in the first case the foreign
bodies may, however, be the starting
point of very serious secondary infec-
tious lesions.

STATISTICS

It is difficult to give statistics relating
to occupational diseases of the eye, as
most statistics deal chiefly with all forms
of oculo-trouble.
Eisenschön, of Prague, found that, of all
the lesions of the 'eyes treated in the
period 1907-1924 in his clinic, only 8.53 per
cent, were of occupational origin, of
which a third was accounted for by
corneal ulcer.
Fuchs, of Vienna, admits that eye-lesions
of occupational origin claim a percentage
of 8; but in order to reach this average he
included lesions with subsequent corneal
ulceration arising from chipping mil-
stones. According to this authority, a
third of the cases of loss of sight are due
to accidents.
The statistics from the Wolffen centre
(Bitterfeld, Germany) may also be quoted;
according to these, eye lesions of occupa-
tional origin in 1926 constituted 12.45 per
cent of all accidents, and in 1927, 11.16.
The German statistics show that it is on
the whole the occupations of stone-cutting
or metal working or work in the chemi-
 cal industry that show the greatest number
of eye accidents due to foreign bodies,
explosions and burns.
English statistics collected at the Home
Office Industrial Museum for the period
1924-1926 are also suggestive. They deal
with 20,459 cases of eye-lesions, about
7,000 a year, of which 8 were fatal. Their
distribution is as follows:

In the U.S.S.R., Meisl and Kybnik found
in 1925 among 2,484 workers at an electric
machinery works at Kharkow, 4,083 acci-
dents, 65% of which were injuries to the
eyes.
The importance of eye lesions of occupa-
tional origin is also clearly shown by
American statistics, which disclose the
fact that the ever-increasing use of pneu-
matic hammers and of compressed air
tools in general is a very frequent cause
of eye accidents. In the United States,
15,000 out of 100,000 eye accidents are of
occupational origin. The National Safety
Council estimates that about 200,000 eye
accidents occur each year, which means
that there is an eye accident every three
minutes, taking the year as 365 days and the working day as twenty-four hours.

In 1923, in Pennsylvania, 669 accidents resulted in the total loss of one or both eyes. Harry Best, in his inquiry into 90,242 cases of blindness, emphasises the fact that occupation is the most important cause of blindness.

During eight years the accident insurance companies of Pennsylvania paid 3,983,679 dollars for permanent incapacity from loss of limbs, upper or lower, as against 6,501,763 for permanent incapacity due to blindness. From 1918 to 1922 the railways of Pennsylvania, employing on an average 236,000 persons, found that 7.6 per cent. of all accidents were eye lesions, with a rate of 9.3 per 1,000 employed.

Some other Pennsylvanian figures, dealing with 691 eye accidents, indicate that 66 per cent. of all eyes lost belonged to coalminers or metal workers; 18 per cent. to 10 different industrial groups, 8 per cent. to those employed on constructional work and 8 per cent. to those employed in such public services as the post-office, telephone, telegraph or electricity.

The Travelers' Insurance Company found during three and a half years that among 1,049 cases of eye lesions, 424 occurred among mechanics, 102 among woodworkers, 76 among smelters, 61 among coalminers, 36 among chemical industry workers, 55 among stonecutters, and 55 among masons.

In the iron and steel industry out of 2,673 eye lesions found in 1923 in a single works, 17 per cent. of the accidents affected fitters, 14.4 per cent. smelters, 13.3 Bessemer furnace workers, 13.3 furnace workers, 12.8 tube makers, 12.5 electricians and 8 mechanics.

In 1922 in an American naval ship-yard (Philadelphia) there were reported 4,343 eye lesions, which had been caused by foreign bodies in 1,620 cases, by rust in 605 cases, by burns in 206 cases, by incrustation of particles in 552 cases and by splinters of steel in 79 cases. In 430 cases there was blepharoconjunctivitis, in 121 contact ulcers, in 162 electrical ophthalmia, in 61 contusions, in 28 chalazion, and in 3, cataract.

**PATHOLOGY**

For greater convenience attention will here be confined to examination of the different ocular lesions according to an anatomical plan, although of course subject to recognition of the fact that the morbid factors generally act on one or several parts of the eye, thus causing more or less complex syndromes.

**Eyelids. —** Pigmentation of the skin is quite common; it may go as far as atrophy with shrivelling in the case of persons working in the open air, such as sailors and agricultural workers. Pigmentation, especially in the form of simple erythema, is due either to luminous or heat rays, in the case of sailors, hunters, agricultural workers, mechanics or blacksmiths, or to chemical products, e.g. picric acid, tar or pitch. The pigmentation in time advances towards a reddish-brown and then to an intense brown. Small incrustations in the skin of the eyelids from small metal splinters are seen, and even small cicatricial points from burns among smelters and blacksmiths.

But it is chiefly the palpebral border which is affected, the irritation being due to dust, vapours, gases and fumes. The blepharitis is characterised by swelling and inflammation of the free border, with inflamed or glandular irritation and oedema. Blepharoconjunctivitis — blepharitis from dust — has been very well described by Le Roy des Barres and Courtois-Suffit, who distinguish the following kinds: simple redness of the palpebral border; an ulcerous form with small crusts on the level of the lashes or of the hair; small nodules of a furunculous kind; cicatricial blepharitis, due to the presence of small cicatrices caused by burns resulting from incandescent sparks, seen among blacksmiths and locksmiths; and obstinate blepharoconioses occurring among pit-saw workers; small turners, weighers of wheat, flax spinners, chemists, persons who crush medicinal barks, hemp spinners, brush makers, horsehair workers, feather dressers and furriers. The blepharitis leads to loss of the lashes, and the cicatrical healing of the lesions is often accompanied by ectropion or entropion.

A chronic eczema, which is tenacious, obstinate and difficult to cure, is caused by several products; it is aggravated by continual lachrymation, and especially by the act of wiping or removing the tears.

Aceneiform efflorescences, with the formation of warts and entropion, have been reported among tar workers.

Tumours are rare; nevertheless, Hessberg and Baer have described cancer of the eyelids caused by the irritating action of tar and pitch dust. Cases of rodent ulcers have been reported as sequelae to burns.

As regards infectious diseases, reference may be made to vibrio gangrene met with by Antonelli among agricultural workers in contact with manure; to the chance occurrence on the eyelids of malignant pustule, of glanders (not common), of botryomycosis, of syphilitic ulcer and the ophthalmomiasises.

In addition to various contusions and wounds, mention should also be made of burns of the eyelids, which may appear in three degrees: as simple
erythema, vescication, or necrosis of the tissues.

As regards the lachrymal apparatus, weeping constitutes — together with shutting the eye — the first line of defence of the eye against the irritative effect of foreign bodies, etc. Simple weeping generally disappears with the cause, but may become chronic in some cases, and give rise to various disorders of the lachrymal apparatus, such as narrowing of the canaliculi and dacryocystitis. Foreign bodies, such as caterpillar hairs, may cause rupture of the lachrymal sacs, with subsequent fistula and eczema of the commissure of the lachrymal sacs, with subsequent dacryocystitis. Foreign bodies, such as caterpillar hairs, may cause rupture of the lachrymal sacs, with subsequent fistula and eczema of the commissure of the eyelids, from constant lachrymation. Although very rarely, cases of actinomycosis of the lachrymal apparatus have been met with (Graefe, Forster). Purulent dacryocystitis is common among agricultural workers, who are frequently subject to cold, and show nasal affections of doubtful occupational origin, the dacryocystitis then being an ascending complication from the lesions of the nose. Among harvest reapers there is found a very high frequency of hypopion ulcer.

Changes due to streptothrix may be found in the lower lachrymal canaliculus, especially in women. It is very difficult to separate from the clinical point of view the lesions of the conjunctiva from those of the cornea, for they arise from the same causes and appear almost always at the same time.

The conjunctiva may show coloration and pigmentation from various products: yellow due to picric acid, violet to benzene, yellow to phosphorus, — and sepia brown — especially in the region of the palpebral opening — due to coal dust. Little black specks have been found on the conjunctiva at the level of the palpebral angle in post office workers, who apply sealing wax and hold it in a softened state in the flame of a candle for long periods. This smoke may cause extensive dermatitis, which is always accompanied by slight eye affections (Freund).

The commonest lesions are those which arise from acute, subacute or chronic irritation or inflammation of the conjunctiva, setting up conjunctivitis, characterised by redness, lachrymation, a feeling of grit or of small foreign bodies, photophobia, and a secretion which may be watery or purulent. Some forms of conjunctivitis are accompanied by small haemorrhagic effusions, as in cases of poisoning by arsenic, and irritation by sulphur dioxide.

Ophthalmia from electric light, following upon exposure to the electric arc, should be mentioned. According to the intensity of its effect, at the end of some hours of exposure to the light a more or less severe conjunctival hyperaemia is observed, with smarting, photophobia, blepharospasm and superficial lesions of the cornea. The cure may occur rapidly, but it sometimes happens, after between eight and fifteen days, that lesions of the deep membranes appear.

This kind of lesion has also been found in cinema artists (see article "Artists").

Workmen who make X-ray tubes are exposed to the effect of X-rays and may show lesions of the eyelids, conjunctivae and even of the lens. Almost similar lesions, but generally more benign, are found in the ophthalmias named after the snow or glaciers, by exposure to which they are caused. Chronic conjunctivitis, due in particular to the constant effect of dust and fumes, is characterised by certain peculiarities. Thus, for example, flour dust, which affects bakers and flour millers, becomes mixed with the lachrymal secretion and causes a diminution in the diameter or a definite blocking either of the lachrymal ducts, accompanied by an overflow of tears and chronic lachrymation, or of the excretory canals of the Meibomian glands, when styes and small abscesses on the palpebral border may result. In the case of men who cut hairs off skins and in the case of elderly hat makers, Haas and Helm have, on the other hand, found a diminution in the lachrymal flow consequent upon a reduction in the diameter of the lachrymal gland openings.

Workers exposed to all weathers may suffer from a thickening of the conjunctiva on a level with the palpebral opening. Tobacco sometimes causes the formation of small vesicles on the conjunctiva.

Pterygium has been observed frequently among masons, lime burners, plasterers, stonecutters, ceiling plasterers and farm labourers.

Cases of serious ophthalmomiasis have been reported among workers in tropical climates. In rare cases anthrax infects the conjunctiva and also glanderers, syphilis and actinomycosis. A case of botryomycosis has been reported by Bargeton. A case of severe conjunctivitis from the projection of vaccine into the conjunctival sac has also been recorded. Cases of trachoma are more common. In countries where this disease is endemic its transmission by means of tools among workmen has been reported. Epizootic aphthous dis-
ease is characterised by vesicles on the conjunctiva.

As a rule conjunctival lesions do not occur alone, but are accompanied by lesions of the cornea in the form of kerato-conjunctivitis.

In the case of wood turners a certain degree of loss of corneal sensibility has been observed; this is dangerous in that workers only notice lesions due to foreign bodies when there is suppuration (Sanovjoloff). Diminution or complete loss of sensation in the conjunctiva and cornea has also been noticed in poisoning by carbon bisulphide, as the first eye symptom in addition to general disorders of sensation (Oblath).

The cornea may also present various discolorations, black due to tar, or yellowish-brown due to aniline dyes, especially at the level of the palpebral opening.

Irritating substances acting on the cornea, may give rise to interstitial opacities (corneal opacities) which have different appearances according to the cause — dull or like porcelain when caused by lime, or thick and non-translucent when caused by superphosphates. These opacities are often accompanied by a tendency to the formation of small vesicles with desquamation, when due for instance to lachrymatory gas or aniline, and always by agonising pains. The changes caused by lime leave a white, indelible scar; those due to aniline have been actually observed by Vogt during experiments on rabbits, which died following severe eye complications.

Small wounds and foreign bodies sometimes cause slight losses of tissue which cicatrize rapidly. Sometimes they lead to the formation of corneal herpes, which may finally result in opacity of the cornea. Herpetic virus is often the cause of keratitis in the form of Fuchs's disc. A deep keratitis has been found in stable boys (very similar to that of Fuchs), which is perhaps the result of superficial injuries due to penetration by very small foreign bodies of vegetable origin.

The cornea of stone workers has a characteristic appearance; it is scattered over with very small foreign bodies consisting of stone particles, which have penetrated the Substantia propria under Bowman's membrane, but which do not cause discomfort to the men. The cornea of these workers likewise shows numerous and very small punctiform or linear opacities, which are the result of very slight injuries, often not felt by the workmen themselves.

Among persons who gather chestnuts there are frequently noted on examining the eyes fine prickles which come from the spinous envelope of the chestnuts. These fine prickles, armed with barbs, on reaching the corneal tissue, set up there a definite irritation; their extraction is not easy (Oblath). As sequelae to these lesions small opacities of the cornea are found.

Wounds by aniline pencils, especially methyl violet, may range from a slight graze and coloration of the conjunctiva to more or less severe affections of the cornea. As sequelae to these lesions small opacities of the cornea are found.

Forms of keratitis are very common in a number of industries, such as dyeing, soap making, sugar refining, and weaving; for example, in the weaving of artificial silk, Krahnstover, after examining a large number of workers with the slit lamp, reported a characteristic superficial inflammation of the cornea, which had the appearance of being spotted with little vesicles.

These lesions have been the subject of numerous researches in several countries (Rodenacker, Colrat, Loriga, Kranenburg, etc.) where experts have often attributed them to the effect of sulphured hydrogen (see article "Artificial Silk"). Superficial corneal changes and conjunctivitis, found among workers at refineries for sugar beet, have also been attributed to this gas (Rochat).

Corneal ulcers are serious lesions, sometimes due to secondary infection complicating lesions caused by inflammation of foreign bodies in the cornea. Among the ulcerations caused by the direct action of chemical products should be mentioned corneal ulcer caused by lime, which may heal, but with the formation of extensive leucomas which are frequently vascular. Granulation tissue, deformity of the eyelids and symblepharon result from the burning action affecting the conjunctiva, and particularly the cul-de-sac. In the most serious cases the cornea and conjunctiva are always affected. The lesion may also produce necrosis with perforation of the eyeball. Thus it is seen that even non-penetrating wounds of the eye may sometimes lead to its loss.

Chemical burns of the cornea may, like burns, be of different degrees of severity, depending on the factors which have caused them: the quantity of the caustic substance, the period of action, the pressure and force with which it has penetrated, the intensity
OCCUPATIONAL DISEASES

of the caustic strength, and its chemical nature. In the case of burns of the skin of the eyelids belonging to the first degree in severity, the inflammation of the conjunctiva rapidly disappears. In the second degree, vesicles and phlyctenules form upon the eyelids, with vitrifaction of the cornea which may even take on a clear whitish-grey coloration, if due to alkalies. Acids precipitate albumins and produce a hard crust; alkalies liquefy the albumins and form alkaline albuminates with soft crusts. Hydrochloric acid causes similar lesions to those caused by ammonia. It also causes opacities of the lens (Fehr). Lime exercises a caustic action, and, in addition, unites with the tissues to form incrustations and impregnations leading to opalescence and a milky appearance of the cornea.

The third degree is characterised by superficial necrosis of the skin, conjunctiva and cornea, with opacity and intense cloudiness. Ammonia is the most dangerous of all caustics. A serious caustic burn by ammonia, according to the description of Abadie, makes an eye look like the eye of a cooked fish. After some days, the eye recovers its normal appearance; but about the eighth or tenth day a sloughing of the membranes of the eye follows, despite every care. The danger arises from the great affinity for water possessed by ammonia, and from the fact that ammonia often enters the eye with force and pressure, for example while repairing refrigerating machines. Even a 10 per cent. solution of ammonia is dangerous, and eye accidents are reported to have led to the loss of the eye, when, during efforts to revive persons who have fainted, smelling salts have been poured into their eyes. Here also, a week after the injury, there superimposed increase in the intraocular pressure (glaucoma) and opacity of the lens.

The degree of heat, the nature and duration of the action of the injurious agent affect the seriousness of burns: redness of the skin, scorching of the lashes and eyebrows, with a sensation of heaviness in the eyes, characterise the first degree; lesions of the conjunctiva, especially the corneal part, with oedematous swelling and the formation of small white superficial scales characterise the second degree; while profound changes in the skin of the eyelids and of the subcutaneous tissue, the healing of which is accompanied by troublesome scars leading to deformities, together with necrotic processes on the cornea, formation of granulation tissue which causes union between the lids, characterise the third degree.

It must not be forgotten that in some cases tears play an important protective part.

Lesions caused by vaccination lymph are characterised by rapid corneal infiltration, with iritis, ulceration of the cornea and irido-cyclitis, terminating with enucleation of the eye (Debord and Villard).

The iris is often involved in the case of lesions of the cornea, and reacts by sero-purulent exudative inflammatory processes. In corneal ulcers, perforation with protrusion of the iris is frequently found, with anterior synechiae and secondary glaucoma, which causes cupping of the optic disc. Secondary glaucoma can also be caused by such inflammatory processes of the iris (iritis with hypertension and posterior synechiae, etc.). Mention must also be made of iritis and nodules of the iris caused by caterpillar hairs, as well as the iritis due to aniline fumes, to podophyllin and to cantharides (Oblath).

Cases of iritis have been recently reported as occurring amongst photographers exposed to the action of ultra-violet rays (Duke Elder).

The lens presents, particularly as occupational lesions, opacities and cataracts, of which the best known is that of glassmakers; it occurs, however, among persons employed in other occupations than glass making for instance among workers employed at blast furnaces, blacksmiths, smelters and solderers. A case of cataract in a doctor who worked constantly with X-rays and radium has even been recorded (Elschnig).

Occupational cataract, that is to say, that of glass makers and workers exposed for long periods to the effect of metals in an incandescent or melted state, starts by a small opacity situated at the posterior pole of the lens. This opacity progresses subsequently very slowly. Sometimes a dehiscence of the zonular lamella on the anterior surface of the lens is noticed, a lesion to which Elschnig attaches great importance for differential diagnosis from non-occupational cataracts. The left eye, which is generally more exposed to the injurious effect, is affected before the right, which, on the contrary, is the more exposed among mechanics. As regards the pathogenesis of occupational cataract, direct action of luminous and heat rays on the lens fibres must be acknowledged, as well as the indirect effect from heat on the ciliary body and iris; whence follow changes in the nutrition of the lens.
Cataract is found in about 17 per cent. of workers exposed to the effect of incandescent masses of metal after not less than ten to twenty years from commencing their occupation. It is quite easy to differentiate the start of occupational cataract in its early stages from congenital or senile cataract. On the other hand, differentiation between fully developed occupational cataract and senile cataract is difficult.

In addition to lesions of the lens, with partial or total cloudiness which may be stationary or progressive, and may appear more or less rapidly after exposure to the injurious rays of the electric arc, cataracts caused by lightning, a somewhat rare form of electric cataract, which is unilateral and congenital, is composed of epithelial cells, at the point where the current has its entrance and exit.

Electric cataract hardly ever appears immediately after the lightning stroke, but more often several weeks later. It probably arises from a lesion of the subcapsular epithelial cells, due to the lightning, whence originates opacity of the lens. This opacity is not situated on the layer of the epithelial cells.

In siderosis of the eyeball, caused by particles of oxide of iron, which spread in the eye by the lymphatic channels, a red coloration of the iris is seen, and a cloudiness of the lens, the surface of which is speckled with yellow spots; cloudiness is also present in the vitreous body with changes in the retina and notably in the yellow spot. The iron particles appear, if they are very recent, as little brown specks; if they are not extracted and remain in the tissues, they appear as little specks of a rusty colour. In the long run they may cause serious injury. Siderosis of the cornea and of the iris, i.e. siderosis of the eye, causes after some months subcapsular changes and, finally, posterior changes in the lens and after a more or less prolonged period, blindness from retinal lesions.

In the case of foreign bodies composed of copper (chalcosis), a greenish-blue coloration of the iris is found, and an opacity of the lens in the form of a whirligig or a wheel, forming the pseudo-cataract of Purtscher. Copper is deposited in particular near the limbus, from which comes the annular form of corneal opacity caused by copper.

Mention should also be made of cataract caused by trematodes (Oblath).

Lesions of the deep membranes of the eye may be due to the action either of toxic products, or of radiations from light, heat or electricity, or of foreign bodies, or even of fatigue of the eye.

The chief symptoms are diminution in visual acuity, asthenopia, hemeralopia, hemianopsia, amblyopia, amaurosis, colour blindness, sometimes coloured vision, for example, red among workers at blast furnaces and foundries, and yellow in cases of arsenical poisoning; reduction of the visual field; scotoma for colours, especially for red and green, due to bisulphide of carbon, and various forms of annular scotomata and central or peripheral scotomata due to light.

Medical examination may disclose the existence of chorioretinal irritation; stasis in the Fundus oculi, with engorgement of the retinal vessels; papillary hyperaemia due to tobacco or carbon monoxide; ischaemia of the optic nerve, with mango-like retinal arteries caused by methyl alcohol. Retinal haemorrhages have sometimes been reported; but the chief injuries are generally from retrobulbar neuritis and neuro-retinitis with changes round the papilla, due to alcohols, carbon bisulphide or lead.

Litten has observed an intense violet coloration of the fundus oculi and optic nerve during poisoning by benzene, with a peculiar appearance of the arteries and veins which were coloured black.

The eye muscles, both intrinsic and extrinsic, may be affected by disorders of occupational origin. Among the extrinsic muscles the external rectus is sometimes paralysed in poisoning by lead, tobacco or carbon monoxide. This gas has also caused ophthalmoplegia with marked exophthalmos. Nystagmus is a very important neuritis, which is the subject of a special article.

The intrinsic muscles may also be affected, for example, during poisoning by carbon monoxide, lighting gas or benzene, with paralysis of the iris muscle. Alteration in the pupil reflex with inequality of the pupil may arise from carbon monoxide, aniline or arsenic.

The ciliary muscles, if fatigued, cause accommodation asthenopia among printers, engravers and watch-makers. They may become paralysed during lead poisoning, poisoning by bisulphide of carbon or benzene.

The myopia which is found in some occupations, as well as eye strain, may be associated with defective accommodation. But, although writers in the past have attached much importance to occupational myopia, the aetiological importance of close work
is nowadays very much doubted. The careful examination of statistics indicates, as a matter of fact, that it is not the occupations which create myopes, but that the myopes themselves have adopted such and such an occupation in consequence of their infirmity (Berhof-Harman).

HYGIENE

The prophylactic measures to be adopted for occupational diseases of the eye comprise general and special hygienic measures. Among the first should be mentioned general measures of hygiene for workplaces, and especially those which are aimed at lessening or suppressing such causes of injury as dust, vapours, gases and fumes, or those which deal with lighting, natural or artificial (see article "Industrial Lighting").

As regards the prophylaxis of occupational cataract, spectacles or special lenses proposed by Crookes and by Vogt may be worn, but they have not been favourably received by workmen. Good ventilation must be provided in front of the openings of furnaces. Above all, automatic and semi-automatic systems of work should be provided which do not expose workmen to injuries from heat, intense radiation, physical exhaustion and eye-strain. The progress of industrial technique may soon result in the disappearance of glass-makers' cataract.

Special measures have led to the protection of the eyes either by means of screens against too bright a light, or by means of breathing apparatus and goggles (see articles under these headings). In Germany some chemical firms have made compulsory, under penalty of a fine, the wearing of protective goggles, and this immediately reduced the number of eye accidents. A similar regulation was laid down by the Italian Government in its Industrial Hygiene Code.

Prophylaxis for eye lesions during manipulation of poisonous products is the same as that for the poisons themselves. Hence arises the necessity for personal cleanliness and for medical examination, either on joining or periodically during work, in order to eliminate persons predisposed to eye lesions, or to detect the first signs of poisoning.

LEGISLATION

Eye lesions which can be regarded as symptoms of an occupational poisoning, either by lead, mercury, benzene or carbon bisulphide, are as a general rule compensated according to legislative provisions which may include a list of occupational diseases. However, in some countries the legislature has extended the compensation to other eye lesions, for example, lesions of the skin and eyelids by caustic liquids, dust or certain products such as tar or pitch (see article "Skin Diseases"). Other diseases of the eye included in notification or compensation lists are the following: conjunctivitis is compulsorily notifiable in the Netherlands in the case of persons employed in briquette works, autogenous welding, sugar refineries, gas works, artificial silk works, and in the transport of pitch or products containing this substance. In Japan, diseases which are caused by substances at high temperature, by irritating gases or dust are compensated.

Ulcers of the cornea and conjunctiva are compensated in Great Britain and in the States of Minnesota and New York when due to paraffin, pitch, tar, bitumen and mineral oils; in Ohio and Porto Rico when due to carbon, pitch, tar or tar compounds; in Western Australia and Queensland when due to mineral oils, pitch, tar and tar compounds; in Venezuela, corneal ulcer from tar, pitch, mineral oil, petrol, paraffin and tar derivatives is compensated. In the Netherlands ulcers are compulsorily notifiable when they occur in the following occupations: agriculture; briquette-making; phototyping; refining; distillation of crude petrol, tar or pitch; incandescent mantle works; work on mas- onry, asphalt and coal; autogenous welding and cutting; the manufacture of incandescent lamps; dyeing of textiles; stone-cutting; forges and enamel works.

Cataract is compensated in Germany when affecting glass workers, smelters of iron and metals; in Great Britain when affecting glass workers, and smelters of iron and steel; in Austria glass workers; in Russia in the case of the continued effect of radiations of great intensity among glass blowers and workers in the metallurgical industry; in Chile and Venezuela in the case of glass workers; and also in Minnesota and New York State in the case of glass workers. It is compulsorily notifiable in the Netherlands for glass workers, steel workers and foundrymen. For nystagmus, see that article.

Retinitis and optic neuritis are compulsorily notifiable in the Netherlands (when occurring amongst workers engaged in coke furnaces, gas works, phototyping and autogenous welding), and in Poland; in Russia there is compensation as for cataract.

BIBLIOGRAPHY

 Ear, Nose and Throat

It may be premised that occupational diseases of the ear, nose and throat do not often lead to incapacity for work, nor is a fatal issue of common occurrence. Diseases of these parts do not therefore figure largely — indeed, may be said scarcely to figure at all — in the lists of compensation cases in the law courts. A boilermaker is almost certain to become deaf in the course of his work, but he does not seem to become less efficient as a workman on that account, nor is his longevity prejudiced. A chrome worker is very liable to develop a perforation of the nasal septum, but is seldom laid aside from his work even during the stage of acute ulceration, and after healing has taken place he is not apparently any the worse. In cases where a fatal issue or incapacity occurs, as may happen in lead poisoning and compressed-air illness, although symptoms referable to the internal ear may be present and even prominent, the incapacity or death is always due to disturbances of the general system.

I. — DISEASES OF THE EAR

Occupations which expose the various parts of the ear to injury of an occupational character are numerous, and the etiological factors, which are constantly increasing as authorities devote increasing attention to their detection, are very numerous.

Sources of Injury

Amongst the sources of injury the foremost are noise and vibration (see article “Noises”). As regards detonations and explosions, it must be stated that in the case of these (accidents, probably so-called, rather than occupational diseases) the organ of hearing is more often injured than is at present recognised. Where symptoms other than those of the ear predominate, this is to be attributed to the fact that the latter are late in being detected, sometimes only after the lapse of several years. The lesions are due to several factors: intensity of speed in pressure changes (where the explosion is produced in enclosed places, secondary shocks add to the force of the main explosive shock); calorific action of the flames from the explosion; atmospheric pressure: at times there is a general superpressure (caisson workers, divers) or merely at the level of the middle ear (glass blowing with the blowpipe); sometimes decreased or increased variation of pressure due to altitude or atmospheric depression — in the case of accelerated movement (aeronautics, aeroplanes, railway travelling); high temperature and radiant heat (metalurgical industry, chemical industry, potteries, mines, glass factories); hot and humid atmosphere (textiles, breweries); rapid changes of temperature, draughts (transport industry, gamekeepers, fishermen, agricultural workers, workers in the building trade, postmen, masons, laundry workers, cooks, etc.).

Very important sources of injury are constituted by dusts (solubility in organic liquids, size and shape of the particles, etc.), liquids, gases and fumes, the action of which depends on their quantity and chemical constitution.

A number of toxic products cause injury to the ear, either by exterior local action, or more often by a general internal action: hydro-carbides of the aromatic series, arseniuretted hydrogen, mercury, nicotine, carbon-monoxide, lead, carbon-di-sulphide, etc. (Voss). Various infective agencies may also become localised in the organ of hearing. Besides violent traumatic shocks, which may cause particularly lesions of the bony part of the ear, Voss recalls the harmful influence of slight and repeated traumatism (headpieces worn by telephonists), foreign bodies (ears of corn, splinters of wood in the case of agricultural workers) electricity, etc.

Statistics

While there is absolutely no doubt that ear disease is current amongst workers in certain occupations, it is nevertheless true that good morbidity statistics for these diseases are lacking (Peyser). In fact examinations carried out in the workshop are often superficial or incom-
complete; the data taken from figures provided by sickness funds and occupational organizations are notoriously inadequate, at least as regards initial forms; it should be added that a great majority of these lesions are mostly overlooked by those who suffer from them, by reason of the fact that they become accustomed to the action of the harmful agencies and to the rather slow progress of the lesions in question (Glogau).

According to Peyser, the University Ear Clinics only recorded, in 1913, 13 cases of deafness of occupational origin, amongst 2,500 admissions to the Breslau Clinic (0.52 per cent.); 80 out of 9,360 at the Berlin Clinic (0.95 per cent.); 37 amongst 1,973 patients (1.9 per cent.) in Roepke’s Clinic at Solingen.

Glogau reports that amongst 60 tobacco workers under his care there occurred 7 cases of ear disease, 70 cases of nasal trouble, 153 cases of disease of the pharynx, 12 cases in which the larynx was affected. Amongst 155 workers in ostrich feather and fur factories and in rope works, the same authority treated 337 cases of nasal trouble, 142 cases of disease of the pharynx, 131 of the middle ear, 49 of the internal ear, and 17 of the larynx.

Amongst 470 patients examined in 18 different factories, Peyser found 256 cases (53.5 per cent.) of ear disease.

The data relative to occupational deafness are more numerous. The facts are dealt with in detail in the articles “Copper Boiler Making” and “Transport Workers” (Railway Workers). It is sufficient therefore to recall that Wiehe (quoted by Voss, 1914) found amongst 65 locomotive mechanics 3 cases of acute otitis, 10 of chronic otitis, 12 of sclerosis and 5 of suppurrative otitis.

The statistics of the Leipzig Fund (1912) show that ear diseases amounted to a case rate of 19.5 per 10,000 members, with an average duration of 20.6 days; whilst the same rate for members belonging to the railway staff (locomotives) was 35 per 10,000 members, with a duration of incapacity averaging 37 days. This category of workers is, according to Boval, subject to affections of the middle ear rather than of the internal ear, many individuals showing predisposition to deafness as a result of a defective state of the upper respiratory passages.

In regard to other occupatations, Gottstein and Kaiser found good hearing in the case of 29 of the 75 blacksmiths examined, fairly bad in the case of 16 and bad in the case of 36. Holt found only 6 bottle-makers out of 40 examined who had good hearing, Barr only 9 out of 100 who had an average duration of employment of 17 years. Habermann found only 1 out of 31. Blevgad found marked diminution of hearing affecting 75 out of 354 telephone employees examined.

Lesions connected with deafness are proportional to the length of employment in the dangerous trade. Thus, e.g., according to Zwaardemaker (quoted by Castex), 25 per cent. of a number of workers suffering from deafness had worked 1 to 5 years; 35 per cent. 6 to 10 years; 50 per cent. 10 to 15; 60 per cent. 16 to 20 and 90 per cent. 20 to 25.

Similarly, Boval found that the incidence of deafness amongst engine drivers increased with age (from 11.7 to 62 per cent.) and with length of service (from 18 to 25 per cent.). In order to verify the current belief that weavers suffer from deafness, the English Inspectorate in 1927 subjected to thorough examination 1,011 cotton weavers (Dr. Henry) who had worked from periods of 1 to 64 years: 246 workers (24.3 per cent.) showed a certain degree of deafness and were sent to a specialist for opinion. The latter reported that deafness was due in 30.4 of the 246 cases examined to chronic suppurative middle otitis; in 27.4 per cent. to a nerve lesion; in 19.5 per cent. to wax; in 17 per cent. to catarrh; in 11 per cent. to a traumatic form. In the case of 0.6 per cent., there was found chronic catarrh of the middle ear with nervous deafness and acute suppurrative otitis of the middle ear.

**PATHOLOGY**

Injuries may affect separately the external, middle, or internal ear, but more often they affect several parts of the ear simultaneously.

(1) **External Ear**

**Pigmentation of the auricle,** by the simple deposit or penetration into the skin (tattooing) of particles of matter manipulated, occurs fairly frequently with colouring, varying in accordance with the products in question: black (coal, iron); grey (emery); bluish (silver); blue (aniline). (See article “Skin Diseases”, Stigmata.) Hypersensibility of the skin of the auricle has been found amongst telephone workers as a result of the constant pressure of the headpieces (Röpke, Blevgad), amongst sisters of charity, due to the wearing of a head-dress (Voss).

**Chilblains** are of frequent occurrence amongst workers in the open or in unheated workrooms (food industry or cooling chambers), or amongst workers subjected to sudden changes of temperature. There has, at times, been noted inflammation of the auricle and perichondritis with thickening and even subcutaneous sero-sanguineous discharge followed in some cases by escharification and necrosis.

**Burns** are equally frequent and may be due to direct contact (molten metals) or to radiant heat (metallurgical workers, glass workers, machine stokers, etc.). It is generally a case of superficial lesions, but at times of burns involving permanent deformity.
Traumatisms play a fairly important role: varied wounds, parochondritis, hematoma (professional sportsmen) (Southan, Ochsen, Körner); wrestlers, acrobats (Bloch, Zanfal, Valentin). Zakaki has reported 29 cases of deformation of the ear due to hematoma amongst 72 Japanese boxers. Amongst transport workers carrying loads on their shoulders such lesions may at times involve atrophy of the auricle (Laubinger-Lehr, Körner, Muller, Kronenberg). Even amongst doctors there have been reported cases of hematoma due to friction of the stethoscope (Ligin).

Amongst accidents there may also be recalled the kicks and bites of animals, explosions, detonations, etc.

A more important place is occupied by forms of dermatosis due to dusts, liquid irritants, irradiant gases, development of which is so often favoured by perspiration and which are frequently aggravated by rubbing, scratching and lack of cleanliness. The most varied cutaneous forms are met with, ranging from simple irritation with erythema, inflammation, eczema, boils, to ulceration. There have also been reported cases of epitheliotma of the auricle due to tar.

At the level of the external auditory meatus there may be noted lesions due to the presence of foreign bodies: metals (blacksmiths); stones (masons); wood (woodcutters); straw, grain (harvest workers); splinters of wood (gamekeepers and hunters); dusts generally involve lesions which vary according to the nature of the dust: ranging from simple obstruction (iron, steel, coal, flour) up to an irritant action (zinc, lead and arsenic ore, or ore containing chrome or cadmium) with diffuse dermatities or eczemas, or even ulceration of the external auditory meatus.

Auto-mycoses are fairly frequent. Siebermann found in examining agricultural workers and carters cases of this to an extent of 29 per cent.

Mycosis of the external auditory meatus (*Aspergillus niger, flavus or *fumigatus*) occurs amongst agricultural workers, weavers, spinners, woolleners, paper-mill tenders and laundry workers. They work in atmospheres and fatty soil favour growth of the spores. Repeated attacks may cause thickening of the dermal coat of the tympanic membrane and so lead to impairment of hearing.

Besides *Aspergillus* and *Penicillium*, harvesters or threshers of corn are exposed to the action of *Ustilago carbo* and *Tilletia Levis* and *Actinomycosis* (Urbantschitsch). Grazzi has met with a case of auto-mycosis due to *Ustilago carbo* affecting a naturalist, and Braustein and Blevgad cases of automycosis amongst telephonists.

(2) Middle Ear

There have been reported cases of redness, congestion, oedema or atrophy of the drum amongst workers in the transport industry, aviators, aeronautical workers, fishermen, sailors (action of air-movement), glass workers and workers in the chemical industry.

Cases of ecchymoses have been noted amongst caisson workers, sponge divers and other divers. Penetration of particles of material manipulated (metal particles, pieces of straw, splinters of wood, etc.) may cause more serious lesions. Ordinary burns and chemical burns due to penetration of molten metal or boiling or corrosive liquids and even, at times, of gases have been recorded by several authorities.

Rupture of the *membrana tympani* may occur from explosions in mining or blasting operations or in gun firing or shell bursting, or among divers and sponge fishers. As a rule speedy repair takes place unless suppuration of the middle ear occurs from infection.

Injured, atrophied or scarred drums are particularly pre-disposed. Shrinkage of the external auditory meatus likewise favours rupture. The drum may also show modifications of its natural convexity towards the interior part of the tympanum due to hyper- or hypo-pressure in the middle ear (aviators, glass-blowers, telephonists, etc.). Such troubles are often accompanied by temporary deafness, nausea, vertigo, etc.

Shrinkage of the drum due to spasm or contraction of the muscles of the middle ear (tensor muscle, stapes muscle and malleus muscle) has been encountered by Blevgad, Peyser, etc., amongst telephonists on the side at which the listening apparatus is applied (Hansen, Borkendahe, Pollack, Urbantschitsch), amongst boiler-makers, blacksmiths, mechanics, engine-drivers, etc. It must, however, be admitted that the question of occupational disease as affecting the muscles of the middle ear is one which calls for further and more detailed research.

Lesions of the middle ear by way of the external auditory meatus and the ear drum are very rare. However, perforation of the drum (not of occupational origin) exposes the victim to middle otites, by penetration of water
(professional bath attendants and divers) and toxic products (nitro-amido derivatives; Kurschmann), but the most important occupational disturbances originate in the mucous membrane of the nose and the pharynx by way of the Eustachian tube. It is in this manner that in the case of workers who are subject to nasal catarrh in the Eustachian tube and to nasal pharyngitis (aviators, orators, divers, workers in the dusty trades, etc.), forms of middle otitis constitute a fairly frequent complication.

Forms of acute catarrhal otitis due to cold, though relatively rare, occur amongst workers in the open air (Opitz, Peyser) and more often amongst workers exposed to sudden changes of temperature. These forms of otitis occur in combination with those due to other causes; dusts, irritating fumes, etc.

Kerr Love has drawn attention to the presence of coal dust in the middle ear of coal-miners. These forms of otitis are chiefly caused by the irritant or infectious effects produced by dust on the mucous membrane of the nose and naso-pharynx.

(3) Internal Ear

By far the most common occupational disease of the ear is nerve deafness induced by exposure to loud sounds (see article "Noise").

These may be manifested by transitory crises (aviators and mechanics engaged in motor testing); neurotic deafness due to the noise of the motor either during flight or in the hangar (Ranken), which likewise constitute initial symptoms of permanent and progressive deafness. This form, which is most frequent amongst boilermakers, is only met with in general after a more or less extensive period of work, (three to five years on an average). At the outset the symptoms of deafness may be attenuated by rest, especially by the Sunday rest, but gradually the lesion becomes more and more deep-seated, reaching a maximum after the lapse of fifteen to thirty years.

An interruption of work lasting eight days brings about no improvement in this deafness. A longer absence (several months) on the other hand may retard the onset of deafness (Holtzmann).

Sometimes deafness sets in more rapidly; development only lasting a few months. However, under ordinary conditions and equal length of employment certain workers are affected, while others remain immune. Early and serious deafness is met with amongst subjects manifesting defects of the Eustachian tube, or more particularly chronic lesions of the rhinopharynx, accompanied by the symptomatic complex of adenopathy.

Occupational deafness once established is characterised by a more or less marked diminution of hearing affecting both ears, or oftener only the ear usually most exposed to noise. Defective perception is confined at first to predominant sounds by which the workers are exposed. For a long time diminished hearing is restricted to high-pitched sounds corresponding to such noises, and it is only ultimately that there is noted diminution of hearing for other sounds.

The clinical data relative to boilermakers' deafness has been adduced in detail by Ritchie Rodger in the case of 50 boilermakers representative of all ages and all lengths of service. A first series of researches dealt with the approximate alternation of the pitch of sounds predominating in boiler shops, varying between 400 and 500 double vibrations per second. Workers were examined with the aid of tuning forks: 1 of 32 double vibrations to test the perception of low notes; 2 forks of 419 and 512 double vibrations, corresponding to the lower and upper limits of the predominant noises; 1 tuning fork of 2,048 double vibrations for testing the hearing of high notes, and a monochord was used to determine the upper tone limit. It was found that all workers in noisy trades, even after some weeks of employment, present some degree of deafness. Amongst the youngest workers the troubles only affected hearing as determined by tuning forks, corresponding to the noises in the workshop. According to Ritchie Rodger, loss of hearing of high-pitched sounds is not characteristic of deafness amongst boilermakers, as has up to the present been affirmed. The first authors to write on the subject (Barr, Hubermann) had to do with workers who did not apply to them except when seriously inconvenienced by deafness. The workers examined by Ritchie Rodger had not reached this stage, and the majority of the young workers vigorously denied being affected with deafness. This authority noted besides that all the workers examined showed loss of perception for tuning forks, corresponding to predominant sounds, indicating atrophied atroophic stretch of cochlea corresponding to that pitch without depreciation above or below. A young worker could even
hear 20,000 double vibrations per second on the monochord and showed normal acuity for 32 and 2,048 per second, whilst his appreciation for tuning forks 419 and 512 was reduced to two-thirds. Amongst men who had been exposed to noise for a longer period, the principal characteristic noted was a diminution of hearing for the highest notes as in the case of all forms of nerve deafness. Hubermann, in his researches effected amongst boiler-makers, came to conclusions which are, on the whole, similar.

The degree of seriousness of the lesions is proportional to the length and intensity of the sounds and noises of varying pitches, and they are generally found in the upper parts of the first spiral and at the commencement of the second (Ritchie Rodger, Van Eicken, Grünberg, Yoshii, Hössli, Hubermann). According to experimental research engaged in by Holtzmann and Maue, the most serious changes take effect in the ganglionic cells whilst the nerve and the organ of Corti are not attacked.

However, where the damaging agent exercises its effect over a long period these authorities have met with serious lesions of Corti's organ, but they have never noted definite lesions of the nerve. The vestibular apparatus is generally said to remain unaffected (Wittmaack, Siebenmann, Yoshii) and it does not begin to be affected until the animals are subjected to vibrations or violent detonations (lesion of the semicircular canals). Other recent observations would appear to prove that the presence of vibrations is not essential in order that noise should cause injury to the ear.

Discussion has for long centred round the problem as to whether injury to the internal ear is air-conducted or due to vibration. All observations made concur in showing that the principal mode of attack of the internal ear is by way of the transmission mechanism of the middle ear. However, the question of indirect implication of the sound-transmitting apparatus as well as that of the existence of changes which, if they be due to noise, do not progressively diminish the conductivity of the principal means of transmission of sound waves to the internal ear, is still sub judice. The clinical observations of Hensen, Bockendall, Pollack and Urbantschitsch show that contraction of the tensor muscle of the ear-drum and the consequent fixation of the apparatus for transmitting sounds, to which is added thickening of the tympanic membrane, constitute amongst workers in the noisy trades
OCCUPATIONAL DISEASES

an obstacle to the transmission of high-pitched sounds.

Pre-existing diseases of the middle ear are said to constitute, according to certain authorities, protection against nerve deafness. These diseases, the most common of which is perforation of the ear-drum, with or without otorrhoea, are said to lead to less forcible impact of the stapes against the oval window, and so to lesser injury of the cochlea. Perforation of the ear-drum is said to be without effect on the outbreak of occupational deafness (Holzmann). Certain authorities hold that this damping effect occurs also in cases of adhesions in the middle ear. In any case the removal of the incus or the induction of middle-ear suppuration in animals obviates the onset of cochlear changes (Van Eicken and Hössl). This favourable influence of middle ear suppuration, noted also by Ritchie Rodger, has not been confirmed by certain authorities who, on the contrary, consider that such conditions exert an influence causing pre-disposition to internal-ear lesions (Gradenigo) is of the opinion that catarrhal lesions of the middle ear play an important role, notably in altering the motility of the incus and malleus muscles, which are considered as the muscles of defence of the labyrinth passage.

Deafness is often accompanied by subjective noises, singing and whistling in the ears and a certain amount of hypersensibility to noise which may be interpreted as phenomena of cochlear irritation, and at times by perversion of the sense of hearing (Layet), with reduced hearing for high-pitched sounds and a sadden loss of perception for low-pitched sounds.

Paracusia, described by Willis, that is to say, improved hearing brought about by the influence of certain sounds, is often met with amongst workers in noisy workshops. These workers even possess the faculty of being able to talk to each other in an almost normal voice in an atmosphere found to be deafening by a visitor.

Forms of vertigo and discomfort, at times accompanied by nystagmus, nausea and vomiting, occur when perceivable vibrations are added to noise and when the worker is exposed over a long period to very loud and high-pitched or low-pitched noises (derangement of the vestibular apparatus). Glass-blowers, sailors, mountain guides, cyclists, motorists, miners, railway employees (especially mechanics and stokers), amongst workers engaged in the making of wines, amongst butchers (due to scratching with fingers soiled by meat juice, which is particularly irritating), divers, sponge fishers and caisson workers (during compression) may very frequently suffer from labyrinth derangements. The symptoms disappear in general very rapidly, but where there is haemorrhage or a lesion of the terminal nerve endings a certain degree of deafness may become permanent.

Derangement of the organs of equilibrium have likewise been noted amongst professional dancers, acrobats and music-hall artists (looping the loop). There should further be mentioned amongst occupational diseases of the ear neuritis of the auditory nerve, accompanied at times by hallucinations and acute labyrinthitis with Ménières symptom complex occurring during certain forms of poisoning (lead, mercury, carbon bisulphide, carbon monoxide, aniline, benzine, etc.: Westmacott).

Finally, it should be recalled that the clinical picture of certain infectious and parasitic diseases includes certain symptom complexes due to derangement of nutrition of the labyrinth (anaemia, ankylostomiasis, etc.).

II. — DISEASES OF THE NOSE

Apart from the action of noise, the sources of danger are similar to those described as leading to diseases of the ear.

PATHOLOGY

The most frequent trouble is nasal catarrh and catarrh of the upper respiratory passages, which constitute a defence reaction of the system since the humid mucous membrane arrests more dust and the inflamed mucous membrane restricts the passage of irritating dusts and gases. They cause anosmia or at least reduce the olfactory capacity, which is not to be confused with derangement of sense organs and of the sense of smell, which may arise in the course of general poisoning when the nervous system is involved.

The commonest form is catarrh.

Hypertrophic rhinitis with nasal obstruction is of frequent occurrence in occupations where workers are exposed to a damp atmosphere (weavers, cotton spinners: Della, Vedova, Westmacott), amongst workers engaged in the making of wines, amongst butchers (due to scratching with fingers soiled by meat juice, which is particularly irritating). Erosions, ulceration and perforation of the nasal septum are met with chiefly in those occupations in the course of which
workers are exposed to the action of certain irritant gases or fumes (nitric and hydrochloric acid, etc.), or certain hygroscopic products (lime, calcined spathic orres, chlorides, cement, etc.). Out of 165 workers engaged in sifting and packing salt, Müller found 45 suffering from nasal catarrh and 42 with perforation of the nasal septum. One of the most specific lesions is without doubt chronic ulceration of the nasal septum with or without perforation, affecting workers handling chromates or chlorates (see article "Chromates "), arsenical preparations (Scheele's green, Schweinfurt green, Paris green), or engaged in mercury gilding, etc.

Ulcerations and necrosis of the nasal cavity have been noted amongst workers due to contact with chromates, lime, hydrochloric acid, etc. There has also been noted rhinolithiasis due to agglomeration of dusts (cement).

Pains in the frontal sinuses are at times experienced by aviators (probably due to increased pressure inside the sinus).

Certain lesions of a traumatic nature are liable to occur to coachmen, stable-boys, sportsmen, etc. Others are merely symptoms of a disease affecting the general system. A typical example of this kind is constituted by glanders (see that article). The most common form is nasal catarrh due to cold, which is, according to Gottfried Müller, of two types. There is an aseptic form and an infectious form due to the action of dusts which affects not only workers in the open but sailors, boatmen and likewise workers exposed to high temperatures.

Nasal catarrh commences in general by itching and repeated sneezing. The symptoms are redness, inflammation, hypertrophy of the mucous membrane with nasal discharge and often accompanied by headache. At times there is epistaxis more or less intense, especially amongst young persons employed for the first time in dusty processes. Besides forms due to irritation, there is an anaphylactic spasmodic form caused by organic dusts.

In serious cases due to irritant gases there has been noted necrosis of a diphtheritic character affecting the superficial layers which have a whitish and at times a brownish appearance and become detached in strips (Sternberg). Thus for instance, ammonia at 0.18 mg. per litre of air (Lehmann) may set up intense inflammation of the mucous membrane accompanied by serous and blood-stained secretions. The epithelium, which is quickly sloughed off, reveals a bright red colour of the mucous membrane. Chlorine fumes cause ulcerations whilst hydrofluoric acid sets up particularly deep seated ulceration covered with white crusts which become readily detached.

Collis has noted, amongst granite cutters and grinders a smooth, dry and pale appearance of the lining membrane of the nose for the anterior quarter of an inch; behind this the membrane, which is probably covered with a crust of dust, is red and inflamed. More especially in the case of certain dusts—cement, for instance—the catarrh is accompanied by an eczematous condition around the nostril, which is probably an indirect effect of the nasal discharge set up.

Acute catarrh often develops into chronic catarrh involving atrophy of the mucous membrane accompanied by loss of the vibrissae. Dry atrophic catarrh is found chiefly in occupations where workers are exposed to hot dry air: laundry workers (ironing), spinners, firemen, blacksmiths, stokers, office employees (due to the action of central heating; Marschik). Atrophy of this type may lead to perforation of the nasal septum which is also noted as a consequence of the action of less harmful dusts: sawdust, cornflour dust, etc.

Traumatic anosmia is the subject of an interesting study engaged in by Woelk (1930). According to German statistics comprising 1,525 accidents, there occurred 738 cases of traumatism affecting the skull (48.53 per cent.), of which 265 (17 per cent.) showed disturbances of the olfactory sense. Out of 265 cases 63 individuals suffered from total anosmia, which was of traumatic origin in 44 cases or 2.9 per cent. (organic origin in 4 cases, functional origin in 17 and mixed origin in 23) and of a different origin in 19.

Anosmia, according to Onodi, may be of organic origin (essential, central or peripheric and respiratory), of functional or mixed origin.

Ziegler quotes the case of a worker who fell for a period of two seconds into a molten bath (sulphuric acid at 5 per cent.) and who suffered from total anosmia.

Cases of other than traumatic origin are not rare. They are met with consequent on infectious disease or following poisoning (by lead, mercury, carbon disulphide, iodine, etc.). Occupational pathology contains numerous instances of cases of anosmia met with amongst workers or employees in chemical products factories and due to
the inhalation of irritant or caustic fumes or gases (nitric acid, hydrochloric acid, chlorine, ammonia, etc.) capable of setting up olfactory disturbances. Whether and to what extent a lesion of this kind can reduce working capacity is a problem which calls for a solution in each particular case to be sought by extremely careful examination of the patient. On the other hand, there are occupations in which the sense of smell plays a very important role. Its loss or attenuation constitutes a serious hindrance to the occupational capacity of the individual.

III.—DISEASES OF THE LARYNX

For diseases of the mouth, see article "Mouth and Teeth".

Acute forms of laryngitis due to exposure to inclement weather, dusts, irritant fumes or gases, are generally manifested by alteration of the tone of the voice which becomes hoarse and by increased sensibility and dryness of the mucous membrane.

The oedematous form following inhalation of irritant fumes (chlorine, bromine, iodine, ammonia, sulphuric acid or even steam) is much more serious and may terminate fatally. Koelsch records a fatal case of chemical burning of the larynx by fumes given off in the course of soldering with copper and zinc where zinc chloride was used as a solvent.

The dry form characterised by atrophy is met with amongst washerwomen and workers obliged to work in a steamy atmosphere.

Chronic laryngitis is a frequent occurrence in occupations requiring vocal effort (artistes, orators, teachers and street vendors, etc.). According to Meyer, a particularly injurious effect derives from speaking in a falsetto voice or with a register other than a nasal intonation. Various lesions have even been met with: small ulcers and fissures of the mucous membrane located on the posterior surface of the larynx between the arytenoid muscles for which situation there is special predilection (Stoerk); erosion and softening of the mucous membrane, slight haemorrhages of the vocal cords (especially in the case of women and chiefly during menstruation); the "vocal knot" or knotty cord of singers, accompanied by diphyony (see article "Artists").

Symptoms of the larynx are also encountered in cases of occupational poisoning by certain products: paralyisis of the laryngeal muscles, for instance, in lead poisoning.

Tanquerel des Planches called attention to aphonia in horses in mines, sometimes necessitating tracheotomy, and Sajous has described adductor paralysis affecting a house painter, whilst unilateral paralysis of the adductors in plumbers has been described by Morell Mackenzie, and paralysis of the transverse and oblique arytenoid muscles which prevented approximation of the posterior ends of the vocal cords by Stiefer. Stoerk finally is said to have found laryngeal pachydermia amongst pork butchers as a consequence of excessive alcohol consumption— an affection likewise encountered in other occupations in which workers are subject to alcoholism.

Prophylaxis

The prophylactic measures to be adopted affect, in the first instance, the various sources of injury and should be effectively completed by medical examination of the workers on entering the occupation especially in the dusty and noisy trades. In this way it would be possible to eliminate individuals predisposed by functional or other defects or at least to call their attention to the risk involved by the special defects from which they suffer (hardness of hearing, labyrinth de-arrangements, etc.). This initial examination is all the more important since the majority of ear troubles, especially in the early stages, are ignored by those who suffer from them. The same is true of certain nasal defects: narrowing of the nostrils; obstruction due to polypi or adenoid growths which enforce mouth breathing and in consequence expose the subject to respiratory trouble. In this connection good vocational guidance makes systematic medical examination of the workers on a uniform plan essential (Peyser). There should further be indicated in detail the proper methods of medically examining the general system with a view to vocational guidance. Finally, it is essential to ascertain definitely the part played by middle ear affections in the causation of occupational deafness. According as to whether these exert a predisposing or protective effect, applicants for work affected should in fact be rejected or admitted.

Periodical medical examination at more or less extensive intervals, leading to the occupations and the requirements in question would also constitute a good preventive measure.
It is essential to investigate and ascertain the best method to be adopted universally for estimating auditory acuity in the workshop and determining the extreme limits of normal hearing compatible with the exercise of a noisy trade without examination by a specialist (Gilbert).

Gilbert considers that an international committee composed of doctors having free access to all the factories in their countries would be in a position to lay down the lines to be followed in an investigation into noisy trades.

Studies of this nature would require to be prepared in such a way that they might serve as a guide to otologists in their etiological researches relative to cases which they encounter.

Further, it is necessary to instruct the workers affected by means of lectures, tracts, posters, etc. A leaflet dealing with causes and prevention of occupational deafness due to noise has been published in Germany by the Health Office in collaboration with the German Association for Industrial Hygiene. This leaflet advises the workers in noisy trades to protect their ears by gauze plugs impregnated with vaseline or wax, to wear shoes with straw, cork, rubber or felt soles which attenuate the effects of vibration in the flooring.

Apprentices with hereditary history of ear disease should not be permitted to work in noisy workrooms. As soon as the worker becomes aware of troubles liable to be caused by noise he should be obliged to notify immediately the first symptoms which occur with a view to early and effective treatment.

The leaflet finally recommends the encouragement of every possible effort tending to reduce noise in workrooms and recommends that the possibility for workers to pass their spare time in quiet surroundings should be assured.

**LEGISLATION**

Ulceration of the nasal mucous membrane is subject to compulsory notification in the Netherlands when occurring amongst workers handling cement, packing chloride of lime or manufacturing soap powders and amongst workers engaged in the chrome and chromates industry. It entitles workers to compensation when caused by dusts in Great Britain, in Western Australia and in the U.S.S.R. (when affecting mud-bath attendants' and when due to manipulation of chromic acid). Hardness of ear and deafness are compensated in Germany, when due to noise in the metal industry. In the U.S.S.R. hardness of hearing due to lesions of the internal ear caused by the action of sharp sounds and affecting weavers, copper-smiths and nail makers is compensated.

The loss of the voice as a result of lesions and knots of the vocal cords is compensated in the case of singers and teachers in the U.S.S.R.

**Occupational Poisonings**

(Physiopathology)

**DEFINITION OF THE TERM "POISON"**

A treatise, from a general point of view, dealing with problems concerning occupational poisoning must, in order to have any scientific value, first present a clear idea of the poisonous substance, and then analyse the various effects it has on the animal body, especially on the human body.

It is difficult to define a toxic, poisonous or injurious substance, although to the lay mind the meaning seems clear. Setting aside old conceptions, now long out of date, of physical poisoning, e.g. by glass or metal in powdered form, as opposed to chemical...
Poisoning, it has been the custom to think of a poison as a substance foreign to the human body and capable of injuring that body by means of its chemical action. This definition is not quite in accordance with facts and cannot be considered as complete. As a matter of fact, there are a great many substances capable of seriously injuring the human body, and in this way of becoming the cause of many common and serious occupational poisonings, which are normal constituents of the animal body, and in particular of the human body, or which at any rate are present nearly every day in food, although in small quantities: mention may be made of arsenic, and such heavy metals as copper, zinc, and even lead. But, in addition, the internal secretions, although constituting the normal products of the endocrine glands, under certain conditions of quantity and quality can seriously interfere with the functions of one or other system and lead to morbid syndromes which are clearly recognised and defined. On the other hand, some substances — for instance sodium chloride, which is so necessary for life — may in certain doses cause sickness or death, and may, under certain special pathological conditions, even be injurious in the ordinary amount used for food. Then, again, it is not by a chemical action only, but also by physico-chemical action, that many substances injure the body. Neither can it be considered, as is commonly done, that every substance is poisonous which may cause a functional disorder when introduced into the body in a small dose, for while that may be true in some cases and even for a great number of poisons, it does not alter the fact that there are some substances injurious in some doses, whilst in other doses they are not only inoffensive but necessary to life; such is the case with sodium chloride as just stated.

Thus, according to Flury, the degree of toxicity is not the attribute of a certain substance, but a relative idea, and, as demonstrated later, the difference between a poison and a medicine is seen to become more and more effaced. In fact it may be said that poisons and medicines both enter into chemical or physico-chemical reactions with the living protoplasm, so modifying its function in some definite way. If this functional disturbance is sought for, or more or less desired, and also is generally useful, the substance which produces it is given the name of "a medicine"; on the contrary, if this disturbance is dangerous and injurious, the substance is designated "a poison". Hence, in the present state of knowledge, it is not easy to formulate an accurate definition of the word "poison". In order to formulate one which, in a certain measure, serves to meet the case, reference may be made to that adopted by Biondi in his teaching, which resembles that of Starkerstein (it is also accepted by Flury and others):

"Exogenous substances and endogenous substances in the body are to be regarded as poisons, which, on account of their chemical or physico-chemical action, and by their quality, quantity and concentration, which differ from those of the body itself, or from one particular organ, are capable of causing functional troubles in the living body."

Hence, in order to define what substances are toxic and capable of causing occupational poisoning, there must be considered as such certain substances possessing the above-mentioned characteristics and properties and found in the materials handled, in the products, in the tools, or in the work-place. These are the sources of poisoning of chief interest as they cause the morbid conditions of which it is necessary to estimate the seriousness in relation to work.

Thus, it must be admitted that besides voluntary poisoning, in which the action of the poison is desired by the taker of the poison, the source of the poisoning must be sought either in an accidental act, which may sometimes come under the legal definition of an industrial accident, or in some condition during the normal progress of a particular piece of work which may lead to occupational disease, or in an act, due to the fault of others, which may come under the designation of delinquency or semi-delinquency.

Portals of Entry for Poisons

When dealing with the portals of entry for poisons, as a general rule there is included the subcutaneous, intramuscular, endovenous, rectal and vaginal paths. But in the case of occupational poisonings there need only be taken into consideration the cutaneous path, the mucous membranes, the digestion, and the air passages.

For a long time, even up to recent years, the general opinion was that in man it was not necessary to consider the healthy skin as a portal of entry for poisons, at least not for industrial poisons. It was believed that the skin, being covered with a thin layer of fat, could not be penetrated by substances dissolved in water, and as
it was thought that substances insoluble in water could not usually be absorbed. The intact cutaneous path was considered the only portal of entry for these substances, but experience has, however, shown that these theoretical conceptions differ from the true facts; there is no denying that, if the epidermal cells of the cornal layer and of the stratum pellucidum with their fatty surfaces or lipoids, prevent the absorption of substances dissolved in water, it does not mean that these solutions cannot penetrate by means of the openings of the sebaceous and the sweat glands, and that by these paths certain toxic substances cannot be absorbed, even in small quantity.

It does not mean either that there cannot be other conditions, unknown at present, but which may, independently of these factors, lead to the absorption of aqueous solutions through the intact skin. One of these conditions may be represented by the alterations which the corneal layer undergoes on contact with certain substances, as for example salicylic acid and phenol. These substances are the most serious obstacles to the absorption of aqueous solutions. Then again, there can be no doubt about the possibility of absorbing through the skin substances which are soluble in organic solvents and, especially, in fats and lipoids. In this way the absorption of anilines and nitro-benzenes is understandable, as well as that of mercury and lead, although until quite recently this was denied. Some gases also undoubtedly pass through the healthy skin, e.g., hydrocyanic acid; the volatile fluid, tetraethyl lead, can also penetrate the skin.

The mucous membranes present a more favourable medium than does the skin for the absorption of poisons; but, from a practical point of view, in the domain of industrial poisons they do not play any particular part. The conjunctival mucous membrane should be specially mentioned, but the reason why the penetration of poisons by this route is of less importance is easily understood; whilst, on the other hand, the mucous membrane of the digestive and respiratory apparatus should be taken into consideration at the same time as the respective systems.

The various parts of the digestive apparatus are all capable of absorbing poisonous substances, but in different degrees, which perhaps also depends on the nature of each of the substances (Meltzer). Absorption may also occur by the mucous membrane of the mouth, although it is not usually considered; in the same way the entrance of poisons by the oesophagus and rectum may lead to more important toxic effects than those which occur by other parts of the alimentary canal, a doctrine being made for the absence of the antitoxic effect of the liver, and for the fact that the venous blood from the mouth, oesophagus and rectum does not pass through the _vena cava_, as does that from the stomach and small- and large intestine.

Also, as regards the alimentary canal, it was maintained up to a few years ago that only substances soluble in water can be absorbed. In this way the possibility of the absorption of numerous industrial poisons was denied; and it is well known that a distinguished industrial pathologist, Hambousek, denied that pure lead sulphide could be absorbed, while all the time Biondi was able to demonstrate experimentally its absorption by the alimentary canal. These theoretical presumptions fall one by one before experimental and clinical proof, and it is now known that the gastrointestinal channel is open also to industrial poisons which are insoluble in water.

The third portal of entry for industrial poisons — not merely for those in the state of gas and fumes — is the respiratory passages. The absorption of gas takes place essentially through the epithelium of the pulmonary alveoli; and its intensity can be understood considering the enormous surface — several tens of square metres — represented by the pulmonary alveoli. But absorption by the respiratory passages is not so simple as appears at first sight, even in the case of gases. First and foremost there is the reflex stimulating the terminations of the sensory nerves and, in particular, of the trigeminal, especially in certain conditions of special neuro-vegetative vagotonic action, can cause arrest of the circulation and respiration sufficient to bring about rapid death, while giving the erroneous impression of a toxic asphyxiating process which has never occurred (Bianchini and his pupils). There are also gases which cause an intense congestion of the mucous membrane of the pharynx, trachea and bronchi, and others which become decomposed on coming in contact with the salt humidity of the epithelium of the bronchial mucous membrane and alveoli, so that a local action is produced, without any absorption occurring; this is so with chlorine and phosgene. In this case there is a mechanical asphyxia caused by the local conditions of the toxic substance and not a general action of the poison on the whole body.

The mechanism for the entrance of poisons contained in toxic dust is still uncertain from several points of view. This fact is of great importance in occupational pathology, for it is well known how common it is for the dust of workshops, foundries and mines to contain poisons. It was at first agreed that dust could be harmless as regards its toxic effect if the dust was fixed by the interalveolar connective tissue or the glands of the hilum, where it was believed that it remained as an inert deposit. But against this conception there was set existence of signs of poisoning in persons who had absorbed certain poisons. It was thought then — and some experiments of Romby, made in the Biondi Institute have confirmed it — that a certain quantity of inhaled dust, and even the largest part of it, was swallowed and passed into the alimentary canal. Further investigations of Biondi (Italian Congress of Labour Pathology, Florence, 1921) have shown that even granules of insoluble toxic material, while they remained as an inert pneumonocoriotic deposit, can by some mechanism that is not yet clearly
understood become dissolved and pass into the circulation.

THE ACTION OF POISONS ON THE BODY AND OF THE BODY ON POISONS

The study of the action of poisons on the animal body presents great difficulties. It was first believed to be due to a pure and simple chemical action, in the sense of a combination between the poison and living protoplasm or the body fluids. It is true that some of these chemical combinations explain the action of some poisons, e.g. of those which combine with haemoglobin. On the other hand, it is equally true that, in the physiopathology of poisonings, it is necessary at the present time to look for other mechanisms of action which are not purely chemical — the action of electrolytes, the effects of osmotic action, of changes in colloidal state, and of the phenomena of absorption — which necessitate taking into account the physio-chemical actions of poisons.

There is no doubt of the serious difficulties which confront those studying the various kinds of action of poisons and their point of attack on the various tissues and organs. As Flury has observed, the cells and the tissues cannot and should not be isolated from their environment, it being granted that the conditions of their functioning depend on the environment, for the cell in its environment represents a biological unit. Thus, when studying the action of poisons, it is necessary to take into account, in addition to the direct reactions between the tissues and the poison, other conditions in the body, modifying the physiological oscillations between the cells and their environment. The osmotic equilibrium between the cell and the body fluids, the colloidal state of organic liquids on the surface of the cells and within them, and also the composition of the blood, are under the influence of variations in ionic charge which can be modified by the action of poisons. In their turn, variations in the internal secretions and in the reactions of the vegetative nervous system can be the cause and effect of the variations in the ionic charge of the body fluids, and, in consequence, the cause and effect of a varying action of the poisons. Cellular poisons, when they do not arrest the functions of the cell, activate them as catalysts, or weaken them, acting not in a qualitative way, but a quantitative. It is thus that the same effects can result from their action as can be obtained by electrolytes, such as calcium and potassium. Hence, according to Zondek, the actions of the vegetative nerves, those of electrolytes and those of exogenous and endogenous poisons, among which are included the internal secretions, may be substituted the one for the other.

In the action of poisons, therefore, quite a number of phenomena are produced which constitute a chain, and it is not always easy to identify the different links, let alone to understand them. For the present, the most important links will be chosen, and attention will be withdrawn from theoretical ideas which are employed in attempting the decomposition of complex actions into their various stages. In the case of occupational poisonings, what is more important is to fix as basis for the above considerations, as shall be seen better further on, that the physiopathology of the exogenous poisons may be identified, not only with that of certain endogenous poisonings, but with variations otherwise produced in the ionic charge, in the production of internal secretions and in the functions of the vegetative nervous system.

In trying to split up these physio-pathological processes it also becomes possible to understand by what means there may be superimposed on, or even substituted for, that which is actually, in force, a classification of poisons which essentially takes into account physio-toxic action in the light of new physio-chemical facts. As a matter of fact, a classification of poisons according to their chemical composition cannot be sustained, even though at the present time it might seem hard for lack of data, to fix as basis for the classification of substances the same chemical composition which are diverse in toxic action, and others, such as curari and camphor, which act in a similar manner without having any chemical resemblance. A classification according to the point of attack of the poisons cannot be upheld any more than the other, either on account of lack of knowledge or on account of interfering modifications in the functioning of one system reacting on that of another. In this way a mixed classification has been arrived at, which takes into account the pharmaceutical action and the point of attack, with a purely empirical orientation.

It may be said that the action of the ions characterises, at least in part, many of the toxic reactions — that of acids, bases, and salts being represented by their ions. The acids dissociate hydrogen ions and the bases of hydroxyl ions. In this way the...
acids and acid salts have a common type of toxic action, which is in accordance with the hydrogen ions: at a certain concentration the pH of protoplasm and the body fluids is lowered, and in consequence there is such increased action of all the processes of metabolism as to constitute a catabolic stimulus.

This modification of the pH of the body fluids causes phenomena of stimulation of the vegetative nervous system, especially of the respiratory centres, and — when certain limits are reached — symptoms of paralysis, until that state of stable equilibrium is reached which is the death of the cell. This state is rapidly attained in local actions, when a certain concentration in hydrogen ions is attained. With acids soluble in lipoids there is rapid penetration into the interior of the cell, so that the functional and structural disturbances are more marked than with mineral acids which are not soluble.

Alkalis act in an antagonistic manner to acids, by dissociating hydroxyl ions. The pH increases when the various buffers do not any longer suffice to maintain the acid-basic equilibrium of the body fluids and the protoplasm within ordinary limits; there results an alkalosis, together with a slowing of the metabolism, and tetany. The action of alkalis resembles more or less, as regards neutralisation, that of salts. Thus, the alkaline carbonates are less active than the hydroxides in consequence of their less electrolytic dissociation.

The intensity of the action of acids, bases and salts depends then, on the one hand on the degree of their electrolytic dissociation. On the other hand, the toxic or antiseptic strength of numerous mineral and even organic compounds is associated with their state of dissociation: when, for example, the dissociation of the salts of mercury diminishes, their antiseptic power diminishes also; mercuro-potassic thiosulphate is not poisonous for cold-blooded animals, for the mercury in that case does not become ionised. But, at a higher temperature, the mercury ion dissociates and becomes poisonous for warm-blooded animals, the blood temperature of which is higher.

In addition to electrolytic dissociation and the molecular concentration of organic liquids, the action of the salts must be considered, which, like that of acids and bases, depends also on the special chemical properties of their ions. Hence, the kations of metal and the anions of acid can take part in the toxic action of their salts. The action of the ions, however, is in accordance with their valency, and is exerted, for example, on colloids and, very probably also through them, on enzymes in proportion to the raising of their valency; hence the antagonism between monovalent potassium and bi-valent calcium, and the possibility of substituting sodium for potassium, both being monovalents.

In the case of the salts of heavy metals, the physico-chemical action of the salt takes place in accordance with the toxic action of their ions. Metallic albuminates, formed by the contact of metallic salts with organic tissues, lead to the death of the cell; if they are insoluble they form a kind of protective barrier for the deep tissues; if they are soluble they act at a depth. The general toxic action is in relation to the solubility of these complexes, their concentration, the degree of dissociation and their chemical properties. Thus, the strong toxicity of the salts of mercury and lead can be understood in proportion as there comes into play the solubility of the fatty acid salts of lead in lipoids.

Another kind of physio-chemical action, in addition to the purely chemical one, is exercised by poisons of the nervous system, some of which, although more restricted in number than the others, concern occupational toxicology. The action of narcotics has been attributed essentially to their solubility in fats and lipoids, in order to explain their tendency to accumulate in tissues rich in fat — to which belongs the nervous system — and also their paralysing action, and, in some cases, painless poisonous actions, which succeed each other in the various sections of this system. At present the tendency is to attribute much importance to the phenomena of adsorption in the mechanism of the physio-toxic action of narcotics, and in the action of most poisons of the aromatic series. These poisons react particularly with the nerve cells and exhibit an action resembling that of narcotics, even though the paralytic phenomena are sometimes masked by phenomena of excitation, and though the order in which the various sections of the nervous system are attacked is different. Further, special chemical actions are accepted, just as they are accepted by hypothesis in the case of alkaloids, the free bases of which, with their complex molecules appear to be readily soluble in fats, lipoids and adsorbables. It has, however, been thought that, in the action of alkaloids,
another modality comes into play, which explains better than other hypotheses the fact of the elimination of certain alkaloids, after their reactions, without any change in their structure. Here it is thought that the penetration of the large molecule of an alkaloid into the liquid contained in certain definite cells does not cause chemical changes therein, but only a disturbance of the physical equilibrium constituting the basis of the normal functions of the said cell. Thus changes can be produced in the physiological condition of the solution of protoplasmic substances which perhaps may lead even to flocculation.

In this way it can be understood that once a foreign alkaloid substance has made a timely disappearance, reversible disturbances may cease, provided that the circulation and nutrition have remained normal between times.

All poisons which do not exert merely a local action naturally pass into the blood, and circulate there, usually without undergoing any particular changes. Others, on the contrary, and they include the blood poisons properly so called—act on the constituent elements of the blood. At present, as regards their action, there are known only those which act on the red blood corpuscles and the haemoglobin. The "haemolytic poisons", acting on the red blood corpuscles, do not develop their action through variations of the osmotic pressure as is the case with hypotonic solutions, which, on the other hand, when introduced into the alimentary canal, do not succeed as such in penetrating into the blood stream. These poisons convert the chemical or physico-chemical state of the membrane of the red blood corpuscles and, speaking more accurately, of the densest peripheral part of the erythrocytic protoplasm into the essential colloidal and cholesterinic components. Among these poisons arseniuretted hydrogen is the one which concerns industrial pathology most. That haemoglobin dissolved in the blood plasma can give rise, apart from haemoglobinuria, to pleiochromic or so-called haemolytic jaundice, is generally recognised today.

Some authors are inclined to adopt the opinion, without sufficient grounds, that another action is produced on the red blood corpuscles, this action being that of some poisons and principally, if not exclusively, of lead, leading to the formation of special granules in the red blood corpuscles. This hypothesis is definitely upset by the researches of Blanchini, who, after treating red blood corpuscles in various ways, only obtained basophilic granulation in the case of young elements containing granulo-filamentous substance detected by vital staining. The only conclusion would seem to be that lead poisoning may cause special physico-chemical conditions of the plasma of poisoned animals, so that in the fixed preparations the endoglobular chromatophile of the not-fully-developed red blood corpuscles shows itself in the form of basophilic granulations (punctate red globules) rather than by a diffuse basophilic of the element (polychromatophile red globules).

The poisons acting on the colouring matter of the blood form with it a chemical combination incapable of giving up oxygen to the tissues. The best known and the most common poison of this group is carbon monoxide, which has for haemoglobin an affinity two hundred times higher than that possessed by oxygen. Carboxyhaemoglobin does not give up oxygen to the tissues as oxyhaemoglobin does. Other poisons change haemoglobin into methaemoglobin, another oxygenated combination incapable of yielding up oxygen, except in the smallest quantity. The poisons of haemoglobin properly so called, such as aniline and potassium chlorate, form methaemoglobin directly; others, on the contrary, form products capable of leading to the formation of methaemoglobin by various processes: by oxidation, as the phenylhydroxylamine of phenylhydrazine; by reduction, as the hydroxylamines of the aromatic nitro-compounds; by splitting up, such as the dioxybenzenes of the phenols.

There are also poisons described under the name of "cellular poisons", which exert their action second-hand, so to speak, by a functional disturbance, or by signs of inflammation at the site of their application, or in the immediate vicinity. All these substances are really capillary poisons and act essentially through the products of the cellular destruction which they occasion.

This account, though brief of the modes in which poisons act when seen in the light of modern biological developments, makes it comprehensible that the symptoms of poisoning, and in particular those of occupational poisonings, may sometimes have no characteristic, and merge not only into the symptomatology due to endogenous ills, but especially also into excessive, faulty or scanty internal secretions, but also into the phenomen-
metatoxic, which are produced at a play, apart from the phenomena called no way connected with exogenous poi-

and of other conditions, which are in endothelial proliferation in the fibroplastic direction, Institute have shown how toxic phenomena persist after the poison has been com-

versed as that special condition which Heub-
distance from the absorption, as well as one can understand how func-
tionaldisorders, secondary to those cause in a secondary way, through changes may be incapable of causing characteristic action of poisons,

what has been already written on the action of poisons, it may be seen how undecided this idea is. In reality it can be understood why some doses of poison may be incapable of causing characteristic symptoms, although they may be able to cause in a secondary way, through changes in the cellular equilibrium or in the internal secretions, diseased conditions which have no definite toxic character. The idea of a fatal dose should not be taken in the classic sense — that is to say, the idea of a dose of toxic substance which is able to cause rapid death — but of a dose of poison which is able to cause death either directly or indirectly with more or less rapidity. It is not necessary either for the toxic dose or for the fatal dose to depend strictly on the quantity of poison which is introduced into the body at one time, or at several different times in succession. It is certain, at least as regards occupational poisonings, that it is not necessary to stop to formulate figures of toxic doses and of fatal doses for various poisons, but it is necessary rather to consider only the morbid changes found which can be caused by a given substance.

It should be borne in mind that with certain doses of numerous poisons an action is developed which, especially as regards repercussion on the functions of the vegetative nervous system, appears as antagonistic to that which is developed after other doses. Thus it is that poisons may act in weak concentration as stimulants of various organic functions, while in strong concentration they may inhibit them; arsenic, for example, is a typical poison of metabolism; calcium in certain doses does not develop the sympathethico-mimetic effect which is obtained very definitely with bigger doses (hariath); and ergotamine is a sympathetic depressant which, as Biondi has been able to observe, becomes a sympathetic stimulant in small doses.

**Toxic Synergism and Antagonism**

Two eventualities may take place when different poisons act on the animal body. One, perhaps the commonest, is that in which the effects of two poisonings are added to each other. These phenomena of synergism, or of the respective reinforce-

ment of different poisons, have a notable importance, especially in occupational pathology, not only as regards such mixed poisons as sulphuretted hydrogen and carbon monoxide, which cause poisoning which would not be expected, taking into account the percentage of each of the toxic gases in the atmosphere. As a matter of fact industrial pathology deals most fre-

quently with the synergisms, on the one hand, between occupational poisonings and volunitary poisonings, and, on the other hand, between occupational poisonings and other injuries as cold and snow poison.

About twenty-five years ago Biondi demonstrated experimentally, in animals poisoned by lead, a lowered resistance to the effect of alcohol; and, about the same time, by histological research Donaghe demonstrated changes in the neuro-fibrils of the cells of the grey horns of the spinal cord, caused by the combined action of cold and alcohol, two types of causes which, taken separately, were incapable of causing them.

Other poisons, on the contrary, acting together, may exercise an antagonising effect. Carbon monoxide has an affinity for haemoglobin much greater than has oxygen; the effect of carbon monoxide on haemoglobin, however, can be influenced antagonistically by carbon dioxide. at strong concentration, causes the carbon monoxide to be detached from the haemo-

globin, when it displaces it (Haldane). The action of a magnesium salt causes a

anoxia which the intervention of a calcium salt does away with; the action of muscarine is antagonistic to that of atropine. These antagonisms should not, however, be confused; that is to say, the physio-toxic should not be confused with
the chemical antagonisms which are not antagonisms properly so called, but only represent mechanisms of defence of the animal body. Among these last should be noted the substances called "stabilisers" or "buffers" which tend to restore the acid-base equilibrium upset by the action of acids, or of alkalis, and the formation of compounds less toxic than those of the substances already introduced. It is necessary to deal somewhat systematically with this defensive machinery.

Elimination of Poisons

The first means of defence which the animal body possesses against poison is that of elimination. That does not mean to say, as shall be seen further on, that particular lesions may not occur due to the failure of elimination and at the site at which it occurs. Poisons may be eliminated in the form in which they were introduced or quite changed. In the second case, after elimination, special processes of oxidation, reduction and decomposition occur, concerning which details must be given.

The first and most important of the mechanisms for the elimination of poisons is that which comes into play before absorption occurs, or when that occurs to a very small extent. This eventuality, which is represented by vomiting and diarrhoeic stools, is rarely met with in occupational toxicology, and it is not necessary to dwell on it here. So attention must be exclusively directed, as already stated, to the elimination of poisons already absorbed, which are eliminated in their original state, in the first place by the kidneys. They are chiefly the crystalloids, i.e. salts of all kinds; they are eliminated by the urine, which, however, also passes other toxic substances. Elimination by the kidneys is effected more or less rapidly depending on the substances and on the condition of integrity of the body, and also depending on the intervention of other substances which are able to accelerate it, such as sodium chloride, iodides and sulphur, in the case of heavy metals. The passage of certain poisons through the kidneys is not, as has been stated above, without effect on that organ; and renal lesions (nephroses) which are caused by the elimination of such heavy metals as mercury and lead are well known. All the glands of the alimentary canal, from the mucous and salivary glands of the mouth and glands of Lieberkühn and of Brunner, and those of the rectum, take part in the elimination of nearly all poisons, especially of the metallic poisons. It is not difficult to confirm up to a certain point that there may be a vicious circle, in the sense that part of the poison which is excreted into the intestine may be reabsorbed afresh. Elimination through the intestine explains the production of certain ulcerative lesions, which were at first attributed to the effect of contact with the poison which entered the alimentary canal, although they were observed equally when the poison was introduced into the body by parenteral entrance.

The elimination of poisons through the mucous and salivary glands of the mouth demonstrates the mechanism by which are produced certain phenomena which are of great importance in the diagnosis of occupational poisonings, such as the blue line on the gums in lead poisoning, and ulcers or gingivitis in those poisoned with mercury.

Another path for the elimination of poisons, which is not confined to volatile poisons, as is believed, is by the lungs. For this particular method of elimination, valuable diagnostic criteria exist for some occupational poisonings, based on the particular smell which the breath of some poisoned persons has. It is sufficient to give, as an example, the case of the smell of garlic from those poisoned by arsenic.

Numerous poisons, and not only the volatile ones, are eliminated by the skin. It is known that in consequence of this elimination special chronic acne lesions are caused, and that the skin may take on special colouring in certain poisonings, as in that by silver. It is, however, still doubtful, as was pointed out by Blondi in 1921, whether there is a pale, dirty tint of the skin due to lead. It is also to be noted that arsenic only reaches the hair tardily, through which it is eliminated very slowly.

Another path for the elimination of poisons, including several occupational poisonings such as lead, mercury and arsenic, is that of the lacteal secretion, which must be remembered when women who are breast feeding are employed on work which involves risk of poisoning from lead, mercury or arsenic.

Accumulation of Poisons in the Body

Poisons are deposited differently in the various tissues and organs before being eliminated with more or less rapidity and being transformed more or less radically. The site of deposit varies with different poisonings, and from one cell to another. It is known that the superficial layer of the cell possesses the power of retaining certain ions and certain molecules, and of allowing some others to pass. In this way is understood the phenomenon, confirmed to-day by biology, of the prevalence of the ions of potassium in the interior of the cells and of ions of sodium in the body fluids. Naturally, it happens that some poisons are deposited in certain tissues and organs, some in others. In some cases, by the activation of processes which will be discussed further on, poisons deposited in certain organs, e.g. in the liver, are changed and rendered harmless, or in any case less injurious. In other cases the poisons are retained, so to speak, indefinitely, for example in the case of arsenic in the hair. In other cases again, there is a gradual process of bodily elimination. In other cases again, and particularly in the case of lead, as Blondi and his followers have shown, there is an elimination by fits and starts which...
sometimes takes the character of a mobilisation of the poison with a repetition of toxic symptoms, set going by intercurrent events, such as malarial attacks, injuries or changes of metabolism. Blindi was able to detect in some old varnishes of Sienna, at intervals, lead in the urine, even twenty years after the last possible source of poisoning, and this after the administration of iodide preparations, or even without any apparent cause.

**The Defence of the Body against Poisons**

Poisons which are not eliminated may be rendered harmless by means hitherto mentioned several times. In speaking of the action of acids, alkalis, and salts, there has already been described how the maintenance of the acid-base equilibrium of the body fluids, when threatened by a lowering or raising of the pH, in consequence of some increase in the hydrogen ions, or in the hydroxylic ions, is assured by the different buffer machinery.

There have also been mentioned the processes of oxidation which are confirmed, for example — if it is desired to refer to an industrial poison — by sulphuretted hydrogen. It is known that in poisoning by this gas, sulphite of soda is found in the circulation, and that it can be changed into the sulphate. There may also be reducing processes, as is the case with poisons of the aromatic series; and processes of more complex detoxication falling into the group of chemical syntheses; and yet others — of which scarcely anything is known — due to the activity of the cells of certain glands and especially of the liver.

A process of detoxication, due neither to buffers nor to chemical processes, is the purely physical one of adsorption, the importance of which is more and more accepted, especially in the domain of occupational toxicology, when, as is known, small quantities of poison are absorbed; for it is notorious that more of a dilute solution is absorbed relatively than of a concentrated solution.

**Mithridatism**

The presence of a poison in the body and even its return into the circulation from deposits, where it has accumulated, does not have as a constant and progressive effect the appearance of toxic symptoms, which remain with an intensity proportional to the dose of poison which has obtained access, no matter how, into the circulation. It has been known for ages that the body develops tolerance of certain poisons, and that stronger and stronger doses can be introduced with more and more attenuated results.

Mithridatism is the name by which this faculty of becoming inured to poisons is known, because it was perhaps on the body of Mithridates that, according to the legend, the knowledge of this singular tendency was established; it has not found any univocal explanation, and still less a definite illustration. It is probable that the processes by which the phenomena can be verified are various. First of all it was considered, and recently Cloetta has returned to this way of thinking in regard to arsenic, that the absorption of poison becomes less with time, as if barriers were opposed to it at the points of penetration. But Joachimoglu has not been able to confirm the researches of Cloetta, having aside the possibility that the phenomena of acquired resistance might be related to a diminution of the intake of poison, it was thought that such transformation of the poison might be produced in the body as was able to render it harmless.

As regards morphine and alcohol, it has been attributed to an increase in oxidation; and as regards camphor to an increase in its combination with glycuronic acid. But these hypotheses, even if they are confirmed, are not sufficient to exclude the fact that, in those cases there has also been an increase in the cellular resistance to the different poisons. For example, as regards alcohol, there is proof of this increased cellular resistance in the fact that alcoholics react with less sensibility to the action of narcotics of the fatty series, such as ether and chloroform. It was then thought that allergic phenomena came into play on the entrance of the poison; where in the case of numerous poisons, e.g. metallic poisons, it seemed impossible to admit antigenic qualities, it appeared that there might be some idea (Centanni) either of meta-antigens, resulting from the combination of poisons with proteins, or of other derivatives. It was estimated that with these meta-antigens it was possible to obtain meta-antibodies, capable of rendering the poison inoffensive. However, the hypothesis of allergic phenomena, even thus corrected, cannot be admitted, at least for industrial poisons; and some unpublished experiments undertaken by Catarzi in the Blondi Institute have dissuaded him from pressing it.

Recently a series of researches engaged in by Bianchini and his pupils
have proved that in defence against metallic poisons introduced in molecular solution, the reticulated endothelial system perhaps also plays a part by the mechanism of adsorption. The function of this system can be activated by increasing the surface by the introduction of suitable doses of colloidal metals. This defensive action of the reticulated endothelial system has been demonstrated in the Biondi Institute by Francioni as regards mercurial fumes. He has, as a matter of fact, been able to decompose the physio-toxic action of the poison in question as regards both its entity and the defence of the reticulated endothelial system; for it seemed to him that the protection against disorders affecting metabolism should be attributed to this system, whilst it would not play an appreciable part in the extra-pyramidal lesions (tremors).

These observations certainly open up large horizons for knowledge regarding the phenomenon of becoming injured to poisons, which, as regards such heavy metals as lead, mercury, zinc and antimony, is the most common source of occupational poisonings — has been denied by numerous authors, although several clinical and experimental observations of Biondi gave an irrefutable demonstration thereof twenty years ago.

CONSTITUTION AND POISONING

In addition to the defences which the animal body can set in action against the effect of poisons, by the help of our processes or another there are conditions still unknown, in which certain individuals do not feel the effect of some poisons, whilst there are others who present a special and exaggerated sensibility to their effects. There is thus a question of some particular resistance to the poisons, as of a hyper-sensibility or of an idiosyncrasy; and it has even been affirmed that some families transmit these special peculiarities in an hereditary way. Others affirm that there is a hyper-sensibility resulting from age, from a decadent condition, or various diseased conditions, and from occupational and voluntary poisonings, which are capable, as has been noted several times already, of rendering an individual more sensitive to the effect of other poisons. It has been further observed that some poisons exert on some individuals an effect not only more or less intense than on others, but more or less at variance with their ordinary effects.

These singular phenomena have been, and still remain, in some degree mysterious. However, new doctrines on the constitution, which have a very firm biological foundation, in spite of the objections formulated with regard to them by those who do not know them and by those who make bad use of them, open the way to clear and sure explanations of the facts. Naturally the constitution must be considered in a wide sense from the somatic and biotonic points of view, from the point of view of the dominating hormone and the neuro-vegetative tonality and the ionic charge. Viewing it thus as a whole, it may be understood that, for example, the haemoglobin poisons — from carbon monoxide to potassium chlorate — may have more serious effects on katabolic individuals than on anabolic; for in the first the basal exchange is higher, and in consequence the oxygen requirement is greater, whether one wishes to regard the action on the tissues as direct, or as assisting dehydrogenation. It would then be understood why the acid poisons, which dissociate hydrogen ions, lead to more serious effects on individuals in whom there is a constitutional tendency to acidosis with lowered pH; and why the alkalis which dissociate hydroxylic ions are more active for some individuals with high pH, and inversely. It may also be understood, on the other hand, according to the researches of Bianchini, why anabolic subjects are more resistant to the action of lead, it being granted that the very great hydrophilia of colloids characteristic of these individuals, would make one expect that their reticulated endothelial system would be quicker to defend itself against metallic poisons. This hypothesis falls into line also with the researches of Biondi on the action of plomberous plasma, which in vitro favours the development of cultures from the reticulated endothelium in the fibroplastic sense, for it is known that the internal secretions which stimulate the formation of connective tissue are those of the anterior part of the hypophysis and of the chromaffin system, which do not predominate at all in the anabolic type.

It would likewise explain why sympathetico-trophic poisons cause more serious phenomena in the case of strong and weak sympathetic systems than with strong and weak vagus systems, and inversely for the, vagotrophic poisons. It is understood how the poisons of the brain have more severe effects in medium weak individuals than is met with
especially among the anabolics. It would also provide an explanation of the fact that poisons which are eliminated by the bile have a less effective action on the constitutional types with a neuro-vegetative direction towards para-sympatheticus, in whom the elimination of bile seems more rapid.

Examples could be multiplied and other tempting hypotheses could be formulated. However, concerning constitutional problems, as for all arguments still and always in process of evolution, it is essential to proceed with all reserve. Nevertheless, sight must not be lost of the luminous track from which irradiates the promise of so many fruitful directions for the prevention of occupational diseases.

With this in mind, it is necessary to collect clinical observations in regard to the constitution, as many as possible, by way of explaining the reasons for idiosyncrasies and resistances, and to seek by experiment to illustrate the neuro-vegetative conditions, both hormonal and electrolytic, which modify the action of poisons and especially of industrial poisons.

Odours

The cause of a substance having an odour is not yet known; it is further not known how to establish a relation between chemical composition and the odour of substances. In practice odours are classified according to characteristics they produce on the senses.

The intensity of odours is very variable; it is very strong for certain substances (musk for example), intense, strong or faint for others. Faint odours, however, for example that of vanilla, may have great penetrating power. Beaunis classifies odours in two categories: perfumes with considerable strength, of which musk is the type, and intensely active odours or odoriferous substances, of which mint is the type; both act on the olfactory nerves. Further, the same expert distinguishes between substances which act at the same time on the olfactory nerves and on the tactile nerves of the pituitary mucosa (for example, acetic acid) and substances which act only on the tactile nerves (for example, carbon dioxide).

Odours are distinguished one from another by quality, which is intimately connected with the molecular structure of substances of the same chemical series. There exist, however, substances apparently inodorous, but possessing odours which civilised man cannot detect.

The substances which are odoriferous are generally volatile. It is then probable that particles liberated from these substances are dissolved in the mucus which covers the olfactory region and act chemically on the olfactory cells. These cells represent true nerve cells situated in an epithelium and, according to embryological and histological studies, are elements similar to the nerve cells of the spinal ganglia.

Nerves of the upper part of the nasal fossae act only for olfactory purposes; but it is difficult to say if there are special receptors or conductors for the different and principal causes of olfactory impressions.

This point seems to have a definite answer, for persons are met with who, while recognising all the other odours, cannot recognise the smell of violets or vanilla (Gley). Investigations made on partial fatigue of the olfactory sense confirm this thesis, as the olfactory sense, when fatigued by a definite odour, remains sensitive to other excitants (Aronsohn, Zwaardemaker, quoted by Gley). Odoriferous particles are transmitted by air and water, but it is necessary for both to be sufficiently charged with odoriferous particles and for them to act for a definite period, which is always very short.

Although by training the delicacy of the sense of smell can be increased, habituation does not always develop the sense, but may diminish the
keenness. As a matter of fact, workmen employed in offensive smelling occupations do not in the end notice anything offensive.

**Origin and Action of Odours**

Odours may have one or several origins; thus, for example, they arise:

(a) from collecting and working up animal matter; when assembling animals and offal; at abattoirs, places for tripe boiling, stores for meat, debris and offal; at knackers' yards; at accumulations of filth, sewers and manure pits; from the treatment of animal residues, for example, in the manufacture of glue and chemical manure; and from threshing and washing of wool;

(b) from warehousing and manipulating certain vegetable substances while threshing, carding, and washing hair, hemp, flax, and feathers for bedding; in breweries and in roasting coffee on a large scale;

(c) from the warehousing and use of mineral materials in stores for asphalt, bitumen, and of solid bituminous materials.

In addition to fumes there are gases and vapours of offensive emanations, which are given off during certain industrial operations. It is, above all, the presence of gas, such as sulphurous anhydride, ammonia, sulphur- etted hydrogen, etc., which make these emanations troublesome.

Then there is a series of emanations which are caused by the mixing of several gases or odours in which it is very difficult to identify the special odour present.

Offensive odours are generally due to decomposition of organic material.

Although odours are the least dangerous of the troubles met with in industry, yet most of the factories which are registered are registered for this cause.

As a typical example of a smell emitted in the course of industrial operations, we may mention the extremely disagreeable smell of mercaptan. This substance is produced when sulphonal is prepared by heating sulphide of sodium with ethyl sulphuric acid.

Quite apart from smells which cannot be eliminated by industry, there is a long series of those which are not necessary and can be easily eliminated. They are especially smells arising from the accumulation of organic materials.

But when speaking of odours, odoriferous substances or perfumes must not be forgotten. These may damage the sense of smell and cause troubles among the workmen who make or handle them. As a matter of fact turpentine, ether, camphor, coumarine, safrol, nitrobenzene, and the whole series of essential oils are not without danger to the health of workers in perfumery works (see article "Perfumes").

Generally speaking, it may be said that odours are not merely a nuisance, but also a cause of ill-health. According to some experts, fetid smells, by rousing disgust, may cause loss of appetite, nausea, vomiting, headaches, weakness, and depression. On the other hand, other facts establish that smells have only a local effect on the olfactory organ without causing general symptoms of poisoning (or very rarely), and, further, that the duration of life and the state of health of the workers concerned are good and even above the average. It must, however, be admitted that, according to certain experiments on animals, there is a diminution of the resistance to infection.

In conclusion, the scientific facts which are available to-day seem to show that workers quite easily become accustomed to odoriferous substances and that smells cannot be considered as a direct cause of organic disease.

**Detection and Estimation of Odours**

While the presence of odours can be realised it is difficult to measure their intensity with the human organs of smell only. Thus, for example, the human sense of smell cannot detect the presence of a gas whose density is at least fifteen times greater than that of hydrogen. It is claimed that certain individuals can detect hydrocyanic acid (which is the limit of this density) in a dilution of two million times its weight of water. On the other hand, the famous chemist, Scheele, was overcome by this same gas, which he had discovered, and its action paralysed his sense of smell.

Experts are almost always faced with extremely serious difficulties if they wish to evaluate complaints made by the public against evil-smelling emanations.

Present-day chemical processes do not allow accurate estimation of odours. Most of them which are capable of acting on the nervous system cannot be weighed in a balance; others cannot be analysed chemically because their composition is not known.

The quantities of odoriferous particles in the air are very often so minute as-
to make errors of calculation inevitable. On the other hand, the reactions suggested for detecting certain substances (for example, acroleine) are very difficult.

Nevertheless, if the chemical composition of an odorous gas is known, the concentration of its molecules can be measured by purely chemical methods.

The idea of estimating odours is not new; it dates from 1787 when the Society of Medicine of Paris brought up the question at their meeting. However, it was only carried out much later by Gérardin, who discovered a method based on the action of odours on permanganate of potash. Gérardin gave the term “ozometric degree” to the weight in milligrams of crystallised oxalic acid, which produces on potassium permanganate the same effect as the organic matter contained in 1 gr. of air (smells, microbes, grains of pollen or dust) measured by purely chemical methods.

It is possible also to estimate odours by physical methods. As a matter of fact the idea of measuring the intensity of the stimulation of the olfactory sense. Some are in favour of a chemical action, others in favour of a physical effect, and others again favour a combined effect.

Watson denies that smell is a chemical phenomenon, for he has found that there does not exist a chemical reaction between several typical odorous substances, such as acetate of ethyl, pyridine and citronella on the one part and a substance of the proteid type, such as white of egg, on the other. Zwaardenmaker, who is similarly in favour of the physical theory, has shown that in vapourising pure water an electric charge is not formed. It is the same with water containing certain inorganic salts. On the other hand, with water containing certain organic salts vapourising produces a negative charge. When water containing dissolved odours is vapourised a positive current is obtained. Further, it has been found that the point of dilution, which allows the perception of electrical phenomena, corresponds exactly to the point of dilution at which the odour becomes perceptible to the sense of smell. Thus the electric charge constitutes an objective standard for the measure of the intensity of odours.

HYGIENE

The methods which are recommended for eliminating odours are very numerous and clearly must vary according to the nature of the industry, that is to say, with the cause and intensity of the smell. The most important methods are as follows:

1. Removal of business premises from inhabited centres and isolation of factories. This measure should be applied chiefly to premises where animal material is dealt with and all other odorous materials which cannot be completely eliminated. Unfortunately it is very difficult to keep factories indefinitely at a distance from dwellings, owing to the presence of houses for the personnel near the factories and of shops. Health regulations enumerate the trades — designated as “offensive trades” — which are subject to this measure.

2. Planting screens of trees. Two or three rows of trees (12 to 20 m. broad), planted parallel to the walls of the factory, will have the effect of preventing odours from spreading by the action of winds, or will at any rate diminish the intensity of the smell. This screen should be arranged according to the direction of the prevailing winds in the locality.

3. The use of high chimneys. By passing odorous emanations into a high chimney, they are carried into the air, where they are diluted. This measure, which is effective in reducing the intensity of smells, has, however, the inconvenience of carrying them to a distance and so causing a nuisance to the neighbourhood. For heavy odorous gases it is best to have low chimneys.

In order to get rid of the gases effectively, it is necessary to burn them, either in generating furnaces or in special furnaces which ensure complete combustion and pyrogenetic denaturation of the volatile products. It may happen, however, that these furnaces do not effect complete combustion, as only apparatus specially constructed for combustion can effect it. Furnaces are required to be of brick or fireclay heated to redness or simply elongated furnaces in which coke or coal are burned.

4. Condensation of odours. Before discharge into a chimney, odours ought to be subjected to a preliminary treatment which renders them inoffensive. The odours should be condensed in water by means of aspiration and well devised ventilation. The most satisfactory results are obtained by adding a disinfectant, such as chloride of lime, to the water which is used for condensing the odours.

5. Absorption of odours by soil. By means of his process of estimating
odours, Gérardin was able to establish the fact that soil possesses the property of absorbing odours. According to this expert, one ought first and foremost to choose soil for catching and destroying odours. As a matter of fact, soil is an agent which fulfils the requirements of both efficiency and economy.

There takes place a biological process similar to that which is associated with the purification of waste waters distributed over fields (see article "Industrial Waste Waters"). Volatile odoriferous substances are decomposed by bacteria, which destroy them by transforming the organic matter into its mineral elements. Thus it is sufficient to pass odorous gases by means of a special apparatus through a layer of soil of medium thickness.

Noxious odours produced by some trades can be suppressed by using activated charcoal as an absorbent, placed in a kind of tower into which the gas is sent for purifying. When it is necessary to revive the charcoal, it is heated in situ by the use of steam or other means. The charcoal which gives the best results is that obtained from coconut shell. This material is found to possess great absorbing power, retaining organic and odoriferous substances rather than steam; it resists crushing well, and is very active in reduced bulk. (Ray and Chaney, 1923.)

(6) Deodorisers. Odours may be weakened by appropriate deodorisers. It is, however, necessary that they be chosen judiciously, for, if not, the new odour may be more disagreeable than that which it is intended to overcome. Among these substances, the most efficient are chloride of lime and formaldehyde.

Bordas and other experts have studied the question of deodorising air by ozone. Ozonised air has an effective action on oxidisable odours. The experiments of Bordas show that most of the odours which arise from the fermentation of organic materials are entirely suppressed by ozone. This action is stronger when ozone is used in a moist atmosphere and in a magnetic field. Troubles caused by ozone, such as irritation of the mucous membranes, are easily removed by passing the purified air while strongly ozonised into a tube containing pieces of india-rubber by which the ozone is completely destroyed.

A process for the suppression of industrial odours invented by Yandell Henderson and Howard W. Haggard (1922) is widely applied in the United States and in Canada, and gives very good results. It is based on the principle of having a single outlet for the atmosphere of any factory, through one pipe or chimney only. The total emanations thus withdrawn are thoroughly mixed with chlorine and directed into the chimney in an accurately titrated amount. Should the emanation contain dust it is arrested by a scrubber (consisting of a thin water jet) prior to the action of the chlorine. Should the fumes not contain a sufficient proportion of humidity, steam is added. Deodorisation appears to be most effective at a fairly moderate temperature. It has been found that a half to 1 kg. of liquid chlorine vaporised per hour suffices to deodorise factories treating considerable quantities of material. The regulating apparatus for the chlorine is similar to that used in chlorinating town water supplies.

Taking for granted that the great majority of noxious odours arise in trades in which organic materials are manipulated, it is necessary to inquire what special hygienic measures should be applied to these businesses with a view to preventing the occurrence of odours.

Raw materials, as well as every fermentable product from which disagreeable odours can arise, should be warehoused and manipulated in the most remote parts of the factory.

Materials should arrive at the factory in the best possible condition and as fresh as possible, and should be so warehoused as not to diffuse odours. Transport should be effected in closed wagons or receptacles and unloading should be strictly controlled.

Warehouses and working premises must be constructed of impermeable materials, such as marble, flagstones, earthenware tiles, and impermeable facings; all soft porous materials and wood must be excluded. All exposed wood must be limewashed. The ground must be impermeable and must slope and have channels to help the escape of liquid residues and water used for washing down. When the floor is soiled with bad-smelling organic residue, it is desirable to scatter sawdust or some other absorbent material on the ground.

Thorough ventilation of the work-places is required, as well as the most careful cleanliness, and frequent washing, if necessary with disinfecting solutions.

Industrial operations should be carried on in apparatus which is sealed or otherwise hermetically closed with efficient exhaust draught and condensation of vapour. No use should be made, for the disintegration of materials and organic tissues, especially of animal origin, of processes based on fer-
mentation or on chemical reactions which give rise to offensive smells.

The use should be prohibited, as fuel of debris from packing, remains of raw materials of a fatty nature, or tarry and resinous, which give off in burning, troublesome and irritating odours.

Residues should be removed as quickly as possible and the places disinfected after each removal.

The accumulation in workplaces of quantities of raw materials above those infected after each removal.

All materials should be transported and kept in closed receptacles, which should be enamelled or tarred and kept in good condition, washed and, when necessary, disinfected every day at the end of the day's work.

If these measures cannot be applied, raw materials stored in workplaces should be mixed with disinfecting and deodorising substances, or covered by absorbent materials.

As regards waste waters, see article "Industrial Waste Waters".

***

Opium

The condensed juice obtained by making an incision in the still unripe capsule of the poppy (Papaver somniferum) gives opium, different varieties of which are distinguished in accordance with their country of origin, or the variety of poppy from which they have been prepared (Asia Minor, Bulgaria, China, India, Japan, Persia). Opium generally takes the form of a light brown coloured mass darkening on exposure to air, with a special smell and a bitter taste. This mass contains small agglutinated seeds (larmes) of chestnut colour as well as minute greyish striated and flaked material. The small seeds or "larmes" represent the coagulated and dried milk of the poppy; the striated and flaked material comes from the detritus of the outer cover of the fruit and leaves.

Opium partly soluble in water, to which it yields about 60 per cent. of its weight, and likewise in alcohol, has a fairly complex chemical composition: resinous substances; salts; peptic, albuminoid and mineral substances; lactic, malic and other acids; numerous alkaloids which may be classed with the morphine and papaverine groups.

Opium and morphia may, though very rarely, exert an injurious action on the skin of workers engaged in their manipulation. Low reports that in the Edinburgh alkaloid factories it has been fairly frequently noted that certain workers are attacked by exanthematos affections several weeks after commencing work, whilst others retain freedom from these even after periods of twenty years. These troubles were at first attributed to strong acids in which the plants undergo maceration prior to their manipulation. Low has proved the dermatitis in question to be due to opium. By rubbing the skin of a worker who had suffered from morphine dermatitis with crude opium he obtained rapid reaction of the skin.

In a case of very extensive dermatitis which had healed, Low obtained, after rubbing for six hours with opium, very violent local reactions and in twenty-four hours a localised dermatitis on the previously attacked parts of the skin. According to his experiments, the opium alkaloid possessing the strongest action was codeine.

There have likewise been reported cases of eruption due to morphia (Bridge, Egli and Rüst).

Amongst the most carefully studied cases is that described by Lewin affecting a worker sixty-one years of age, who had been employed in the same factory for thirty-four years and on manipulation of apomorphine for twenty-five years. After transference to a morphia factory, this worker, after a few days' work, suffered from shivering fits and from a state of general excitement with fever and discomfort accompanied by a crusty eruption localised chiefly on the upper part of the body. The eruption disappeared at the end of a few days on quitting work and reappeared immediately on resumption of work. The factory doctor ascribed the eczema observed to the action of a warm solution of morphia which the worker was obliged to filter through a cloth, during which operation he came in contact with hydrochloride, acid, charcoal and lime. There occurred reappearance of the eruption, which broke out after a lapse of eight weeks from the first eruption, no longer yielded to treatment and resulted in the death of the patient. Lewin attributed the injury in this case to the fact that the acid employed had acted as a vehicle for the alkaloid, the solution penetrating into the layers of the skin which was somewhat swollen by immer-
Osmium

French and German: Osmium. — Italian and Spanish: Osmito.

Osmium is a rare metal (symbol Os) belonging to the platinum group, associated with the latter in its natural state, and likewise with iridium in the various platiniferous ores of Colombia, the Ural Mountains, Tasmania, Borneo, etc.

Osmium is extracted from insoluble residues resulting from the treatment by aqua regia of the above-mentioned ores, melted with zinc, which has the effect of concentrating the rare metals which they contain. The molten metallic mass is treated with barium peroxide, and the whole mass is thereafter washed in water; then the residues containing osmium and iridium finely powdered are treated with steam and aqua regia. The osmium is volatilised in the form of tetraoxide, which is then transformed into sulphur, calcination of which gives metallic osmium.

In the pure state it is a bluish white metal, with a metallic lustre, which melts at 2,700-2,900° C. Heated to 400° C. it burns by becoming transformed into tetraoxide. Tetraoxide of osmium or osmic acid is prepared by oxidising osmium finely divided by aqua regia and fuming nitric acid. It takes the form of yellowish crystals, with a nauseous smell, recalling that of chloride of sulphur, and with a bitter and burning taste. It melts at 40° C., giving an oily liquid boiling below 100° C. and giving off fumes at an ordinary temperature which irritate the eyes and the nasal mucous membrane.

Osmium was one of the first metals used in making the metallic filament of incandescent electric lamps.

At present it is replaced by tungsten. It is also used as a catalyst, in the preparation of synthetic ammonia, for measuring the rapidity of explosion of gun-cotton, in the manufacture of platinum alloys (scientific apparatus), with iridium (gold pen-nibs for fountain pens, tipping engraving tools for designing on glass), etc.

Osmic acid is used for activating solutions of chlorate of potassium; in work in histological laboratories, for fixing, hardening and colouring of certain preparations, etc.

Vulpian and Reymond as far back as 1874 drew attention to the occurrence of pains in the eyes and eczema on the hands among workers engaged in separating osmium from mixtures of iridium and platinum. The use of osmium cements (aqueous mixture of osmium and osmium chloride) in the construction of electric lamps, for fixing the filament on transmission wires has often caused irritation of the skin, as a result of contact with the chloride. The use of this product has now been abandoned.

Osmic acid likewise produces injuries. Deville suffered from serious derangement of sight in course of its preparation, in consequence of the deposition of small particles on the cornea.

In histological laboratories in which attempts have been made to regenerate reduced osmic acid by means of peroxide of hydrogen, splashes of the product have often caused lesions of the skin and the mucous membranes. Winkler noted, in the case of a doctor engaged on this operation, dermatitis of the hands which lasted several weeks.

Types of cutaneous necrosis met with as a sequel to the therapeutic injection of salts of osmium in the treatment of obstinate neuralgia provide adequate illustration of the caustic properties of the product.

***
Oxalic Acid

Oxalic acid, of which the formula is CO₂.HC₂O₂.H and the specific gravity 1.64, is found in the form of oxalate in a great number of plants (common sorrel, wood sorrel, etc.). It is often formed in the oxidation of organic substances (sugar, wood, starch) by means of nitric acid, permanganate of potash and molten caustic potash. When crystallised, oxalic acid occurs in the form of rhomboïd crystals, odourless, colourless and transparent with a marked acid taste. It melts at 96° C. (in the anhydrous form at about 201° C.) and readily dissolves in water. It is a powerful reducing agent.

It is prepared either by the action of alkaline hydrates on cellulose at a temperature approaching 240° C., or by converting formates into oxalates (by heating a mixture of formate and calcium carbonate; the alkaline oxalate is taken up by the water and precipitated by the lime as an oxalate which is then decomposed) or by treatment of the molasses with sulphuric and nitrate acids.

Small quantities of oxalic acid are also recovered from the residual waters of certain industries (manufacture of trinitroresol).

Oxalic acid is used in tanneries to plump hides and bleach skins; in the textile industry in dyeing and printing material (dyeing of printed calico); in the chemical industry in making formic acid, glycolic acid (electrolytic reduction), for refining glycine, stearine, tartaric acid or cream of tartar; in dry cleaning (removal of rust and proteinaceous substances); in the manufacture of blue ink (dissolving Prussian blue), for certain artificial colours, in photography; etc.; in the metal industry, especially in the polishing of utensils of copper and brass; for bleaching straw, etc.

Besides its general toxic action (very rare in industry), oxalic acid has a local caustic action on the skin and mucous membranes. Elimination is very slow. Although Hayhurst has described cases of poisoning by concentrated oxalic acid among workmen engaged in polishing brass and copper articles, industrial poisoning is very rare. It can be set up by the vapour of oxalic acid and is characterised by irritation of the mucous membranes of the oesophagus, stomach and intestines. A bluish coloration of the nails has been described; these at the same time become friable. Peripheral circulatory troubles (especially of the hands), cardiac weakness, spasms, convulsions, etc., have also been noted.

Hygiene consists in preventing escape of toxic vapour during the manufacture of oxalic acid, in using closed receptacles, or, in place of them, covering the boilers with hoods connected up to efficient exhaust ventilation. The vapours and fumes should be led to the furnaces and burnt.

Legislation.—Employment of women is prohibited in Argentina, France and the Netherlands; that of lads under 16 years of age and girls of less than 18 in Canada (Quebec) and in Greece; lads of less than 15 in Italy; less than 16 in Spain, less than 18 in the Netherlands; and girls of less than 21 in Spain and Italy.

Oxalyl Chloride

Oxalyl chloride (CICOC1) is a colourless liquid which boils at 64° C. and is obtained by the action of two molecules of penta-chloride of phosphorus on one of oxalic acid. On contact with steam, fumes of oxalyl chloride give rise to oxalic acid and hydrochloric acid.

Egli and Rust refer to a case of an assistant who, in stirring potassium with oxalyl chloride in a closed metallic tube, produced such a violent explosion that the persons present in the workroom were hurled out of the window.

Oxygen

Oxygen (symbol O) is, in the pure state, an inodorous gas, with a density of 1.1053, which liquefies at —118° C. and 50 atm. (critical temperature and pressure).

Liquid oxygen has a density of 1.13, boils at —183° C., and is azure blue in colour. One litre furnishes 790, 830 and 870 litres of gaseous oxygen at 0°, 14° and 27° C., respectively. It is transported in special brass, glass or porcelain receptacles, with double walls, and a vacuum between the two (Dewar and d’Arsonval bottles).
Oxygen is an important agent of combustion. Together with hydrogen, it forms a detonating mixture. It combines likewise, with other elements, to form oxides, carbonates, nitrates, sulphates, phosphates, etc. The combustible and oxidisable substances in the atmosphere (combustible gases, explosive liquids, dusts, etc.) burn and oxidise better in the presence of oxygen and at a lower temperature than the surrounding atmosphere; they furnish besides, together with oxygen, detonating mixtures which may also be formed with certain inert substances (oils, rubber and ebonite).

On the market it is generally sold in steel cylinders under a pressure of 12, 150 or 150 kg. These cylinders are provided with stop cocks permitting of dilution.

Oxygen was formerly prepared industrially, in accordance with the methods of Thessié, Mottay and Maréchal, by utilising manganate of soda; of Mallet by utilising cuprous chloride; of Kassner by utilising plombate of calcium; of Brin by using oxide of barium.

Modern technical methods follow the lines of fractionated distillation of liquid air or electrolysis of water. In the Claude process, after purification, compressed air at 40 atm. undergoes dilution on two successive occasions, the work being effected externally. After liquefaction, the air passes into a rectification column, which furnishes liquid oxygen. In the Linde process the purified air, compressed to 210 kg., is liquefied after cooling and dilution, and flows into a separator, at the exit of which the liquid oxygen is obtained.

The Joubert process, derived from the Linde process, enables either gaseous or liquid oxygen, as desired, to be obtained from the same apparatus.

Oxygen is used alone or mixed with air; for activating forges, kilns (metal-lurgy, glass works, etc.), for obtaining high temperature flames (enamelling, tinning, metal cutting, autogenous welding; oxyhydrogen, blowpipe with hydrogen; oxyacetylene, blowpipe with acetylene); in the artificial stone industry; in the chemical industry for the regeneration of purifying mixtures from lighting gas, for ageing of alcohols, cognacs, etc.; in oxidation processes connected with bleaching and refining of fatty oils, in the preparation of ozone and acetic acid, starting with acetaldehyde, etc. When projected on to a block of quicklime and zirconium, the oxyhydrogen flame produces an extremely bright light ("Drummont light").

Liquid oxygen is principally employed as an explosive in mines. It was utilized in piercing the Simplon Tunnel. Its use was subsequently abandoned, and has only been reverted to since 1910, and more generally since 1915, in Silesia and Lorraine. The explosive consists of a fuel (liquid oxygen) and a combustion agent (mixture of various highly oxidisable substances: powdered aluminium or magnesium, soft coal, carbohydrates, hydrocarbides). Once the two substances have been brought into contact, ignition takes place by lighting a slow fuse (fuses or primers) or by the electric spark. The cartridges, according to their composition, may provide the whole series of effects obtained by ordinary explosives, and the explosions may take place under water.

Apart from its use in mines and for piercing tunnels, where it is often prepared on the spot at the moment at which it is required in special apparatus, liquid oxygen is likewise very often employed in large-scale metallurgical works for breaking pieces of iron and steel.

The sources of risk connected with the use of oxygen consist principally in the risk of explosions and accidents, and belong in consequence to the sphere of safety rather than hygiene.

It has been reported that liquid oxygen is capable of causing fairly serious burns by prolonged contact. On the other hand, some discussion exists as to whether, during its use as explosive, it liberates noxious gases. Whilst, in accordance with research effected in 1922 by the Technical Committee of the Miners' Association of Alsace-Lorraine, it has only been possible to detect in some badly ventilated development ends incalculable traces of carbon dioxide without any influence on the system, other authorities are, on the contrary, of the opinion that liquid oxygen is productive of more carbon monoxide than dynamite gelatine, unless when ignition occurs six to seven minutes after the charge. Further, it would be advisable to arrange for the lapse between successive explosions of a period of six minutes at least to be devoted to ventilation.

In pyritic mines there occurs production of sulphur dioxide which, though not nearly so poisonous as carbon monoxide, also exerts an irritant action.

Hygiene measures are restricted to provision of good ventilation.

In a factory for the production of oxygen and nitrogen, fairly serious accidents were met with, consisting in
multiple and extensive burns due to contact with the pure oxygen. Various recommendations deal with the risk of fire. The sparks produced during working on metal are liable to set oily clothing on fire. Ventilation of trenches ought to be adequate, energetic and continuous. The workers should have at their disposal facilities for rapid first-aid treatment, and should wear fireproof clothing for all work bringing them in contact with oxygen (Leclerc and Müller, 1931).

In Greece, boys under sixteen and women under eighteen, and in Italy, boys under fifteen and women under twenty-one years of age are excluded from the preparation of compressed gases, etc.

---

Ozone

French: Ozone. — German: Ozon. — Italian and Spanish: Ozono.

Ozone is a condensation product of oxygen found in small quantities in atmospheric air, especially during storms accompanied by numerous electric discharges, and in peroxide of hydrogen. It is also produced: in air under the action of ultra-violet rays emanating from a mercury lamp, X-rays, etc.; during the slow oxidation of humid phosphorus in air; during electrolysis of water.

It is prepared industrially by subjecting atmospheric oxygen in a very dry and pure state to the action of electric discharges, or, what is better, electric glow discharges in special apparatus (Andreoli, Tindal-Schneller, Siemens-Halske apparatus, etc.). In all these cases there is generally obtained ozonised air which has to be liquefied and subjected to fractionated evaporation in order to give pure ozone. Pure ozone is a comparatively stable gas which decomposes slowly at an ordinary temperature and rapidly towards 400° C. Slightly soluble in water, it dissolves and combines with etheral oils, and, better still, with turpentine oil, aqueous solutions of quinine, etc. It is an oxidising and deodorisation agent, a strong microbicide, and is currently used for sterilising water and air. It is used in the preparation of heliotrope, vaniline, and artificial camphor. It is utilised for bleaching textile fibres, fatty amylaceous substances, and hydro-carbonaceous products, and as an oxidising agent for oils and spirits, etc., its action on the human system is similar to that of chlorine.

If it irritates the mucous membranes, in particular the respiratory and ocular membranes, and a dose of 0.001 grm. per litre causes perceptible irritation, whilst by a dose of 0.002 and a period of exposure lasting an hour and a half, coughing and fatigue are caused, and with a dose of 0.006 and an exposure period of one hour, coughing and somnolence. Experimentally a dose of 0.01 grm. per litre is found to kill animals by causing pulmonary haemorrhage (Lehmann). Dablez (1929) has confirmed by experiment the toxic action of ozone. A concentration exceeding 1 mg. per cubic metre of air gives rise to an irritation of the respiratory passages, diminished arterial pressure, etc. Its toxicity is, however, fairly slight in the case of human beings, since it is not "deep seated", and its forces become entirely dissipated in the first layers of tissue which the ozone encounters.

In 1932, Quarelli drew attention to the incidence of troubles produced by ozone in persons preparing or using this substance (physicians, chemists, workers, etc.). Nevertheless, from the aspect of industrial hygiene, ozone may be regarded as innocuous, the derangements noted amongst radiologists, etc., being rather attributable to certain gases liberated during the formation of ozone, notably oxides of nitrogen in laboratories where numerous electric discharges occur (Zangger).

***
Painting Industry

The occupational dangers in the painting industry, connected with painting houses, coaches, and ships, have so many points in common that they may be studied together. They differ, however, sufficiently one from another, by the nature of the work and the materials used, to make it necessary to study the technique of these different branches separately.

TECHNOLOGY

An account of the technique adopted is only given in sufficient detail to clarify the causes and the variety of the pathological manifestations, as well as the methods of prevention, which will be described later.

House Painting

Colours used in house painting are composed of two elements: a solvent, or liquid, which acts as a vehicle, and a pigment or colour properly so called. The solvent most used is linseed oil (which may be replaced by other vegetable oils: poppy, tonka-bean, Chinese wood, etc.); it is used to soak and dissolve the pigment so as to give it certain special properties. Quite often the solvent is composed of two liquids: linseed oil, the solvent properly so called, and a volatile spirit. That most often used is spirit of turpentine, which acts as a diluent.

Although numerous cheap substitutes for turpentine exist, including various mixtures of turpentine, heavy benzene, petrol spirit, benzol, or petrol, they are little used in Europe, but "white spirit" is used considerably in the United States. Two other substances, however, obtained from naphthaline, are to-day recommended in place of turpentine, viz. tetraline and decaline.

Tetraline is naphthaleine upon which 4 atoms of hydrogen have been fixed. This substance has a density of about 0.976, boiling point about 205° C., and a flashpoint of 78° C. If 10 atoms of hydrogen are fixed on to naphthaline, decaline is obtained, in which about 20 per cent. of tetraline is always present.

White spirit is a special spirit of petrol which replaces turpentine, the price of which has considerably increased.

By refining illuminating oils, petrol which is used for illuminating is obtained (see the article "Petroleum"); various types of white spirit come from splitting up the original fractions, yielding spirits with densities varying generally from 0.760 to 0.800. White spirit is always a very irregular product, a fact which makes its density an insufficient characteristic for distinguishing it. Dangers from fire, explosion, and poisoning are especially associated with this material. In order to counteract the peculiar and disagreeable smell of white spirit, amyl acetate is sometimes added to it in small quantity, and spirit of Mirbane (nitrobenzene)—a method not much employed.

On the other hand, pigments are very numerous; the white pigments are the most important, forming usually the basis of all paints. Examples are white lead and zinc whites which have been used for many years, titanium white, antimony white and lithopone, which is a compound of zinc sulphide and barium sulphate. Attention must be directed to the fact that the science of pigments is ever turning towards composite pigments, called mixed pigments, in the composition of certain of which lithopone, for example, is an important factor. Other pigments are used only to give to the paint the desired shade by mixing them with the white pigments. The ochres are ferruginous clays of a yellow or red colour.
There are also Prussian blue and ultramarine, chrome yellow, greens (certain of which, derived from copper, are very poisonous), varnish (which is a combination of sulphur and mercury), as well as others.

Minium, a red oxide of lead, in particular is often used, as it preserves iron from rust very effectively. It is not prohibited, as white lead is, but in view of its toxicity several substitutes, such as oxide of iron, and paints with a chromate and graphite basis have been proposed which may perhaps suppress its usage entirely (see the article "Red Lead").

Besides colours properly so called the house-painting trade employs:

- varnishes, mixed or not with benzene and a drier;
- driers, added as liquids containing oil, benzine, manganese, and litharge, or in powder, e.g. salts of zinc and manganese;
- encaustics mixed with water, such as wax, white soap and salt of tartar and water, or yellow wax, American potash and water; or mixed with spirit, e.g. wax dissolved in spirit.

The silicates of potash or soda, as well as another silica salt, sold under the name of silexore, are also used, mixed with Spanish white or oxide of zinc to make special distemper, which can be applied to surfaces which are quite porous, and in particular upon new cement; it has besides a special affinity for zinc and glass.

Painting work can be divided into two chief categories: (1) preparation; (2) finishing.

(1) Preparation work.—Before any painting can be done, it is necessary for objects and surfaces which are to be painted to undergo beforehand certain preparatory operations of which the chief are dusting, smoothing, burning or scraping, washing or cleaning down, and application of the priming coat.

As regards new surfaces which are more or less soiled during the period of seasoning, or old surfaces of walls and woodwork more or less covered with dust, a kind of general cleaning (dusting) is necessary. This applies to all parts, objects and surfaces to be painted, before the operation both of preparation or of finishing. The work is carried out from the top downwards by means of a small brush. Smoothing is particularly necessary for plaster work and has for its object the removal of all particles resting on the surface to be painted. These two operations are specially necessary with new work. For maintenance work, such as on old walls plastered with mortar, thorough scraping by means of a triangular scraper must be used to remove the smallest scrap of such paper; cleaning is particularly required when old paint is sticky or is peeling off in flakes, and when coats of a lighter colour than those already on are to be applied.

The different methods of cleaning down are: with potash, by using a solvent, or by burning. It is important to emphasise that in the second method the following are used as solvents: acetone, amyl acetate, alcohol, benzene, methyl alcohol, nitrobenzene, and especially a combination of these substances. The solvent is applied either by a bristle brush or a knife, according as to whether it is liquid or a paste. There is thus danger of poisoning, explosion or fire, according to the toxicity or the inflammability of the materials used.

The process of burning is carried out by means of a burning lamp using petrol spirit, which is able to give a flame of which the temperature reaches nearly 2,000° C. Modern lamps are provided with safety valves which regulate the flame; their use generally does not present any special dangers.

After the two preliminary operations comes the priming coat, which is applied to a surface carefully dusted and rubbed down, not soiled by the least dirt or grease and perfectly dry. This coat should leave upon the surface to be painted a thin layer which will act to some extent as a foundation and will facilitate not only the success of the following coats, but also the operations of rubbing down and stopping.

The whole of the priming coat should next be rubbed down with glass-paper to remove the rough particles of paint, so as to make a foundation as trim as desired, and to allow the colours to lie even. Then follows the process of stopping, which is very important in painting; it consists in filling holes and removing splinters and flaws.

(2) Finishing work.—When the preparatory work has been finished, the stopping quite dry, and the mastic set hard (for which time must be allowed), the finishing work is proceeded with, that is to say, the application of coats of paint and the operations which that entails. The products used vary according as to whether the work concerns woodwork,
metal surfaces, walls or ceilings; and further as to whether these surfaces are interior or exterior, that is to say, more or less exposed to deteriorating influences and to bad weather conditions.

Work upon walls as well as woodwork is finished with lacquered or enamel paint; most of those which are used at the present time in the trade have as their base zinc white and special oils of linseed (Europe) or fish oil (America). These paints contain also variable proportions of white varnish called "crystal varnish".

Outside walls and woodwork receive a priming coat and can then be washed down with silicate.

Outside ironwork is treated thoroughly with the hammer, knife and glass-paper; a coat of red lead or oxide of iron is then applied directly to the iron. This question of the protection of iron against rust is specially important as regards shipbuilding (see later).

Finally, coats of paint are applied, which vary according to the tone required, and then varnish.

Walls of interior courtyards may be whitewashed with lime with the double object of providing light for rooms which face them and giving the walls a clean appearance.

Generally speaking, it should be noted that, according to the opinion of most experts, white pigments are the only ones that can be actually employed with every reliance from the point of view of complete protection. Other paints generally, even the ochres, present a surface out of doors which is not comparable to that given by the two whites, and only lasts in proportion to the amount of white in the mixture.

Painting of Boats and Ships

A technical account of the painting of vessels intended to act as a means of transport upon water is difficult for several reasons.

First comes the multiplicity of types according to dimensions and uses; then the variety of materials of which they are constructed; then the necessity of using different processes according as to whether protection is being given to submerged parts or ships' bottoms.

Exposed to the action of water, seaweed and shell-fish, or, on the other hand, to upper works which escape such exposure.

Preparation and painting of new surfaces. — Wooden vessels should be considered first because they are the oldest, and are still at the present time most used for carrying light tonnage. Besides, "though it may be said that wooden ships practically disappeared before the war from maritime commerce, circumstances have so enhanced the cost of sheet steel, indispensable in the construction of modern steamboats, that certain Governments, the chief suppliers of commercial tonnage, have ordered the construction of a number of wooden ships of large tonnage, hundreds of which have been constructed and are at present ploughing every ocean " (H. Craen).

For covering wood with a priming coat to protect it against rot; this priming coat is put on in a different manner depending on whether it concerns the ship's bottom, the superstructure or the interior of the hull.

The simplest method of protecting the wooden bottoms of fishing vessels, trawlers, etc., consists in the direct application upon the wood either of pitch kept at boiling point by the aid of braziers close to the worker, or of vegetable varnish, called Norwegian pitch, applied cold.

For vessels of greater tonnage — merchant ships, pleasure boats, etc. — the wooden bottoms are generally treated as described in the following paragraph.

First comes puttying, if required, using a base of linseed oil and white lead or zinc white, particularly using zinc white made by the direct method, with the object of filling all the cracks and crevices; this is followed by rubbing down with pumice stone, either dry or with water, in order to ensure an absolutely smooth surface. One or several coats of lead paint, using red or white lead, are then applied; this application may be made immediately without preliminary puttying. It should be borne in mind that workmen using putty have the habit of working it frequently in their hands in order to keep it supple, and from this there is danger of poisoning if the putty is made with white lead.

When once these coats have been applied it is necessary to take into account the fouling of the hull by seaweed and shell fish, which tend to develop there until they constitute a thick covering. The severity of the fouling varies much according to diverse factors: the kind of water, e.g. that of ports is full of diverse factors: the kind of water, e.g. that of ports is full of
resistance of the surface, which from being smooth becomes rough and so hampers progress; on the other hand, it forever lays little by little the oily material which has acted as the vehicle of the paint, which then becomes friable and comes off on friction.

Clearly then a fight must continually be waged against fouling. The sheathing of wooden bottoms with a covering of copper, commonly used formerly, was a very efficient means of protection. The copper on coming into contact with sea water becomes transformed little by little into chloride and carbonate of copper which drops off carrying away the growths which have fixed upon it. This sheathing has, besides, the advantage of protecting the wooden hull against attack by certain organisms and particularly by the shipworm or teredo, a lamellibranch sea mollusc, which perforates the wood of piles and ships not protected against it.

There is to-day a tendency to increase the use of special coats, or different compositions, containing poisonous salts of arsenic, copper or mercury, which preserve the wood against shipworms and other parasitic organisms, and also volatile solvents, such as benzol, benzene and xylol, the presence of which causes the coat to dry rapidly in the air and to harden firmly in water. This dried coat exfoliates little by little carrying with it the algae and shell fish and so leaves the hull clean.

Among the numerous products employed against fouling we may mention "Schweinfurt green" made into a paste with benzene, the "Antifouling" colours, "Copper antifouling paint", "Algicide", "Anti fouling composition", etc.

Moreover, as regards wooden hulls made of valuable kinds of timber, they are sometimes, without any painting, simply sanded, rubbed down and varnished (see the article "Poisonous Woods").

The upper works of wooden ships (the holds) are often covered with limewash which effectually prevents the development of organic germs. The limewash is prepared by diluting slaked lime with water; gelatine added to the milk of lime improves the adhering quality of the wash, which however does not hold sufficiently. Similarly pitch is used, or bitumastic derived from pitch and bitumen; it is used hot, and, like pitch, gives off a decided smell of creosote.

As for the cabins they are either varnished, or painted with white lead, or zinc.

In steel shipbuilding the first and most important question which presents itself is that of protection against corrosion by the formation of rust.

It is known that rust, ferric hydrate, is a friable and porous substance, produced by the oxidation of metallic iron by the action of atmospheric air or of air dissolved in water. The deterioration at first goes on very slowly; but as soon as the first touch of rust is found, the iron oxide being electro-negative in relation to the iron, oxidation is accelerated.

Steel, which is of complex composition, placed under the same conditions as iron becomes oxidised much more rapidly. When steel first came into use it lacked homogeneity and its oxidation proceeded rapidly; to-day its corrosion is slower. Mechanical changes assist defects in permanent homogeneity by favouring oxidation.

In addition two other matters have to be considered: protection against fouling, and means for avoiding troubles proceeding from the conductivity of steel plates as regards cold, heat and noise.

All corrosion could be prevented if a coat could be obtained perfectly adherent and impermeable to air and water. In practice this result is impossible to obtain. On the one hand, external mechanical causes cannot be avoided, such as shocks and friction, which partially remove the protective coating. On the other, constant exposure to water, as regards the hull below the water line, and exposure to storms, as regards part of the upper works, result in a disastrous infiltration of water, at some points penetrating the protecting paint. Then atmospheric oxidation are formed with the setting free of hydrogen, which pushes up the paint and forms blisters — openings which facilitate further infiltration of water.

But if this corrosion cannot be totally avoided, it can be at least partially avoided by two courses: first, preliminary protection, as complete as possible, of all defects in homogeneity; then application of a protective coating.

When construction work is carried out quickly and the preliminary exposure to the air is of short duration, mechanical scraping must be more thorough. This must also be done for certain metal hulls of particularly fine build. This is done either by brushing with a metal brush, or by rubbing with pads of tow dipped in sea water full of slime and sand, which is removed after two days, or by cleaning with a sand blast; this last process has
PAINTING INDUSTRY

For the superstructures, cabins and living quarters the cleaning of paint and varnish calls for the most perfect technique, sometimes pumice stone is employed, sometimes scraping combined with the burning lamp, sometimes rapid rubbing down with a solvent or a lessive (see above).

Double bottoms, tanks, and store-rooms require to be emptied before painting repairs are undertaken, for they contain accumulations of bilge water, bodies of rodents, and other things, the fermentation of which causes the production of noxious gases, such as carbonic acid and sulphur dioxide.

When once these places have been cleaned out, paints preserving coats are applied similar to those used when the surfaces were originally new.

**Coach Painting**

The ordinary work of freshly painting carriage work, or of renewing the paint, is generally based upon the same principles described above when describing the painting of wood or metals. But when high-class work is concerned, as, for example, the bodies of motor-cars, the technique is very complex. Following is a list showing the different categories of workers employed.

1 Preparers deal with the coach on its passing from the hands of the carpenter. They apply the priming coats, called preparatory coats.

After a preliminary cleansing with spirit of turpentine, eight coats are put on successively. The first is a coat of linseed oil and varnish (wood filling) and does not contain any elements of lead. It has the drawback of drying slowly and is not used if time presses.

White lead or zinc white is used for these coats. When the first coat is absolutely dry, it is rubbed over with very fine glass-paper and a second coat of a greyish tinge is applied. After thorough drying, preparation coats are next proceeded with. Seven or eight preparation coats may be replaced by three or four protective coatings applied with a knife which is broad, short, and rigid. All roughness is completely removed by rubbing with pumice stone. According to an enquiry by Hein and Agasse-Lafont the preparers are the men most exposed to risk of poisoning.

---

The categories of workers in Great Britain are not in every case the same as in France. Hence the names used in the text must be considered as translations rather than as technical terms used in the coach-painting industry.
(2) **Painters** or **foundation men** do the putty work and dressing down, and then apply coats of paint. The colours are ground in spirit.

**Mixers** and **apprentice painters** help in the preparation of the colours and the paint. Throughout the large majority of works, coach painters receive almost all their materials ready for use so that these workmen are not principally employed in grinding the materials as in days gone by.

The painters’ labourers, who do the rough work, the skilled painters, filet painters, the touchers-up and the letter writers, like the foundation men, all do work which necessitates the use of colours ground in spirit.

(3) **Finishers** put on the varnish.

(4) Rubbers down pass pumice stone over the coats of paint to smooth their surface. Rubbing down is done with pumice stone and water, the object of the moisture being to prevent the generation of dust containing lead. It is considered that they are not exposed to much risk. We shall see what weight can be attached to this opinion.

(5) **Polishers** have a similar rôle with regard to varnish, which does not contain lead compounds. The polishing of varnish is done with pumice stone powder and water, the moisture preventing the formation of dust, which is, nevertheless, considered almost harmless in itself.

It is obvious that, though, taken as a whole, all these workers are exposed to lead poisoning, their exposure arises from the conditions of work, and undoubtedly varies in degree.

In addition to applying paint with a brush, which is the most usual method, two other very important methods of painting have to-day to be considered: pneumatic painting (aerostyle) by means of spraying machines, used particularly for the painting of large surfaces or a succession of small articles; and painting by dipping, a rapid, final and complete process suitable for dealing with a large series of articles.

There is no need for a compressed-air installation to work painting machines; it is now possible to use cylinders of compressed air or of nitrogen or carbonic acid. The first atomisers were used for projecting colours mixed with water or for limewashing. Walls should always be carefully dusted down and scraped. The application of paint by an atomiser has advantages: rapidity of execution, economy of manual labour, the possibility of reaching surfaces difficult of access, very slight wear and tear of apparatus, a short apprenticeship for the workers, and perfect uniformity of the paint. But it also has serious disadvantages. Injuries due to the inhalation of diluting agents and volatile solvents utilised in cellulose paint are dealt with in detail below. Besides the waste which the formation of vapour entails, in the long run it renders work very difficult for the operator, who moves in a veritable atmosphere of paint, and if the preparation used has a lead basis, such as white lead or red lead, the danger is very great (see below). It is necessary therefore to provide a thorough system of ventilation by which the particles of paint in the air are rapidly removed and even to install hoods with localised exhaust draught — which, indeed, has been done already. The absolute solution of the problem would clearly be to use non-poisonous paint.

Middleton (1930) found that in samples taken at the level of the workers’ mouth during spray painting with products with or without lead content, but diluted with water, the particles of mineral substance attained the figure of 2800 cubic cm. of air; 90 per cent. of these particles were under 2 μ in diameter. When water is the medium there occurs dispersion of the solid substances many of which are sufficiently small to reach the lungs. Risk is therefore in proportion to the composition of these solid substances.

On the other hand, with an oil medium the solid particles remain in the vapourised droplets varying in diameter from 2-15 μ whilst each droplet contains numerous solid particles. The number of droplets is about 60 per cubic cm. The difference between the kinds of vapour produced is dependent on regulation of the air and paint supplied to the spraying apparatus. Technically speaking, it is not at all essential to have a visible mist. A young worker who during one month had applied by spray without localised ventilation paint containing 52 per cent. of soluble lead showed in early but distinct haematological symptoms. Middleton met with similar symptoms in another worker who had several weeks previously left his occupation, in which he had been engaged for six months for alternating weeks.

But there are other sources of poisoning which must be considered: solvents, especially those which dry rapidly, such as benzine, etc.; and more particularly submarine protecting coats, “anti-fouling” paints which,
to fulfil their purposes, must contain compounds notoriously poisonous, such as oxide, chloride, sulphate, arsenite or arseniate of lead; sulphocyanide or ferrocyanide of copper; yellow oxide or dichloride of mercury. From the technical point of view there are disadvantages connected with it: waste of paint, lack of adherence of the coating applied, difficulty in obtaining coats of uniform thickness, and blocking up of the tubes of the apparatus.

But we must acknowledge that the painting machine is being improved day by day and that most of these disadvantages can be modified or abolished.

This method is largely used in the application of cellulose paints which includes the following operations. After the metallic surface has been cleansed with alcohol and phosphoric acid, puttying and smoothing by hand follow. Then the foundation or preparation coat is put on, followed by a second foundation coat. Wet rubbing down with pumice stone and one or several coats of cellulose paint follow, and then, after drying, comes the finishing coat of enamel.

Varnish is a solution of nitrocellulose in a mixture of amyl alcohol, amyl acetate and acetone.

Where the surrounding temperature is moderate and the benzene content of the paint does not exceed 15 per cent., the risk is non-existent provided the work is done under an effective system of local ventilation. There is a growing tendency to substitute xylene or toluene for benzene.

In her enquiry, Dr. Overton (1930) studied the application (in winter) of cellulose varnishes used under a localised system of ventilation. The paint contained 30-40 per cent. of toluene and 60 per cent. of xylene with impurities consisting of traces of benzene. She found three parts of toluene and xylene per 10,000 parts of air. She found only one case of a worker suffering from purpura.

In several countries contracts require that paints shall not contain over 5 per cent. of lead.

Various Kinds of Painting

Painting by dipping is largely employed in America in metal works and the workshops of builders and producers of chemicals and varnish, and in oil works; it only consists in the rapid application of a special enamel by immersion. The plant comprises a dipping bath, a draining table and a drying place. During the operation of dipping there stands by the side of the bath a barrel of spirit of a density of 0.720° to 0.730°, for thinning down the mixture, for replacing spirit as it evaporates, or for washing over articles that have been too thickly coated. The system of draining on "a fixed double table" compels the worker to move his position in carrying the vessels to the table by straightening himself to his full height. According to experts, experienced workmen do not complain of fatigue or pain in the back, which, on the contrary, is very prevalent with tables of other patterns, where the workman in continually obliged to bend right down to dip the vessels and deposit them before him and take up two others placed on the ground by his side.

In the drying rooms, it seems, the methods vary according to the special conditions of each case. From the health point of view, if the paints contain poisonous substances, draining upon the floor and handling done without observing special precautions may easily cause poisoning. The evaporation of spirit solvents from the baths and especially from the dipped surfaces may also vitiate the air and presents risk of fire or explosion.

Mention must also be made of the lacquering of machines, such as motors, large and small apparatus of the electrical industry, and machine tools, which includes ordinary mat paint and highly brilliant paint. The technique is always the same. The final coat consists of good varnish which resists heat. Some small articles are lacquered with colour-enamel applied by spraying or dipping; and then dried in an oven.

STATISTICS

It would be interesting to give here some statistics of sickness and mortality in the different categories of painting work. Unfortunately such a study presents great difficulties and is subject to numerous sources of error. As a matter of fact, when it is desired to make an enquiry in a workshop or a factory, only the workmen who are in full active work are seen. Nothing is known of the absentees, as to whether their absence is due to mild or serious causes. Precise information can only be obtained concerning the medical history of those present and who are therefore comparatively well at the time of the enquiry. If then few sick casualties are reported, it cannot be concluded that such casualties are exceptional. Men severely affected are necessarily eliminated from an enquiry of this sort; some only recover of actual sickness at the time; others may have definitely left the trade: some indeed may have died from industrial
disease. Thus, a blank exists which cannot be filled in without knowing the exact number of workmen employed in a factory during a fixed period of time, and determining the percentage between those present and those absent, and in the case of the latter finding out the cause of their absence, their condition at the time of the enquiry, or at least their condition when they left the trade.

The Medical Sub-Committee of the Committee on White Lead appointed by the Third International Labour Conference (Geneva, 1921) concluded, concerning painters who use white lead and other compounds of lead, that "lead poisoning is the chief occupational danger; nevertheless statistics are unreliable; as regards the death rates (a) in the first place because deaths due to lead poisoning may be excluded and appear under other headings, and (b) secondly, by reason of the inclusion under the heading of lead poisoning of deaths due to other causes; as regards sickness, statistics are unreliable due to omissions in notifications and verification and to other imperfections." The Sub-Committee formed the opinion that "compulsory notification of suspected cases of lead poisoning by medical men and verified by independent medical practitioners would not only give, as now happens in certain countries, satisfactory statistics."

Though the cases of wrongly diagnosed lead poisoning are not at all numerous (which is proved), the cases given in statistics should be considered as a minimum. But, in spite of this statement, statistics show the existence of a state of things which demands the attention of experts and legislators.

Australia, New South Wales. — During an official enquiry conducted in 1921 figures relating to painters and workmen in other industries liable to lead poisoning were collected. It was found that about 60 painters were engaged in the trade; it was considered that the figures for that year were less liable to variations in statistical accuracy due to unusual conditions and that according to these statistics the death rate was highest for painters between 50 and 54 years, whilst for carpenters taken as a standard it was between 60 and 64 years.

For painters the average age at death is 43.5, for carpenters 60.9 and for workmen in general 57.1. These figures deal with workers from 15 years old and upwards. But if the figures start with workers from 20 years old, then the following are the results: painters 54.5, carpenters 61.6, other workers 57.8.

Without entering into details one may call attention to the following passage in the report: "If the death rate of painters grouped according to age was applied to the active male population, the resulting death rate would be 15.7 per thousand (instead of 12."

The excessive mortality due to certain diseases among painters is 296 for lead poisoning, chronic nephritis (against 0.4), 152 for chronic nephritis (against 55.3) and 128 for tuberculosis (all forms) against 90.4. Hence per thousand deaths, the excess mortality attributable to the influence of lead is 150.

As regards mental diseases, the figures collected enable the conclusion to be drawn that for a thousand deaths reported each year among painters, about 1.2 are due to mental trouble following lead poisoning, whilst among other workmen of the male sex the proportion is 0.8.

Canada. — A report upon occupational risk of lead poisoning from the use of paint by spraying was presented in 1922 by the Institute of Pharmacology of Toronto. According to the author, makers of such sprayers certainly realise the danger which arises from the use of their apparatus and recommend in its use the adoption of protective measures, such as the wearing of masks and helmets.

The enquiry showed that thirty firms in Toronto, and perhaps more, each employed one to three sprayers either for the interiors or for exterior work. The enquiry was confined to interior work where it was not possible to extract the dust and spray.

Pneumatic painting of articles of small size is carried on in workshops provided with exhaust draught and only the casual workmen use masks. In every case, except one, where paint containing 3 per cent. of lead was used, the workmen declared that as far as they knew the use of lead paint was very rare.

It was difficult to determine the exact part played by sprayers in causing a risk from lead poisoning, for workmen who do not use lead paints, or who use paints containing little lead, were nevertheless occupied on other work which might be a source of poisoning.

It was, therefore, decided to make some tests with paints containing 10%, followed by white lead prepared according to the formula required for use in sprayers. Without entering into details, it is sufficient to state that the following facts have been noted: an unmistakable mist existed at 3 metres from the operator; a mask was covered with a fine coat of paint, especially at the level of nose and mouth; the hands and arms of the operator were soiled with paint; a slight sensation of suffocation was experienced which persisted even some time after the cessation of work. Investigations into means of protection, carried out in a workshop where small articles were being painted, wherein a kind of cabinet was used, furnished with excellent extracting arrangements and an opening for the introduction of the article to be painted, proved that the workman did not experience any difficulty in breathing and that he had no traces of paint either on his clothes or face. Only his arms and hands, introduced into the cabinet for handling the articles were soiled with paint.

In the course of tests for spraying interiors, the investigator found from 135
to 417 mg. of lead per 10 cubic metres, which means that under these conditions a workman during 8 hours might inhale 60 to 180 mg. of lead per day.

In another test lasting three days the urine of a painter, who had worked in the interior of a building for four or five hours a day, was analysed. The urine was found to contain 0.3 mg. of lead and the lead was less than 2 mg. The presence of lead in the urine after so short an exposure is very significant.

The enquiry also dealt with various types of masks which are used to protect workmen. Experience showed that a type of mask of gauze, cotton wool and animal charcoal could not be tolerated by any worker; and further that the animal charcoal did not arrest the lead. Any mask becomes unfit for use when it is covered with a coat of paint. Experience shows that a really efficient mask could not be worn without causing the workman inconvenience, and also it was established that in the use of a sprayer for applying paint with a lead basis to the interior of a building, there is always a danger of absorption of poison.

In painting small articles, danger of lead poisoning is considerably reduced by using cabinets supplied with an efficient exhaust draught. These cabinets sometimes have defects which must be carefully looked for and eliminated. Further, the worker in this case more than any other is exposed to poisoning by the volatile contents of the paint. An enquiry upon this point is about to be organised.

France. — Cases of lead poisoning notified under the Compensation for Industrial Diseases Act (1919) from 1921 to 1928 reached the figure of 8,628, of which 391 occurred in the painting industry. It is important to note that the cases of lead poisoning amongst painters numbered 13 out of a total for all industries of 141 in 1921, 64 out of 797 in 1922, 76 out of 1,025 in 1923 and that they were only 42 out of 1,040 in 1927, 43 out of 1,525 in 1928, 37 out of 1,848 in 1929 and 36 out of 1,652 in 1930. The 1921 census shows a total of 25,535 painters. The total for 1926 is 47,000 in round figures.

By way of example the results of an enquiry recently made by Heim, Agasse-Laurent and Feil, of Paris, among a group of 88 coach painters, represent by no means a selection, but almost the total number of workmen employed in two factories doing work exposing them to poisoning; as a matter of fact the men temporarily absent and those who objected to examination were very few (about one-fifth). It is then legitimate to consider that the results obtained represent an average and can be generalised.

These workers, for the most part men (77 out of 83), were of very variable ages, from 13 to 72 years; they carried on their trade of painting during a similarly very variable length of time, from 3 months to 50 years. In connection with this last point it is important to bear in mind that two-thirds, 53 out of 83, had worked in the lead trades for more than 5 years.

As to the nature of their work, it can be divided into two groups:

(a) Preparers, painters or foundation men, mixers and apprentice painters, layers-on of paint, skilfed painters (filet painters), touchers-up, letter painters and finishers, who directly handle injurious substances.

(b) Other workmen employed in perfecting by smoothing with pumice stone the coats of paint and varnish.

The blue line on the gums was present, very clear in 25 per cent. of cases and slight in 40 per cent.; a total of 62 per cent. positive.

The presence in the blood of red corpuscles with punctate basophilia was found in 56 per cent. of cases.

As regards the other blood changes, the presence has been noticed; almost constantly of red corpuscles with a basophilic protoplasm and a tendency quite marked to mononucleosis (44 per cent. of cases). This is of much less importance than the preceding.

Further, search for lead in the urine, which is very important from the point of view of diagnosis, as well as regards the pathogenesis of renal conditions, could only be made on 16 workmen who were taken by chance and not selected. The result was positive in the proportion of 81 per cent. of cases.

The preceding signs when they exist alone are typical of latent plumbism or a pre-poisonous stage.

As regards actual morbid conditions of lead poisoning, that is to say, of confirmed lead poisoning, among the workmen examined by Heim, Agasse-Laurent and Feil, two morbid manifestations have been met with, i.e. lead colic (6 per cent.), and hyper-arterial tension (27 per cent.) — concerning which, however, it is very often difficult to estimate how far the pathological features may be due to lead poisoning alone or to other common causes of renal sclerosis.

On the other hand, if, as a starting point, the presence of lead in the urine is taken, all the characteristic signs and all the lesions reported among the men examined, i.e. blood corpuscles with punctate basophilia, mononucleosis, blue line, hyper-arterial tension and lead colic, are found proportionately more frequently among those men who have lead in the urine than those who have not.

As regards the age of the workmen, it is interesting to note the comparative rarity of mononucleosis in the case of old men, which is doubtless due to a diminution of the activity of their blood-making organs and of their vascular endothelium; and, by way of contrast, the frequency among them of hyper-arterial tension.

The study of the period of active work in the trade, which may be comparatively independent of the question of age, shows that the presence of lead in the urine and mononucleosis are frequently early signs, as also is lead colic. On the contrary,
the blue line and the presence of cor-

puleses with punctate basophilic increase

mordecialy with the length of expo-

sure.

As regards the nature of the work, Heim, Agasse-Lafont and Feil have re-
ported not only the painters and polish-
ers, who do not directly handle sub-
stances containing lead and work with

moisture to avoid the inhalation of dust, 

would appear, a priori, from this fact to

be less exposed than others; in reality 

they are more exposed. Without being 

able to make allowance for considera-

tions of age or for length of employment 

at the trade, they exhibit as high a per-

centage as do preparers and painters as 

regards blue line, granular red cor-

puscles, mononucleosis, and definitely higher as 

regards lead in the urine and hyper-

arterial tension.

Germany. — A very detailed enquiry is 

that of Kneisch relating to Bavarian paint-

ers, which, however, deals with the years 

1910-1911. It concerns about 3,000 work-

men, most of them between twenty and 

forty years; 8 per cent. only were more than 

50 years. About 13.8 per cent. showed 

signs of lead poisoning; about one-third 

had one or more acute attacks. Eighty-five per cent. of the workers under 

consideration suffered from colic and 3.5 

per cent. from paralysis. Although among 

these workers in no case of cerebral trouble 

had occurred, an enquiry made in the 

hospitals of Munich brought out that 

there were several cases of encephalop-

athy. About 29 per cent. of workmen 

examined showed either objective or sub-

jective symptoms of lead poisoning; a 

blue line on the gum in 11.8 per cent.; 

anaemia in 6.5; and also troubles of the 

digestion, the circulation, and the kidneys.

According to the statistics of the Leip-

zig Sick Fund (1910), the frequency of 
sickness among 100 painters, lacquer-

ers, and varnishers (that for 100 insured 

workers is shown in brackets) is given in 
definite figures as follows: cases of 
sickness, 43 (40); deaths, 0.72 (0.77); 

days of sickness, 1,017 (855); infections, 

156 (142), of which pulmonary tubercu-

losis, 76 (62); poisoning, 178 (0); diseases of the 
nervous system, 52 (46); respiratory dis-

cases, 146 (149); circulatory, 34 (31); 
digestive organs, 104 (92); diseases of the 

skin, 50 (58); of locomotion, 59 (78); neg-

tional injuries, 117 (170); accidents, 61 

(94).

The statistics of the Chemnitz Sick 

Fund for 1936 of "workers engaged on 

constructional work", including painters, 

provide data regarding incapacity for 

4,190 workers. Cases of sickness during 

1926 reached 4,695, of which 583 affected 

members under twenty years of age. 1,897 

for those aged twenty-one to thirty years; 

870 for those aged thirty-one to forty years 

of age; 633 for those between forty-one 

and fifty. Deaths reached a total of 37.

Those diseases showing a high rate are 

the following: respiratory diseases, 556 
cases; diseases of the digestive system 

and of the liver, 524; of the locomotor 
system, rheumatism, gout, 898; other dis-
eases of the locomotor system, 194; 
pulmonary tuberculosis, 232; poisoning 
accounts for only 6 cases. The ages most 

affected are in general those between 
twenty-one and thirty especially for res-

piratory circulatory diseases, affections of 

the locomotor system and accidents. The 

latter amounted to 1,078.

Great Britain. — From 1910 to 1921 the 
cases of lead poisoning reported in the 
painting industry as notified to the 
Factory Inspection Department were (the 
fatal cases being shown in brackets): 1,470 
(230) for painters employed on buildings 
(for which branch of the industry notifi-
ication is voluntary), 550 (39) for coach-
painters, 247 (27) for ships' painters, and 
366 (19) for painters in other industries. 
From January 1927 notification became 
compulsory also for painters in the build-
ing trade.

For the period from 1925 to 1930 the 
notified cases are classified as follows:

<table>
<thead>
<tr>
<th>Year</th>
<th>House painting</th>
<th>Coach painting</th>
<th>Ship building</th>

</tbody>
</table>

The cases occur particularly amongst 
older workers, but the restricted num-
bers make it difficult to draw any con-
clusion. Other figures for the same 
periods according to the ages of the 
painters affected are as follows:
more numerous than elsewhere, but there must be taken into consideration the numbers of those exposed to the work in question.

According to the report of the Departmental Committee on the Danger of Lead Paints of 1923, the proportion of workmen affected can be estimated approximately for some of the lead industries. Any estimate is most difficult as regards house painters. The figures given below must be accepted with all reserve. The number of painters is that given by the Committee on House-Painting as an average for the period comprised between the census of 1901 and that of 1911; the number of workmen exposed to poisoning in coach-painting is that given for the year 1912 in the report of the Committee on Coach-Painting:

**COMPARISON OF THE RATES OF FREQUENCY OF LEAD POISONING AMONG LEAD WORKERS IN CERTAIN LEAD INDUSTRIES**

<table>

1 For house-painting the rates have been calculated in two ways, as follows:

(a) By the aid of the number of notifications and death certificates during the year. These figures, however, do not represent the total frequency, as notification is not compulsory for house-painters.

(b) By taking for granted that the relation of deaths due to lead poisoning to cases of lead poisoning is the same among house-painters as for lead workers in factory industries. This relation is known for lead workers in factory industries, while the number of deaths due to lead poisoning among house-painters is obtained from the death certificates which the local registrars receive.

For the period 1928 to 1930 the annual average incidence for 150,000 painters appearing in the census was per thousand 0.6, 0.5, and 0.4 as contrasted with an annual average incidence of 10.3, 6.5 and 10.1 amongst lead founders: 6.4, 4.5 and 7 amongst workers in storage battery factories; and 7.7, 4.4 and 1.1 amongst white lead workers.

The statistics submitted by Dr. Legge to the Committee on Coach-Painting covering 14 years (1900-1913) give the following results: out of 219,889 persons employed in the painting industry, 29,308 were employed upon work involving the handling of compounds of lead. But the number of cases of lead poisoning in this working population has been 1,026, giving an annual average of 73 cases, of which about 6 per cent. were fatal. During this period the sickness rate for lead poisoning has been 2.50 per 1,000 and the death rate 0.149 per 1,000.

Two remarks should be made on the subject of these statistics. The first is that out of the 29,308 workmen reported to have handled lead, a large number only handled it irregularly or to a slight degree. The second is that as regards sickness, only those effects of lead poisoning which cause working incapacity have been taken into account, and not, as in the French statistics reported above, blood changes and clinical symptoms.

The National Society of Painters of Great Britain records for the period from 1900 to 1923, 216 deaths among its members, of which 30 were due to chronic lead poisoning (13.8 per cent.), 24 to arteriosclerosis (11.1 per cent.) 123 to chronic nephritis (56.9 per cent.) and 29 to paralysis (18 per cent.). Besides, the society reports 674 other deaths which may be connected indirectly with lead poisoning. There were 203 deaths caused by diseases of the central nervous system, 460 deaths
from diseases of the circulatory system and
11 by diseases of the digestive organs.
From 1924 to 1925 the Society reported
14 deaths from lead poisoning.

Italy.—The Industrial Diseases Clinic
at Milan always follows up the state of
health of painters; Rubino (Genova, 1919)
made a very full enquiry into ship-paint-
ers; Ranelletti (1913) reported on house-
painters in Rome; Carozzi (1912-1914) made
a national enquiry upon the use of white
lead in the painting trade. These pursuits
carried out an enquiry concerning paint-
ers in Milan (1911-1931).

In Switzerland for 1901 to 1925, 278
deaths amongst painters were reported
as due to lead poisoning. According to the
statistics of the National Accident Insur-
ance Fund, from 1920 to 1925 the cases of
lead poisoning notified with a view to
compensation reached a total of 119; 106
were confirmed and granted compensa-
tion: 86 recovered; 8 involved invalidity
and another 8 were fatal; the result of one
case remained unknown. The 1920 Census
covered 5,154 painters.

United States.—An enquiry made by
the Commission of Industrial Diseases of
the State of Illinois has brought to notice
that among 578 cases of lead poisoning,
painters figure with a percentage of 27.
Dr. Alice Hamilton conducted in 1913 a
very exhaustive enquiry into the painting
industry; another enquiry by Hayhurst
dealing with 100 painters dates from 1914.
The result of a painting by Harris, relat-
ing to the state of health of 400 painters,
appeared in 1918. In 1917 Wade Wright
reported that during the first year’s work-
ing of the Industrial Clinic of the Massa-
chusetts General Hospital, 148 cases of
lead poisoning had been diagnosed, whilst
during the five preceding years only 147
cases had been reported in the different
departments of the hospital. Out of the
148 cases (of which 10 were non-indus-
trial), 70, that is to say, 50.2 per cent.,
ocurred among painters employed in
painting houses, ships or coaches. Ac-
cording to Hoffman, the causes of 2,783
deaths of painters were as follows:
pulmonary tuberculosis, 23.8 per cent.;
other respiratory diseases, 9.6; lead poison-
ing, 15; diseases of the nervous system,
10.7; of the heart, liver and kidneys, 25.9.

From 1914 to 1924 there were reported
841 deaths from chronic lead poisoning
among painters whose average age at
death was 51.3.

Chronic or acute nephritis accounted
for 193 cases (average age at death 49.2),
cardio-vascular diseases for 113 (32.8),
arteriosclerosis 97 (28.2), digestive dis-
ases 52 (43.7), respiratory diseases 44
(52.7), apoplexy 38 (52.6), anaemia 38 (54.9),
encephalopathy 23 (48.6), paralysis 23
(54.9), etc. It should be noted that of the
193 fatal cases among painters due to nephritis,
17.6 per cent., were aged 30-39; 31.1 at the
age of 46-49 and 29.5 at the age of 50-59
(Hoffman).

Another recent enquiry is that of the
Painters' District Council of Chicago
(1921). Detailed information was required
from its members as to the occurrence of
lead poisoning, of diseases of the heart
and kidneys, of inflammation of the joints
of the upper and lower limbs, and upon
accidents; it revealed that 53 per cent.
of members who replied to the question-
naire suffered from one or more of these
conditions which had caused a loss of
1,447 working days by 100 members during
the year 1921. The average age of mem-
bers was 42 years. Only cases of disease
recognised by a medical man have been
included in the statistics.

The most characteristic feature reported
on the subject of lead poisoning is its
considerable incidence during the first
decades, from ages 20 to 39. From ages
40 to 70 the disease seems to be stationary,
rendering, on an average, 17 per cent. of
members incapable of work. Although
the report does not give the reasons for
no greater increase among the old work-
men, it must be supposed that over 90
per cent. of the cases of sickness registered under general
terms and not requiring medical treat-
ment are nevertheless due directly or in-
directly to lead poisoning which may or
may not have been discovered by a meticulous
medical examination.

Six per cent. of members affected with
lead poisoning suffered at the same time
from diseases of the heart. As many
cases of heart disease may advance for
years without causing much suffering,
information given by individual members
cannot be relied on. In consequence the
report of the District Council takes into
account only those cases of heart disease
which prevent the patient from following
his usual occupation.

Under the heading "Diseases of the
kidneys" are entered non-specific cases
including acute and chronic nephritis.
Their incidence commences with 9 per
cent. between ages 20 and 29 and rises up
to 22 per cent. in the 60th year.

These figures show that most of the
workers affected by these diseases are in
the most active period of their lives, that
is, between 40 and 50 years.

The report presents the incidence of
these three industrial diseases (lead pois-
oning, diseases of the heart, and kidneys)
as follows: from ages 20 to 29 inclusive,
18 per cent.; from 30 to 39, 23; from 40
to 49, 34; from 50 to 59, 36; from 60 to 69,
51. It is only recently that inflammation
of the knee joint has been recognised as
an industrial disease of painters and infor-
mation on this subject is lacking.

Whereas the official report of the local
association (No. 194) for the years 1910-1920
enumerated 43 cases of inflammation of the
knee joint, elbow and shoulder with an
average duration of 47 days, the report
for 1921 based upon the information of
individuals contains figures which are
much higher; thus, 11 per cent. of cases of
inflammation of knee joint and 30 per cent.
for inflammation of the elbow and
shoulder. The last form of this affection
is the most common.

A report of the Association of Painters
of New York published in 1923 drew atten-
tion to the fact that certain workmen, without showing characteristic symptoms, are affected with chronic, ill-defined troubles which do not immediately permit of definite diagnosis.

As regards the frequency of accidents, the report emphasises that the number of fatal accidents is 15 per cent, higher for painters than for masons and bricklayers. It is considered that the inhalation of fumes is such as to produce serious organic troubles of which the first symptoms are headaches and vertigo; this would explain the frequency of accidents among these workmen.

If causes of death taking place among painters and the general population are examined, the rate for lead poisoning, in its cerebral and nephritic forms, is found particularly high for painters, who show a rate of 19 per cent, for tuberculosis, whilst that disease shows 10 per cent. for carpenters and 7.2 per cent. for an average population of at least 20 years of age (1930).

According to an official table, out of 9 trades that of painting shows the lowest average age; it does not in reality exceed 48.6 years. The statistics of the Association of American Painters show an age still less (45 years). According to these figures, the average expectation of life of a New York painter does not exceed 46 years, whilst for the rest of the population it is 62 years.

Hayhurst, who examined 267 painters who had worked in the trade for at least 7 years, and in the majority of cases for more than 15 years, reported, following on three successive examinations, that 60.33 per cent. suffered from occupational diseases, 33 per cent. from non-occupational diseases and less than 7 per cent. were in a normal state of health, and that was in spite of the fact that the majority of painters were young or of middle age.

The cases of lead poisoning notified to the Department of Labor in the State of New York during the period 1912-1925 numbered 890 with 105 deaths, of which 375 with 67 deaths occurred in the painting industry.

In 1924 Dean, of New York, described an epidemic of lead poisoning among painters employed on coach work in a motor-car factory at Detroit; 67 workmen employed in dry rubbing down coats of lead paint were admitted to hospital. The enquiry held by the Public Health Service of Detroit showed that these cases were caused by the inhalation of lead dust; that a handkerchief applied in front of the mouth and nose during one working day alone contained 84 mg. of lead, and that the injurious effect of work in the said factory was only due to an inadequate system of dust extraction.

First grinding, and then mixing and applying paint to new surfaces, create a risk of poisoning, especially by direct contact. The toxic product is introduced either in the course of the work itself, or, more particularly, during meal-times if the hands and the nails have not been scrupulously cleaned. Splashes of lead paint scattered upon the clothing, the ground, or the tools, on becoming dry disintegrate to liberate a poisonous dust. But the entrance by the respiratory system of dust and small drops must also be placed in the forefront, as well as poisons liberated as fumes, when cleaning by burning, or from diluents and the like.

The repairing of damaged surfaces not only entails the dangers of the preceding operations, when new coats of paint are applied, but the injurious nature of the preliminary cleaning process must not be forgotten. Whether through rubbing down with water or scraping the surface with metal and wooden instruments while dry, the old paint which is removed impregnates the hands of the workman and, by inhalation in the form of dry dust, may enter directly into the digestive organs or lungs.

As regards the causes of poisoning and the nature of attacks, they vary according to the nature of the substance used.

These are first and foremost pigments and compounds of lead, such as white lead, minium, and litharge, with the possibility of all the acute and chronic manifestations of lead poisoning. (See article "Lead Poisoning").

It is necessary to emphasise the grave danger involved in spray-painting when the paint used contains toxic pigments. In a German automobile factory, there occurred between 1921 and 1924 an actual epidemic of lead poisoning brought about by dry rubbing down of layers of paint applied by spray.

Of the 86 cases reported 72 affected workers engaged in dry rubbing-down, 4 of whom suffered from an encephalopathic form. Twenty-six workers had been working for a month at least, 7 for 9 weeks, and 1 for 3 days. In a handkerchief held in front of the mouth 84 mg. of lead were found.

Some other poisonous metals such as arsenic, mercury, copper, etc., are used, particularly in the composition of special products to prevent fouling; volatile substances, such as turpentine, benzine, methyl alcohol, white spirits, banana spirit, benzol and xylol, are used in the preparation of paints.
Poisoning, often of a complex nature, results, in which it is difficult to determine exactly the toxic agent or agents absorbed or inhaled.

According to Goadby, these different diluents and solvents are all dangerous and their use constitutes a very serious danger for painters.

In 1921 some English writers supported the hypothesis that among painters exposed simultaneously to lead salts and spirit of turpentine, it is not the lead but the spirit of turpentine which is the principal cause of certain conditions of ill-health, generally considered due to lead; particularly cardio-renal conditions nephritis and hyper-arterial tension.

It is not the first time, however, that this opinion has been put forward. It is of practical and fundamental importance. If it was correct it would seem useless to insist on white lead being replaced by harmless products, and the intention of laws made with this object would not be justified.

An enquiry by Heim, Agasse-Lafont and Feil, made with the object of casting light upon this problem, has established the fact that spirit of turpentine can certainly exert a toxic action on the organs; it is capable of causing complications in the kidneys (nephritis) or of the blood vessels (hyper-arterial tension). (See article "Turpentine").

But is this the case where spirit of turpentine is not absorbed but inhaled in small quantities? Can a chronic poisoning exist among painters which in the long run can cause nephritis or hypertension?

Spirit of turpentine is never employed alone in the preparation of colours; it is always mixed with oil in larger or smaller quantity, for colours prepared with spirit without the addition of oil would result in defective paint, as brittle as if the paint had been prepared only with water. When paint with a glossy surface is desired, much oil and very little spirit is used; when on the other hand paint with a flat or dull surface is desired, more spirit than oil is used. Glossy paints are generally divided into very thick ones (all oil, no spirit) and thick ones (half oil, half spirit); the first are used principally upon walls and exteriors; the other for kitchens and staircases.

Flat surface paint, also called sign-writing paint, contains two-thirds spirit and one-third oil; as it produces a handsome effect, it is reserved for reception rooms, halls and dining rooms.

Further, spirit, which is not so expensive as oil, is often used in bigger proportions than it should be, with a view to economy; but it is at the expense of the durability of the paint. These considerations apply as well to zinc white paint as to white lead paint, both of which include practically the same quantity of spirit of turpentine.

At this point it should be noted that oil mixed with spirit of turpentine materially prevents evaporation of the spirit, and, in consequence, danger which might result from its inhalation.

Now, the enquiry made upon 35 workmen who handled either spirit of turpentine alone or with white lead, as well as his previous enquiries, enabled Agasse-Lafont to come to the following conclusion:

Among working painters, though the inhalation of spirits of turpentine may exert an injurious effect upon the cardio-renal system, such effect will be in every case negligible in comparison with that caused by such salts of lead as white lead which should entirely, or at the least to a great extent, be held responsible for originating disease.

This opinion is supported by figures furnished by Dr. Stevenson, of the English Registrar-General’s Department, to the Commission of Enquiry Into Industrial Painting. According to this expert, mortality statistics do not confirm the hypothesis according to which turpentine is the cause of a great part of the excess of cases of nephritis among painters. He did not find in the reports relating to the last ten years any certificate attributing death to poisoning by turpentine.

Investigations made among workmen in contact with turpentine may also be quoted; they do not establish the existence of any special occupational pathology, nor of any of the symptoms peculiar to lead poisoning, e.g. colic, nephritis, paralysis, and the like. The same conclusion has been arrived at experimentally by Francioni (1924) who was able to show that poisoning by lead and by turpentine are absolutely different, particularly with regard to blood changes.

Injuries due to the inhalation of diluents and volatile solvents used in cellulose paints are referred to in the articles "Solvents", "Toluene", etc. Workmen who are employed in places of small dimensions and who, either on account of the actual work, or in order to obtain more rapid drying, have very often to use defective means of lighting and heating, are exposed to carbonic oxide poisoning. In the same way the repainting of double
bottnoms of ships necessitates a preliminary cleaning which entails a complete clearance, in the course of which deaths may occur from carbon or sulphur dioxide gases.

The occurrence of lesions, mostly produced mechanically, on the skin, mucous membrane and lungs should also be noticed.

So far as the skin is concerned, the lesions are due to the corrosive action of certain substances used before preparation work, especially for the prevention of fouling on ships, or for cleaning down with acids, soda, or caustic potash, or alcohol, or for cleaning machinery with benzene or petrol prior to painting; from these causes arise cracks on the ends of the fingers and changes in the nails.

The mucous membranes of the conjunctiva, larynx and bronchi are affected by the fumes set free by certain substances, especially when they are used hot, such as pitch, tar, varnish and bitumastic, which last is a patented material with a base of pitch and bitumen, possessing a strong odour of creosote and causing attacks of coughing.

The lungs may also become infiltrated with inert particles, the accumulation of which sometimes produces serious effects, resulting in pneumoconioses which may simulate tuberculosis clinically and radiologically. One form of pneumoconiosis is seen particularly among workmen who clean sheets of iron with the sand blast.

Two cases of poisoning by tetraline were reported in 1922 at Vienna by Arnstein. They were two painters who were working in a confined air space with bad ventilation, and showed irritation of the mucous membranes, marked lacrimation and headache. The urine was coloured green. The poisoning developed quite rapidly; albuminuria was reported as a sequela.

Goldmann (1930) met with a case of acute retrobulbar neuritis, due to using cellulose paint applied by spraying.

According to the reports of German factory inspectors, paint for boilers, containing as a solvent a homologue of benzene, caused nervous troubles of the hearing. Another containing an aromatic derivative (1931) known under the name of “Interol” caused cases of poisoning. Nitro-triphenyl methane, according to Sachs (1911), which had been used by a painter for nine months, caused tumours similar to papillomata, which occurred on the face and forearms.

Finally, in 1907, Gelly, of Nancy, who has studied the stigmata of decorative painters, said that he did not find the right thumb flattened as described by Tardieu, but had; on the contrary, found in seven workmen a callosity on the radial side of the right middle finger and another smaller one situated on the ulnar side of the right index finger. These callosities due to friction from the handle of the brush, held between the middle and index finger and kept in position by the opposition of the thumb, are said to be quite characteristic.

For the pathology of lead poisoning see article “Lead Poisoning”.

HYGIENE

As has been now seen, the principal danger to the painting industry is derived from the use of lead and its compounds. It is then the substitution of less harmful or inoffensive materials for lead which forms the first and most certain measure of prophylaxis.

In the naval departments of several countries, in particular France, a considerable move has been made in this direction by prohibiting the use of white lead, litharge and putty containing red lead and even of linseed oil fortified with litharge.

The French administration has also called for the suppression as far as possible of the use of red lead in paint, which should be reserved for exceptional cases where there is great and persistent dampness and maintenance work is very difficult, e.g. in holds and double bottoms, the lower parts of boilers, and propeller shafts. Particularly should the use of red-lead paint be given up for painting piping red; an artificial inoffensive vermilion should be used or some other special red, not containing lead, as for example the signal-red used for signalling on railways.

As regards house-painting, it is generally admitted that for white paints on interiors it is possible to do without lead. It seems that it is the same for the exterior. Zinc white paints, titan white, etc., can with advantage be substituted for white lead in the majority of cases.

In consequence of the necessity for allowing, on the one hand, the use of pigments containing a certain quantity of lead, as well as a small quantity of lead in the composition of dryers, and, on the other, the fact that it is desirable to allow the use of oxide of zinc made by the direct process, the English Departmental Committee on the Danger
of Lead Paints has considered the question of recommending a restriction upon the use of lead compounds by limiting the strength of soluble lead to a maximum of 5 per cent. In other countries similar conclusions have been adopted. Thus, for example, in France the Committee appointed to report upon the degree of purity of materials used in painting have recommended that materials which do not contain more than 3 per cent. should be considered as lead-free. In Belgium, the management of the State railways, where only leadless paints are used for all purposes, have fixed 4 per cent. as the limit. The Geneva Convention provides for a limit of only 2 per cent. of soluble lead (see later).

As regards coach-painting, it is above all fine carriage work which, on account of the great care taken and the long series of operations, gives rise to the greatest risks. The application of white lead for the first coats, called priming and preparation coats, and rubbing down, which should be done before the next coat is applied, constitute the two principal causes of poisoning to be avoided. Efforts are made to improve matters by replacing dry rubbing down with wet rubbing down carried out by means of pumice stone and water. But it must be said at once that from the technical point of view wet rubbing down is not accepted without reserve; for painting on wood, which does not stand moisture, dry rubbing down only may be recommended according to technical experts.

As for the suppression of white lead and other lead compounds, according to the English Committee’s report, the arguments in favour of a complete prohibition are more numerous than in the case of house-painting. There is reliable evidence that some important carriage building works do not use lead at all.

According to the New South Wales report quoted above, the Metropolitan Board of Water Supply, for example, has for two years (the date of the report is 1921) made great use of pigments with a zinc basis. The State railway workshops, where 400 painters are employed, use substitutes for white lead for the painting of the interior of railway carriages, and they even found a satisfactory substitute for painting the roofs of railway carriages. Cases of lead poisoning are very rare in these two concerns. In the tramway workshops at Randwick also very little lead paint is used. In the shipyards lead paint is used for the interior of ships, but only for the first coat of paint.

Other administrations have prohibited the use of white lead in carriage painting (as, for example, the Belgian and Italian State railways, etc.).

When lead compounds cannot be entirely abandoned, some temporary measures are useful to diminish much of the risk. As far as possible, contact by the workman with lead must be diminished, and the generation of dust containing lead must be avoided or the dust removed outside by localised exhaust draughts. Rubbing down with water has this in view, but its use is criticised as regards several kinds of work — upon wood and high-class work of the interior of houses — it has also the disadvantage of being more onerous and less rapid. There is also the further fact that the workman has his hands constantly smeared with a paste of white lead, exposing him to risk under another form, but perhaps as formidable. The inquiry of Heim, Agasse-Lafont and Feil has led them to the conclusion that men rubbing down with water exhibit, in a large proportion, the signs of lead poisoning.

The workmen should, in addition, be compelled to wear special overalls and to take them off as soon as they leave the workshop. Overcoats and outside clothes should naturally be kept in cupboards protected from dust. Washing accommodation, soap, nail brushes and towels must be provided for the workmen.

The workman must be warned of the danger. He must observe prophylactic measures for which his collaboration is necessary: no eating or smoking during work, thorough washing of the hands and mouth, cleansing of the moustaches and hair before meals and at the end of the day.

Periodical medical examinations are invaluable for detecting signs of lead poisoning. Reports of these signs, their degree and their aggravation, are salutary warnings which should cause timely and energetic action and so prevent serious developments. Blood examination in particular tends, from this viewpoint, to take more and more the place which is legitimately its due. The importance of systematic examination of the blood in the prophylaxis of lead poisoning has been repeatedly emphasised in France and Germany by doctors of the Health Insurance Offices and by experts. Nevertheless it must be confessed that to detect lead it is excellent in practice where work is carried on at a workshop or factory, insurmountable difficulties are met with as regards house-painting for reasons very easy to understand. It has had,
as a matter of fact, a complete setback in the countries which had adopted it — Germany and Belgium, for example.

Precautions of the same kind should be imposed for other poisonous substances which ought to be replaced as far as possible by less injurious or inoffensive products. The use of poisonous paints for spraying open surfaces should be forbidden unless the workman is protected in the most thorough manner. This method of painting small articles should only be done in a closed apparatus provided with an efficient exhaust draught.

Workmen exposed to poisonous fumes ought to use masks of known efficiency or work only under the protection of a current of fresh air, when painting, for example, in holds and cabins of ships.

A clinic reserved for members of the City of New York Painters’ Decorators’ and Upholsterers’ Brotherhood was opened in 1921. The painters are examined there medically once a year and can be looked after; and researches are pursued into means for combating industrial diseases among this class of workers. The clinic has been organised by the Health Service of the Painters’ and Allied Trades, a service instituted with the aid of the Workers’ Health Bureau, itself established in 1921.

It is interesting to note that under the auspices of the said Bureau an agreement for the protection of the health of painters — was signed in 1924 — between the Association of American Working Painters and that of the employers — the painters and decorators of New York. This agreement, which affects several thousand workers, lays down measures which concern the ventilation of places where painting work is carried on; and prohibits the use of paints containing benzol, lacquers dissolved in methyl alcohol, dry rubbing down, etc. It demands that the use of paints suspected of being dangerous may be regulated or prohibited after investigation by the Trade Board, and that receptacles containing poisonous substances be labelled.

The Health Service of Painters’ and Allied Trades of New York is certainly the first trade union institution organised for the purpose of preventing industrial diseases. The service was opened in July 1921, and the staff, under the direction of a medical man, includes a dentist, a nurse, a practical radiographer and a laboratory attendant. There is a radiographer’s department and a physiological laboratory, and the service has the advantage of the co-operation of eminent specialists in occupational pathology.

Among the agreements signed by the Industrial Diseases Clinic of Milan with the workmen’s associations is one which concerns painters and which has been included in the contract of work.

**Legislation**

For some time past, under the stimulus of the International Association for Labour Legislation, the protection of painters has been envisaged by certain States and certain local authorities who had already prohibited, for example, the use of white lead in the painting of public buildings. Regulation of the use of lead paints is intimately allied to regulation of the poisonous substance concerned (see articles “White Lead”, “Red Lead”, etc.) by measures controlling their sale, use, grinding in oil, and sale in receptacles with special labels.

Measures for the prevention of lead poisoning have been laid down in the form of a general ordinance in France (Ministerial Decree, 1 October 1913, in Great Britain (Factory and Workshops Act, 1901, Part I (i), section 1 (1, d)), and in Switzerland: in the United States in factory legislation where measures are laid down against dust and fumes (Iliinois, Act of 1911 amended in 1921; Missouri, Act of 1913; New Jersey, Regulations for the Lead Industries, 1914, Ohio, Act of October 1913; and Pennsylvania, Act of July 1913, for the prevention of lead poisoning). Measures for individual hygiene are provided by the United States (in the Acts of the States concerning work, lavatories, etc.); France (Ministerial Decree, October 1913); Great Britain (Women and Young Persons Act, 1900); British Columbia (Alberta: 1917, sections 28-31; British Columbia: 1911, section 12; Manitoba: 1913, section 132; Nova Scotia: 1901, section 16; Ontario: 1915, sections 39, 43; Quebec: 1909, Nos. 94, 104, etc.).

The First Session of the International Labour Conference (Washington, 1919) adopted a Recommendation on the protection of women and young persons against lead poisoning (see the article “White Lead”) and the Third Session adopted a Convention (see below). Legislation in accord with the Convention has already been passed by several countries.

Periodical medical examination is provided for by German legislation (half-yearly examination for painters and persons occupied in the colour and varnish industry) and by the Acts of monthly where more than 20 workmen are employed).

In Belgium the examination has fallen out of use since 1914 and has not been revived.

Legislation special to painters is in force in Germany: Order of 27 June 1905 regulating painting work of every kind in
workshops, shipyards or any undertaking. This Order prohibits direct handling of lead pigments in the dry state unless done in such a way that the workmen are protected from dust. It prohibits grinding and mixing these materials by hand; it prohibits scraping and dry rubbing down. It calls for compulsory wearing of overalls and head coverings during work; and for the provision by employers of all washing facilities for the workers. It makes it obligatory to instruct workmen as to the dangers of poisoning and as to the general precautions to be taken. It forbids eating and the consumption of alcoholic drinks in workplaces. It makes it obligatory to instruct workmen whose duty it is to spray paint containing white lead on the outside of buildings, and for those who are employed upon scaffolding and do occasional work.

In Austria the Decree of 15 April 1908 prohibits the use of lead paints for work on interiors and makes strict regulations of health records compulsory.

In Belgium an Act concerning the use of white lead and other white pigments of lead conforming to the scheme of the Geneva Convention, was passed in 1923. (See article "White Lead ").

In France the Act of 20 July 1909 only prohibits the use of white lead and linseed oil containing lead; it does not refer to other compounds of lead. The arrangements apply only to employees; the small employers working with their own hands can still use the injurious materials. Supervision becomes particularly difficult when a master, while working himself, employs workmen at the same time. Though the use of white lead is prohibited for house-painting, it nevertheless remains legal to use it for painting coaches, boats and ships.

Several countries which have not so far ratified the 1921 Convention have adopted measures of protection for painters: Germany (Order of 1930, Great Britain (Act of 1926), Switzerland (Federal Orders, 1928), etc. As regards spray-painting, certain legislative measures have been issued in the line of the Draft Convention of 1921 in: Czecho-Slovakia, Finland, France, Norway, Rumania, Spain and Sweden. Other countries have issued measures by special legislation: Germany (1930), Western Australia (1928), Belgium (1929), Great Britain (1926-1927), Northern Ireland (1928), Switzerland (1928), U.S.S.R. (1930) and several States of the United States of America.

In Yugoslavia the Act of 25 October 1921 provides for the prevention of lead poisoning by prohibiting manipulation of materials with a white lead basis with the bare hand, and dry scraping and rubbing down. In Czecho-Slovakia Regulations for painting work, decoration, etc., date from 12 June 1924.

On 5 August 1924, following a lawsuit brought by the Union of Painters and Decorators, a verdict was given by the Arbitration Court of Perth (Western Australia) which not only coincides with the scheme of the Geneva Convention (1921), but upon some points goes still farther. In fact, the verdict definitely fixes the maximum length of the working day and the number of hours per week, the tables of minimum rates of wages, compels the employer to allow the workmen five minutes for washing their hands before meals and before the end of work, and to supply the necessary soap and hot water. The grinding of white lead paints is prohibited inside buildings, and also dry rubbing down and scraping of lead paint, from three months after the date on which the verdict was given. An increase of wages is provided for workmen whose duty it is to spray paint containing white lead on the outside of buildings, and for those who are employed upon scaffolding and do occasional work.

The first Safety Code of the Association of Standards in Australia (Code for the Use of Paints, 1929) dealt with the prohibition of workers handling paints containing more than 5 per cent. of lead expressed in terms of metallic lead. It refers to decorative and commercial painting and painting in coach works and painting of vessels either with the brush or by spraying. The Code recommends the use of colours in the form of paste, or for applying the brush, labelling of receptacles, measures of personal cleanliness (working clothes, washing accommodation, etc., notification of cases of lead poisoning, cleanliness of tools, measures concerning the use of solvents (benzols, methyl alcohol, carbon bisulphide, etc.), exclusion of lead paints when the paint is applied by spray and indoors. Precautions in dry rubbing down, localised ventilation in spray painting of small objects, and the use of leadless paints in ship-building (interior work).

In U.S.S.R. the Commissariat of Labour has by Decree prohibited the preparation, sale, and use of white lead (18 January 1925). The Decree prohibits the erection of new white lead works, the exportation of this product abroad, and the registration of factories actually working. From 1 July 1925, the sale of white lead is prohibited in the dry state and only allowed if ground in the form of paste. From 1 January 1928 the use of white lead for the painting of the interior of houses was declared illegal, and from 1 January 1930 the sale, preparation and use of white lead in any form whatsoever was prohibited.

The International Labour Conference at its Third Session held at Geneva in October-November 1921 unanimously adopted the following Convention.

**Article 1**

Each Member of the International Labour Organisation ratifying the present Convention undertakes to prohibit, with the exceptions provided for in Article 2, the use of white lead and white lead pigments, of all products containing these pigments, in the internal painting of buildings, except where the use of white
lead or sulphate of lead or products containing these pigments is considered necessary for railway stations or industrial establishments by the competent authority, after consultation with the employers' and workers' organisations concerned.

It shall nevertheless be permissible to use white pigments containing a maximum of 2 per cent. of lead expressed in terms of metallic lead.

Article 2
The provisions of Article 1 shall not apply to artistic painting or fine lining.

The Governments shall define the limits of such forms of painting, and shall regulate the use of white lead, sulphate of lead, and all products containing these pigments, for these purposes in conformity with the provisions of Articles 5, 6 and 7 of the present Convention.

Article 3
The employment of males under eighteen years of age and of all females shall be prohibited in any painting work of an industrial character involving the use of white lead or sulphate of lead or other products containing these pigments.

The competent authorities shall have power, after consulting the employers' and workers' organisations concerned, to permit the employment of painters' apprentices in the work prohibited by the preceding paragraph, with a view to their education in their trade.

Article 4
The prohibitions prescribed in Articles 1 and 3 shall come into force six years from the date of the closure of the Third Session of the International Labour Conference.

Article 5
Each Member of the International Labour Organisation ratifying the present Convention undertakes to regulate the use of white lead, sulphate of lead and of all products containing these pigments, in operations for which their use is not prohibited, on the following principles:

I. (a) White lead, sulphate of lead, or products containing these pigments shall not be used in painting operations except in the form of paste or of paint ready for use.

(b) Measures shall be taken in order to prevent danger arising from the application of paint in the form of spray.

(c) Measures shall be taken, wherever practicable, to prevent danger arising from dust caused by dry rubbing down and scraping.

II. (a) Adequate facilities shall be provided to enable working painters to wash during and on cessation of work.

(b) Overalls shall be worn by working painters during the whole of the working period.

(c) Suitable arrangements shall be made to prevent clothing put off during working hours being soiled by painting material.

III. (a) Cases of lead poisoning and of suspected lead poisoning shall be notified, and shall be subsequently verified by a medical man appointed by the competent authority.

(b) The competent authority may require, when necessary, a medical examination of workers.

IV. Instructions with regard to the special hygienic precautions to be taken in the painting trade shall be distributed to working painters.

Article 6
The competent authority shall take such steps as it considers necessary to ensure the observance of the regulations prescribed by virtue of the foregoing Articles, after consultation with the employers' and workers' organisations concerned.

Article 7
Statistics with regard to lead poisoning among working painters shall be obtained:

(a) As to morbidity — by notification and certification of all cases of lead poisoning.

(b) As to mortality — by a method approved by the official statistical authority in each country.

By 1 January 1934 the Convention concerning the use of white lead in painting has been ratified by the following States: Austria, Belgium, Bulgaria, Chile, Colombia, Cuba, Czechoslovakia, Estonia, Finland, France, Greece, Latvia, Luxembourg, Norway, Poland, Rumania, Spain, Sweden, Uruguay, Venezuela, Yugoslavia. Ratification has been approved by the competent national authority in Italy and the Netherlands and recommended for approval in Argentina.

BIBLIOGRAPHY
Craen, H. "Quelques notes sur la peinture des carènes, superstructures et
Paper Mills

Paper consists essentially of a thin felted web, tissue or fabric resulting from the interlacing of vegetable fibres, the principal constituent of which is cellulose. The determining feature of a good quality resides in the distinctly fibrous structure of the raw material. This structure determines the nature and variety of the operations to which the various vegetable fibres are subjected.

In the earlier stages of the paper-making industry production was effected either by mechanical treatment of fibrous leaves or by chemical treatment of linen rags, cotton, flax and straw fibres, esparto and other cellulose parts of plants. It was not until the middle of the nineteenth century, however, that a suitable raw material was obtained from wood for the industrial manufacture of paper on a large scale, rags being exclusively retained for the preparation of special types of paper (paper of superior quality).

TECHNICAL DATA

A. — Raw Materials

Rags (see that article) of flax, cotton, etc., are opened out when they arrive in bales, freed from dust by heating, sorted and graded according to the nature of the material, the fibre and the colour, shredded either by hand, or in a special machine known as a "willow", and sometimes cleaned mechanically in a drum washer which may be combined with the breaking machine.

Waste material (scraps and ends from clothing establishments), together with pieces of linen, rope or string, etc., are included in this type of raw material.

Subsequent to cleansing with quick-lime, caustic soda, carbonate of soda or a mixture of that with lime in boiler, the water is allowed to drain off and the rags are passed on to breaking machines, in which bleaching by chloride of lime may also be effected. Impurities and soluble substances are carried off by water, and there is obtained at this stage the "half stuff".

Various types of straw — wheat, oats, barley, and especially rye — are first of all cut up in a grinding machine and then freed by a current of air from any dust and impurities they may contain. They are subsequently cleansed by boiling under high pressure and at a high temperature. The straw pulp or paste obtained is

Dr. Agasse-Lafont
(Paris.)
washed, drained and passed on to the process of bleaching. Straw requires a large amount of caustic soda for cleansing. Esparto (alfa) straw is submitted to the same treatment as other kinds of straw; being less ligneous it requires less energetic treatment. After opening of the bales it is subjected, passed through a lye solution, washed in water or steam, drained and sent to the breaking machines. The "half stuff" obtained is then sent to be bleached.

Old paper is submitted to operations of sorting, breaking, boiling and washing.

Wood is at present the most important raw material for the paper industry. It is transformed into wood pulp or "half stuff" by three different processes: mechanical process, chemical processes, and steam process.

(a) The mechanical process gives a mechanical pulp used for paper of ordinary quality, and especially for newspaper. The wood is cut into well-barked logs which are freed from knots and are about 30-50 cm. in length. These are disintegrated in a revolving grinding mill which liberates the fibres. These fibres are then carried away by a current of water towards cylindrical machines which effect further grading and they are thereafter directed to a bolting machine. If the wood pulp is for immediate use it is drained; if for export, it is put through a press and centrifugal dryer.

(b) The chemical processes employed comprise treatment with caustic soda, treatment with sulphate and treatment with bisulphite. In the first process the wood, after being cut into small round pieces or shavings, is subjected after boiling to high pressure in a pulp digester. A caustic soda lye is introduced and brought to a high temperature. The pulp is washed in stacks or in a washing machine. The lye is recuperated and concentrated, and about 70 per cent. of the caustic soda used is recovered. The sulphate treatment is a variant of the caustic soda treatment, sodium sulphate being added to the regenerated soda instead of the more costly carbonate.

This method produces organic sulphurated compounds which render its application almost impossible in inhabited centres. There should also be noted the importance of the processes for recuperation of by-products derived from the pulp (resin, turpentine, etc.). The bisulphite treatment utilises a solution of bisulphite of lime or magnesia. There is also used a solution of sulphur dioxide and of sulphite of lime. Sulphur dioxide obtained by treating sulphur pyrites in special furnaces is cooled, led into receptacles containing the calcarious material and brought into contact with a water spray which enriches the sulphur dioxide and bisulphite of lime. The wood undergoes a series of more complicated operations than those necessary in the treatment by caustic soda. The by-products contain ethyl and methyl alcohol, turpentine, tannic substances, lignosol, etc.

(c) The steam process which gives a semi-chemical pulp consists in treating the wood with steam at high pressure. The "half stuff", of a brownish colour, is chiefly used in the manufacture of brown wrapping paper. During the manufacture of paper a certain amount of waste is obtained ("broke") which, together with rejected paper and paper slightly soiled by use, etc., is re-utilised in the manufacture of new paper. The "half stuff" obtained is of a mediocre quality.

B. — Manufacture of the Pulp

This comprises bleaching, refining, and the addition of loading, sizing and colouring materials.

Bleaching, the object of which is to free the fibres from all non-cellulose components, may be effected in accordance with three different processes: bleaching by chloride of lime, bleaching by chlorine fumes and electro-chemical bleaching.

The chloride of lime process is sometimes effected in a breaker taking the form of a stack, or more often in a special type of stack known as a bleacher.

The chloride of lime is diluted with a volume of water sufficient to permit of effective mixing of the mass. Washing and draining follow. Chlorine fumes are obtained by causing hydrochloric acid to act on manganese peroxide. This is a violent bleaching process which demands more manipulation than the above chloride of lime process.

In electrolytic bleaching a solution of alkaline chlorides (sodium, magnesium) is decomposed by means of an electric current.

Beating, which constitutes a process of refining, has for its object to impart to the pulp as it leaves the bleaching stacks a certain homogeneity of texture. This operation is effected in special stacks.
The addition of loading materials (clay, calcium sulphate, "pearl hardening," kaolin or china clay, casein, rosin, gelatine, talc, ochre, etc.) is usual in the manufacture of all kinds of paper except for very superior qualities.

Sizing, the object of which is to prevent the paper from absorbing ink, is effected by the use of rosin soap (added to the beater before the pulp goes on the wire and known as "engine-sizing") fixed by means of alum or aluminium sulphate. Sometimes felcia, starch or gelatine is used. Gelatine-alum sizing is required for hand-made papers ("animal" or "tub-sizing"). Sizing is applied in a different manner according as to whether the paper in question is intended eventually for printing or for writing.

Colouring of the pulp may be effected by aniline colouring agents or mineral substances. Smalls", finely powdered glass, coloured with cobalt blue, are used for hand-made papers. Ochre colouring agents are used to a certain extent and constitute at the same time loading materials. Chrome yellow, ultramarine blue, Prussian blue and indanthrene blue (for high-grade papers), and for newspaper methyl and ethyl violets, blues, greens and reds, are also used.

C. — Manufacture of Paper

The "half-stuff" prepared in paper factories or bought from the pulp factories serves in the manufacture of hand-made (very little practised) and machine-made paper.

Mechanical manufacture of paper comprises a long series of operations, which may be briefly enumerated as follows: mixing and stirring of the pulp slurry in mixing vats and "stuff chests". The pulp is fed in a continual stream, by means of regulating drums, into a continuous machine and is led by means of special piping to sand tables or a sand trap which retains impurities, and thereafter to purifying filters or strainers which remove knots, lumps, etc. It is then transported to the "breast box" and thence to an endless wire cloth made of brass wire mesh, which covers the manufacturing bench, the first portion in which the pulp slurry is transformed into a wet web being designated the "wet end" and the drying and finishing portion the "dry end". Exhaust hoods arranged under this bench remove the greater part of the water from the pulp. The sheet of paper thus commences its formation. It is afterwards pressed between two cylinders covered with felt, for the purpose of rendering the fibres still more dry. It then passes over an endless belt of felt, which transports it successively to cylinders of the first press and, finally, to the second press.

The sheet of paper thus formed is then led to drying cylinders varying in number and steam heated, usually separated by "din rolls" or smoothing — in order to flatten the paper before quite dry — which completes the operation of drying. Both sides of the paper are made thin and smooth by passing through calenders. Better-class types of highly glazed papers undergo additional treatment in super-calenders consisting of a stack of rolls alternately of heated cast-iron and compressed cotton or paper. The sheet is thereafter rolled in the form of a reel.

The successive operations comprise glazing, cutting (lengthwise or in reams), inspecting and packing.

Hand-made paper is used for special purposes such as banknotes, Government stamp-paper and high-grade paper. For this purpose the pulp prepared from unbleached rags is run into "stuff chests" and thence into vats and, after maintaining, is made on a wire cloth mould surrounded by a movable frame or "deckel", which is dipped into the vat. It is then shaken to cause felting. The "deckel" is removed and the mould is inverted on to and pressed against a felt, being transferred, or "couched" from the wire to the felt.

The sheet of paper is then covered with a piece of felt of the same dimensions and inserted into the stack, and the stack of sheets and felts passes into a press with the object of removing the excess water. The felts are thereafter removed and the sheets of paper pressed between plates in order to remove the marks left by the felts. Sizing is effected by passing the sheets through a tub of hot solution of gelatine or vegetable glue, or "hand sizing", or through a gelatine solution containing a large percentage of alum. The operations of dressing, drying and glazing, and stretching of the sheets one by one follow.

Mention may here be made of the manufacture of cardboard on a huge continuous machine, the making of cardboard and paper, and the varieties of manufacture of special kinds of paper. Amongst these reference should be made to parchment paper (unpashed paper attacked by sulphuric acid), waterproof papers (impregnated or coated by coal-tar pro-
ducts, pitch, resin, paraffin or vegetable or mineral oils), cardboards treated with bitumen obtained by plunging the cardboard into a vat containingitur heated to a certain temperature (one layer being covered with sand), glass paper, emery paper, flint paper (obtained mechanically), glazed and coloured papers (by application of colouring agents and talc), gilded and marbled papers (treated in vats or by machinery), wallpapers (preparation of colouring materials, printing or designed by machinery), gilded papers, velvet papers with design in relief, washable papers, etc., playing cards.

It should, in conclusion, be remembered that the paper industry consumes chemical products and mineral and organic materials in ever-increasing quantities (referred to above), as well as large quantities of water. The latter ought to be of guaranteed purity, free from mineral or organic matter in suspension, and free from certain salts, notably salts of iron.

**Sources of Risk**

Brief reference may be made to the risk of accident, which is naturally dependent to a great extent on the industrial methods followed. According to Lorange, the annual number of absences due to accidents was in Norway, during the period 1922-1927, 17 in the grinding shops, 12 in the pulp factories, and 15 in the wood-pulp factories.

Certain categories of workers are more exposed to risk of accident than others — for instance, workers engaged in removing bark by machinery, in sawing or in cutting of the wood, or in shredding in a grinding mill for obtaining mechanical pulp, which involves exposure to burns or splashings of the hot pulp. The risk is great in the older types of workshop, where barking of the wood and cutting of the pulp are done by hand.

The great source of risk in the manufacture of wood pulp and in that of paper is humidity. Often the flooring is wet and slippery, especially in those factories which follow the sulphate process, with the result that accidents due to falls are not uncommon.

A hot and humid atmosphere is typical also of the drying rooms and of the workrooms for the pressing and drying of the pulp and for the manufacture of paper. According to Pedley, it is necessary to evaporate 2 tons of water in order to make a pound of paper, with the result that machines delivering 80 to 90 tons of paper per day evaporate 7 to 8 tons of water per hour.

High temperatures are met again in boiling and washing rooms and in workrooms for the manufacture of paper by continuous machinery where operations of recuperation are carried out (sulphate and soda processes)

Obviously, during winter the presence of steam often renders the atmosphere disagreeable and hinders the work.

An enquiry effected in 1926-1927 by Atterbom in regard to the state of the atmosphere in thirty-two Swedish pulp factories gave relatively unfavourable results. It must, however, be stated that improved ventilation installed in many factories in the course of the last three years has succeeded in rendering the atmospheric conditions almost satisfactory.

The products used (alkalis), as well as those liberated in the course of the various operations in the chemical pulp industry, constitute the source of various health risks.

In the sulphate process, for instance, there is the formation of mercaptans, sulphuretted hydrogen and methyl sulphide fumes, which, however, can easily be captured and evacuated by modern technical methods. On the other hand, fumes charged with nauseous gases which are emitted from the autoclaves are more difficult to eliminate in a satisfactory manner. These gases, however, should not be considered as dangerous, nor even as presenting great inconvenience for the workers. The recuperation of sodium sulphate and caustic soda from the boiling liquid liberates large quantities of nauseous fumes (mercaptans), which, however, only constitute very slight inconvenience in modern factories with adequate hygienic plant.

Filtering and drying of the pulp and cleaning of drying machines expose the workers, especially in winter, to damp and to chills in older factories or where the workrooms utilised for these processes are underground.

Clouds of steam liberated from continuous machinery at the moment at which the leaves of paper, still damp, pass through the first drying cylinder constitute not only an important source of risk for the health, but also a hindrance from the technical point of view (interfering with the conservation of metallic structure, condensation of drops of water on the reels in course of formation, etc.).

The typical risk connected with the sulphite process is due to the presence
of sulphur dioxide in the dust raised by the pyrites and sulphur and other sulphurous substances employed in the preparation of sulphur dioxide. These unfavourable elements may be reduced to a minimum by adopting the system of closed transporting machinery, air-right piping, and adequate mechanical plant.

The preparation of chloride of lime used for bleaching the pulp exposes workers to the liberation of dust and fumes of chlorine gas.

Another form of risk is represented by the great heat given off from the sulphur dioxide furnaces when there is no automatic system for charging these.

In the course of the last thirty or forty years, during which the manufacture of wood pulp has developed into an extensive industry, sanitary improvements have succeeded in attenuating or eliminating the majority of health risks experienced by the workers. Yet there remain as potential sources of risk certain inherent factors connected, for instance, with gas escapes, ruptures of pipes or furnaces containing sulphur dioxide, or, again, connected with the large quantities of toxic gas capable of invading the whole factory in case of accident.

Where a factory utilises rags, steps must be taken to prevent the danger of infection proceeding from the dust raised during manipulation or storage of these. In an enquiry covering eighty establishments, the Massachusetts Board of Health ascertained the fact that where clean rags are used, little dust is involved by their manipulation, but that the rags generally used liberate much dust, whatever kind of plant or systems of ventilation are applied (Kober).

Sorting of old papers is equally a dusty and very unhealthy operation (Bailly).

Certain types of dust (alum, resins) and notably those liable to contain lead or resin might — especially in former times, since they are at present prohibited in most countries — likewise represent a source of risk.

Chmaladze (1925) referred, in addition, to the following harmful factors: fatigue of the senses of touch and of sight and overstrain of the capacity for attention, tension and uniformity of muscular movements and of the movements of the upper limbs.

Attention should finally be made of causes of inconvenience affecting the neighbourhood. Pulp factories may liberate disagreeable and nauseous odours which invade the atmosphere for miles around, and which are due principally to mercaptans. Diluted as they are, these gases cannot in practice produce toxic effects, yet their nauseous odour may seriously affect the comfort and welfare of inhabitants in the neighbourhood. It would, however, appear that many people become rapidly accustomed to them and are not further affected by them.

**Statistics**

Statistics relative to health conditions of workers engaged in the wood pulp and paper industries are not numerous.

In Sweden a detailed enquiry effected in 1913-1914 at the instigation of the Minister of Labour dealt with the health of the staffs of thirty-seven out of eighty-four of the wood-pulp factories then existing in the country. On the basis of notifications lodged by twenty-seven factory doctors, it was ascertained that the state of health of the workers in wood pulp factories and of those inhabiting the neighbourhood of these factories was not worse than that of workers in other industries (sawmills, for instance) or that of workers inhabiting neighbouring regions or of agricultural workers.

Medical examination of 239 workers employed in the pulp factories engaged in the bisulphite or sulphate process only revealed 3 cases of latent pulmonary tuberculosis, 20 of bronchitis, 6 of kidney troubles, and 31 of rheumatism.

In accordance with information which Würzen was able to collect in 1930 from forty-one factory doctors engaged in wood-pulp and paper factories, the state of health of the workers engaged in this industry is not in any respect worse than that of the remainder of the population. Certain doctors even expressed the opinion that, as regards tuberculosis, the workers in this industry were in a more favourable position than the other inhabitants in the region.

In a factory known as one of the oldest in the world, there were found workers enjoying excellent health.

In Germany, according to the statistics of the Leipzig Sickness Fund (1910) workers in paper factories in the age-group 15-34 showed 67.9 cases from all diseases per hundred workers employed as against an average of 36.6 for all occupations, and 77.7 for the age-group 35-54 as against an average for all occupations of 44.4. Respiratory diseases, including tuberculosis, showed relative figures of 10.2 and 12.5 for the two age-groups in question, as

---

1 According to Fischer and Penzoldt, mercaptan liberates a very strong odour with a dilution of 1/115,000 mg. per litre of air, and its sickening odour is said to be even distinct at a concentration of 1/23,000,000 mg. per litre of air (Lit.: Ann. de Chimie, 1887, p. 131).
contrasted with an average of 5.6 and 7.6; diseases of the muscles and joints 7.4 and 11.2, against 2.8 and 6.3; and accidents 22.1 and 25.4, as against averages of 9 and 9.7.

Similarly, data with regard to the mortality of workers in paper factories are neither abundant nor typical. According to the Report of the Registrar-General for England and Wales for 1921, for example, the manufacture of paper is stated to be a healthy industry, since the workers engaged in it show a comparative mortality figure of 761 (standard figure, 1,000) and a mortality rate at all ages upwards of twenty-five which is inferior to the average.

PATHOLOGY

The occupational pathology is essentially dependent on the nature and manipulation of the alkaline liquids, which cause these lesions. The lesions in question are naturally more serious in the case of the use of hot lyes.

In summer, when there is profuse perspiration, these products set up dryness and irritation of the skin, and it is then advisable to institute short working shifts where mechanical processes have not been installed.

Robertson refers to the possibility of chlorine acne affecting bleachers of wood pulp.

The colouring agents utilised may give rise to types of dermatitis, but the quantities used are small, and the number of workers who handle them is likewise very limited.

Fig. 52. — System of ventilation adopted in a paper factory. Elevation and cross section.

methods of production of the pulp. The manufacture of paper is not very trying work, and may even be engaged in by workers of weak constitution (Beiniker).

Contact with the numerous chemical products, and particularly the alcalis utilised during the preparation of the pulp, its bleaching, etc., is, of course, liable to cause dermatitis and lesions of the mucous membrane and nails. It is in particular such products as quicklime, caustic soda, chloride of lime, carbonate of lime, sulphate of soda, and the bisulphides, etc., either during recuperation of the lyes used (Pedley) or during preparation and

In 1929, Taginuchi drew attention to the occurrence of a form of dermatosis known locally under the name of "sadare" or "tako", and due to a blastomycete which affected the paper works in the province of Gifu (Japan), and which he himself designated as _erosio interdigitalis blastomycetica_. This dermatosis, which occurs in summer and more rarely in winter, is located in the interdigital spaces, and consists in maceration of the skin, followed by erosion, with violent itching. Slight cases of bronchitis and colds are not of rare occurrence, but these manifestations may be considered as a reactivation of a slight chronic state
of irritation of the respiratory passages, to which these workers have become accustomed.

Rheumatism due to the hot and humid atmosphere is said to be fairly frequent (Wirgin).

The effects of sulphur dioxide appear to depend to a great extent on individual susceptibility. Numerous workers possess almost total immunity to the amounts of this gas generally encountered in the atmosphere of factories, whilst others react by irritation of the upper respiratory passages (fits of coughing, breathlessness).

As a general rule the workers become quickly accustomed to the atmosphere, and certain experts even consider that sulphur dioxide exerts a favourable action on health, protecting the workers against influenza and colds.

Anaemic and weak individuals complain of stomach derangement and vertigo, which they attribute to the effect of sulphur dioxide (Beintker).

Cases of acute bronchial catarrh are of relatively frequent occurrence amongst those who work in a hot and damp atmosphere (wood-pulp factories) and are exposed to sudden changes of temperature, and patients are said to recover less rapidly when continually exposed to an atmosphere charged with sulphurous fumes than if they were working in the fresh air.

The same should be said of workers engaged in tending the continuous machinery, who, besides suffering from respiratory affections, are often affected with rheumatic pains (Gaudiot).
The inhalation of methyl sulphide and of methyl disulphide is said to have caused several deaths amongst workers in Finnish factories utilising the bisulphide process.

It is hardly necessary to refer to accidents of various types which may arise from the use of machines for barking of an ancient pattern, from the use of boiling liquids, etc., or from falls due to slippery flooring on which sulphate solution has been spilt, etc.

It may be said in conclusion that work in the pulp and paper factories does not involve any essential or specific risks for health where it is effected under normal conditions and with provision of adequate measures of accident prevention.

**HYGIENE**

General measures of hygiene comprise the construction and maintenance of the factories (situation, lighting, temperature and humidity, cleanliness, cloakroom and canteen accommodation, etc.).

Special measures of hygiene peculiar to pulp manufacture and the paper industry consist principally in collection, elimination or neutralisation of products liberated or which are transformed into residues in the course of preparation of the chemical pulp (sulphur dioxide, mercaptan, turpentine, methyl-alcohol, methyl-sulphide, etc.).

The provision of adequate apparatus for localised ventilation and the provision of fresh or warm air, as the case may be, in the workrooms is important.

Furnaces, autoclaves, piping, etc., should be constructed in accordance with the principles of modern technique. High chimneys should be provided to facilitate dispersion of smoke in the atmosphere.

Dust should be collected and removed (from pyrites, carbon-dioxide furnaces, sulphur, chloride of lime, etc.) by means of suitable devices.

Transport should be effected in closed receptacles. Localised ventilation combined with good general ventilation is very effective in operations connected with manipulation of rags (see that article), sorting of old paper, cleaning of wood, etc.

Dusty operations should be effected in separate workrooms. The dust collected often contains important products which it is advantageous to recover.

Respiratory apparatus and masks, though essential in certain repair work and difficult operations connected with emptying and cleaning boilers, etc., are on the whole too uncomfortable to be tolerated during ordinary work and cannot be worn for long at a time.

Certain firms place at the disposal of their workers special solutions intended to neutralise acids.

It is desirable to have adequate and effective means of ventilation to attenuate the inconvenience of undue heat and humidity, especially in pulp factories, where treatment by hot processes liberates at times considerable quantities of steam.

Clouds of steam forming over the continuous machinery should be as far as possible absorbed and dissipated by means of the introduction of hot air at the level of the drying rolls.

Fig. 52 shows the system of ventilation adopted in one paper factory. The fresh air arrives in the workroom through the roof and is exhausted through a heating apparatus whence the air is blown out into different parts of the factory. It is important that the dry, warm air should be distributed to the machine room from the adjoining workrooms by passing through apertures close to the floor. The exhausted warm and humid air from the paper machines gives off its heat to the fresh air by passing through the heating apparatus on the top of the building prior to being cast outside.

Workers should be protected against humidity (provision of waterproof overalls, aprons, etc.).

During operations in the course of which workers are exposed to splashing of liquid (bleaching of pulp), the floor should be kept in a satisfactory condition of cleanliness, especially near the vats, where the passage of heavy loads and the effect of acid solutions are liable to render this somewhat difficult.

The addition of toxic colouring materials to the wood pulp should be prohibited and they should be replaced by the use of harmless products.

All rags should be disinfected, and the staff called on to manipulate these should be vaccinated against smallpox.

Adequate means of individual protection against accidents should be taken — such, for instance, as the wearing of glasses to protect the eyes from particles of wood, harmful fumes, etc. — and likewise adequate protection against contact with machinery should be ensured.

---

1 According to Rekowski, the quantity of methyl-mercaptans capable of causing poisoning and death to an adult may be reckoned respectively at 1.750 and 9.100 mg. (Arch. science biol., 1893, Vol. II, p. 263.)
Workers subjected to the effect of sulphur dioxide should be transferred from time to time to workrooms where this gas is not present to any extent.

The question of the disposal of waste water (see article "Industrial Waste Waters") is highly important. Waste water from the paper factories may not be evacuated into water courses without special treatment, for the small particles of fibre which it contains, the presence of sulphur, of colouring materials or putrescent substances are liable to injure fish and plants. Waste waters should therefore be decanted in sedimentation tanks and filtered over cinder filters (biological purification) prior to being evacuated.

It is further of every advantage to factory management to recuperate, as far as possible products contained in these waste waters or to regenerate other products (soda lyes from the pulp).

The lyes coming from the sulphite process after passage through steam give a black, sticky mass utilised for pulp making (Beintker).

Methods of treating residues and waste waters adopted in recent years by pulp factories have succeeded in attenuating or even eliminating the harmful effects of these factories on the neighbourhood.

LEGISLATION

In Spain, boys under fifteen and girls under twenty-one are excluded from the sorting and preparation of rags, and likewise in Italy, unless adequate apparatus for elimination of dust is provided. They are also excluded from colouring of paper by means of toxic products. In France, boys under eighteen are excluded from the sorting and preparation of rags. In Greece, boys under sixteen and girls under eighteen are excluded from certain operations. In certain of the United States, young persons are excluded from tending machinery for making glass paper, etc.

In Austria, the Order of 25 September 1911 contains provisions of safety and hygiene relating to workers occupied in paper manufacture. It prohibits manipulation of contaminated or insufficiently disinfected rags, provides for dry cleaning of rags by mechanical means, and likewise for the sorting and shredding of these in special workrooms. It regulates also the cleaning and ventilation of workrooms, requires provision of lavatories, cloakrooms, baths, working clothes and respiratory apparatus. The Order prohibits smoking and the consumption of food in workrooms.

Resolutions passed by the State Council in Finland and dated 30 December 1924 deal with factories engaged in cutting and grinding wood, paper factories and factories engaged in the sulphite and sulphate treatment of cellulose.

In Belgium, France and Italy, paper factories are subjected to measures provided by the Acts dealing with trades scheduled as dangerous, unhealthy and offensive.

The Compulsory Order dated 3 November 1922 issued in the U.S.S.R. concerns the installation and maintenance of paper factories.

In Czechoslovakia the Regulation of 26 May 1923 contains measures analogous to those included in the Austrian Order referred to above, and contains the further clause that persons subject to epilepsy, cramp, syncope, vertigo or suffering from deafness or other defects or physical infirmities shall be excluded from such processes as involve serious risk.

A similar Regulation was adopted on 25 October 1921 in Yugoslavia.

Paraffin

CHEMISTRY

Paraffins are generally mixtures of the higher saturated hydrocarbons of the methane series \((\text{C}_n \text{H}_{2n+2})\) boiling at high temperature (from the octadecane \((\text{C}_{18} \text{H}_{38})\) to the penta-triacontane \((\text{C}_{30} \text{H}_{62})\) and are therefore called, because of their inactivity from the chemical point of view, "parum affinis": slight affinity.

Paraffins are obtained by the distillation of petroleum lignite tar, bituminous
PARAFFIN

The paraffins set up occupational lesions in the distillation of petroleum, tar, etc., for the workers cannot avoid soiling themselves, particularly when cleaning the pipes, retorts, tanks, etc., containing the resinous residues, and in working and cleaning the filter presses. The persons engaged in cleaning the receptacles especially come into direct contact, for hours at a time, with hot masses of paraffin and their fumes. The use of paraffin and like compounds may also be prejudicial to health.

The paraffins exert not only a local external action on the skin and mucous membranes but also a general action due to the absorption either of the paraffin or inhalation of the volatile compounds. The action on the skin is firstly mechanical (the particles obstruct the pores, the orifices of the sebaceous and sweat glands, from which arrest of the secretions and a very remarkable irritant action results), and secondly chemical. The gaseous or liquid hydrocarbons, alone or as compounds of crude paraffin, dissolve the fatty covering of the skin and thus remove its natural protection. In many cases the impurities irritate the skin on account of the oxidisable substances, i.e. the non-saturated hydrocarbons, terpene, acids, lime salts, sulphates, phenols, cresote, ichthyol, empyreumatic substances, or of the chemical residues left in purification (alkalis, sulphuric acid).

The most important action, however, without doubt is that of inducing proliferation of the epithelial cells (dermatitis from crude oil and paraffin, paraffin cancer), an action very variable and related to the degree and nature of the impurities contained in the paraffins. Really, the latter, deprived of their empyreumatic substances and of the chemical products added for their purification, do not exert an irritant action. Experience with "war vaselines" therapeutically used is very interesting in this respect. When these were used as ointments or cosmetics, acute and chronic eczematous affections of the skin were produced. Besides folliculitis, with or without comedones, analogous to those found in petroleum and paraffin workers, etc., warty growths have been observed on the body, especially on the face. In this case, it is a question of abnormal epithelial proliferation with keratosis associated with an inflammatory infiltration of the upper cuticular layers. On the covered parts of the body...
papular outgrowths or warts are observed, horny protuberances associated with pruritus, and burning sensations. followed by headache, fever with a temperature of 40° C., nephritis, etc. In children, headache, palpitation, dis-

Among the general manifestations, excitement and insomnia have been noted. Its use by injection has been quieting cyanosis, vomiting, weak pulse, somnolence, etc., occur. In the later occurrence of pigmentation and
melanosis, no doubt certain photochemical actions come into play. It is a question of the peculiar, well-known property belonging to certain chemical bodies, among which are certain derivatives of naphtha, such as vaseline and paraffin, of setting up, in the presence of light, the morphology and physiology of unicellular animalcula and agglomeration of cells, whereas in the dark they are without action. The human skin is very sensitive to traces, even infinitesimal, of these substances which “sensibilise” it to the photochemical action of these common rays;

FIG. 55. — Chronic indurated dermatitis (warts, scars).

The numerous researches undertaken.
FIG. 56. — Papular dermatitis (after two months' work).
with the object of isolating the active agent have not, up to the present, been successful. Although acridine (hydroacridine), anthracene (methylanthra-
cene), arsenic and its compounds, etc., have all been accused, there is no
doubt certain external conditions also have great importance in the causation of
the more serious skin affections, as, e.g., insufficient cleanliness of the ma-
chines as well as that of the workers; fair and red-haired workpeople are
more affected than dark. Workers newly employed are regularly attacked,
but later acclimatisation seems to establish itself.

Bridge is of opinion that the injurious action of this substance is due to the
heavy mineral oil; others lay the blame on the traces of arsenic introduced
into the product by treatment with sulphuric acid, always containing ar-
nenic as an impurity (Norman Tate); others again are of opinion that the
sulpho-acids or ammonium sulphate
remaining in the paraffin after refining
are at fault.

The solvents of the fats contained in
the crude oil, the crude tar and paraffin are also the cause of a general action
because when they get into the circulation they affect the cellular
chemical combination by dissolving the lecithins and other lipoids. Their
action is the more intense as their solubility in fats is greater and their
solubility in water is less. The lesions are, further, the more marked the
richer the organ is in fats. Thus it is that in the central nervous system
the effects are most pronounced (see articles "Benzene", "Petroleum",
"Shale Oil Industry", and "Tumours of Occupational Origin (Occupational
Cancer)").

STATISTICS

The data as to the frequency of occupu-
tional affections due to paraffin are not
numerous. The cutaneous lesions are cer-
tainly the most frequent and the most severe.

In Austria, the inspectors of factories
describe 29 cases of "itch" among 63 paraffin workers; in 1913, several cases
were reported from a pasteboard factory, and
7 more or less severe during the war
(1914-1918). An enquiry made in the centre
of the crude oil industry in Galicia revealed
13 cases of cancer, almost all localised
in the scrotum, and operated upon
in a space of 8-10 years. Ullmann collected
particulars of 13 cases of cancer of the
skin in 10 years (1900-1912) as a result of a
questionnaire addressed to 20 paraffin
works.

In France, Barres and Courtois Suffit
in 1903 described pustules, ulceration and
especially papillomata of the skin among
the cleaners of boilers and tanks containing
the residues of the final refining of
petroleum. In 1892 Derville and Guermonprez described cases of warts among
petroleum refiners.

In Germany, Eckhardt (Diss. Halle, 1886)
reported 4 cases of paraffin cancer, Michel-
sohn (Berlin, 1888) and Voigt (Berlin, 1892)
published a dissertation on the epidemic
which were studied also by Liebe in 1893.
Gawrowsky (Diss. Halle, 1904) examined
the subject anew in relation to some cases
observed by himself. Inspectors of facetries report annually cases of severe
injury to the skin more or less due to
paraffin.

In Great Britain, Ogston (1871), of Edin-
burgh, and Bell (1895) reported the first
cases of paraffin cancer; Bellat (1878) de-
scribed a case of scrotal epitheliomata. Kirk
studied others in 1903. Legge (1922) in the
Medical Inspectors' Report gives the statistics for the years 1911 to 1919: 12 cases
of epitheliomatous tumours due to paraffin.
In 1920 notification of epitheliomatous
ulceration contracted in a factory or
workshop became obligatory on all med-
ical practitioners, and since that year they
numbered 3 in 1920, 6 in 1921, 5 (1 death)
in 1922, 6 in 1923, 2 (1) in 1924, 4 in 1925,
2 in 1926, 4 in 1927, 2 (1) in 1928, 4 in 1929,
0 in 1930, 2 in 1931 and 1 in 1932. Cases
of simple dermatitis due to paraffin were
much more numerous: 98 from 1927 to
1930.

According to age the cases cited by
Legge were as follows: one aged from
31 to 40 years, a second from 41 to 50, and
a third from 51 to 60: three others were
over 60 years of age. They had been em-
ployed from 15 to 20 years in 1 case, 20 to
30 in 3 cases, and 30 to 40 in 2. The
lesions were localised in the scrotum in 2,
on the forearm in 4, the neck in 1, and
the eyelid in 1.

A. Scott, who as a certifying surgeon has
been able to follow the cases closely for several years among the thousands of
workmen in the oil refineries of Scotland,
has collected records of 65 cases, of which 19
were engaged in the crude paraffin sec-
ton employing in all 200 men (a morbidity
of about 5 per cent. per annum).
Only 3 were less than 40 years of age,
23 from 51 to 60; 13 from 41 to 50; the other
26 were over 60. While among the 19
paraffin workers the lesion was situated in
63 per cent. of the cases on the hands and
forearms, in 16 per cent. on the face,
and in 16 per cent. on the scrotum, among
the 46 cases set up by petroleum the lesion
affected the scrotum in 61 per cent., in 20
per cent. the arms and hands, and in 15
per cent. the face. Duration of employ-
ment in all cases had been long. Of the 19
paraffin workers 12 had worked from 18 to
39 years. Only a small number of the
lesions become malignant and, according
to Scott, the personal factor plays an
important part when they do.

In 1913 W. Walker described three cases of
paraffin tumours situated on the back
of the foot, on the scrotum and on the
back of the hand (necessitating ampu-
tation of the arm); Brown described 5 out of 10 workmen as suffering from severe ulcerations, etc., and Wilson noted several cases of warts, etc., in paraffin refineries. Several cases, moreover, cropped up in the period 1914-1918 in the Scottish shale mines, and in 1919 a voluntary agreement was come to between the employers, the employed, and representatives of the Factory Department with a view to improving conditions of work at the paraffin refineries. Walker's enquiry on paraffin factories and petrol refineries was carried out in 1919. From that year dates also the quarterly medical examination of those employed in the green sheds (refinery).

**Symptoms**

The term, now classical, of "paraffin cancer" comprises quite a number of skin lesions, such as comedones, folliculitis, pustules, simple erythema, papular erythema, etc.

These lesions, which affect about 50 per cent. of the workmen engaged in the refineries, commence some weeks or months after first employment; they last all the time work continues and disappear (at least the less chronic forms) a short time after giving up work.

The different kinds of dermatitis (papular, pustular, erythematous, etc.) are due to direct contact with some chemical substance which by giving rise to warts and cellular indurations acts as a predisposing agent.

1. Dermatosis. — This presents several types of which one or more may be found on the same individual. The skin is the seat of intolerable itching; neglect leads to a chronic condition with rhagades and hyperkeratosis. Sometimes the skin shows a brownish-black pigmentation and diffuse thickenings; sometimes an eruption of pimples on the face, on the extremities or on the scrotum. The number of the affections varies with different oils and the technical manner in which the processes are effected.

(a) Comedones: these occur on the uncovered parts of the skin; are purely mechanical in origin, the paraffin substances obstructing the sebaceous glands, or, by thickening of the superficial layers of the epidermis, resulting in blocking of the sweat glands. They are of little importance from the point of view of the production of malignant lesions.

(b) Folliculitis, perifolliculitis, follicular dermatitis: this is the commonest of the lesions among paraffin workers (40-50 per cent. are affected) in the first 10 to 12 days of work. As a result of a moderate inflammatory reaction, the hairs and hair follicles are destroyed, and the skin is red with black projections without fluid contents and without itching. This form has a typical distribution occupying the forearm (ulnar surface), wrist and back of the hand; in 20 per cent. of the cases the legs are also affected.

(c) Pustular dermatitis: two types occur, the one characterised by numerous small pustules on the anterior surface of the body and its extremities, the other by a pustular eruption due to the typical papule, which is the commonest form of the occupational eruption.

(d) Papular dermatitis or papular erythema: consists in an eruption of small round elevations of reddish colour, varying in size from that of a small grain of pepper to that of a small pea. It occurs in some 40-50 per cent. of the cases of dermatosis.

(e) Simple erythema: this is a moderate hyperaemia in which the erythema is uniformly distributed over the forearm.

(f) Erythematous dermatitis: a subacute or chronic type due to the irritating action of a semi-refined paraffin on the tissues of the skin for a sufficiently long period (7 to 8 years). It represents an extension of the erythema in which the congestion has gradually passed into a state of chronic inflammation of the different layers of the epidermis and of the "cutis vera", followed by thickening and, in the most advanced cases, by a partial or complete destruction of the skin of the parts affected. Tendency to the formation of small, flat, squamous, oval or circular warts is also common. Once this stage has been reached, the formation of characteristic epithelial overgrowths occur, sometimes long after the workman has ceased to have any contact with irritating paraffin substances.

2. Epithelioma. — Among workers over 40 years of age and with duration of employment of more than 20 years, epithelial growths may develop from epithelial layers of the warts and papules, followed by ulceration and necrosis. In general, only one epithelial ulcer develops in an individual, but there are instances in which several, one after the other, have occurred in the same person. These tumours usually start from a hard wart or papule and co-exist with an advanced condition of erythematous dermatitis. The clinical picture is
that of an epithelioma developing slowly in the midst of a chronic dermatitis, with numerous warts or indurated papules of papillomatous nature, one of which has taken on malignancy. The colour of the skin of the face, arms and chest becomes yellower or brownish ; the sclerotics are similarly yellow ; the lesion is situated commonly on the back of the hand and forearm; the scrotum is also not unfrequently the seat of growths, which may be explained by the delicacy of the skin in that situation, by constant contact with dirty clothes, friction, warmth, and eventually by soiling with contaminated fingers during micturition. At the external or internal angle of the eye, the lesion assumes the form of a rodent ulcer.

The clinical development of the cancer is relatively benign for a long time, and is finally that metastases with severe generalised symptoms occur. (Cachexia). Excision may lead to curing the individual, but metastases and recurrences elsewhere have occurred after the operative treatment as frequently as at the site of the scar. If the workman gives up his employment in time a cure or remission is possible; if he continues his work, new growths with their sequelae develop. All changes in the skin of these workers should be watched, especially because of the difficulty of diagnosis as to whether the tumour is cancerous or not when situated on the scrotum. (See article "Tumours of Occupational Origin (Occupational Cancer").)

Numerous observations have been made on the cutaneous lesions set up by grease and impure crude oil, especially during the war when those engaged in engineering works suffered in every country. Lack of pure mineral oil on the one hand, and of fatty tar oils on the other, led to the use of the products of distillation of lignite and naphtha which are rich in creosote and in unsaturated aliphatic hydrocarbons, and, no doubt, on technical grounds, contain little paraffin. (See article "Petroleum").

Attention should also be drawn to the relatively high frequency of burns among the refiners.

**General disturbances.** — Inhalation of volatile hydrocarbons contained in crude oil and paraffin, and absorption of them through healthy or unhealthy skin, give rise to affections of a general nature, the picture of which varies with the nature, origin, degree of purity of the product, and its contents in hydrocarbons boiling at high or low temperatures. Finally, it is of importance to know whether it is a question of air very rich in the concentrated vapour and insufficiently supplied with oxygen (as e.g. in air in boilers, tanks, vats, small workshops).

In these cases rapid loss of consciousness and even death occur unless the victims are very rapidly brought into the open air. Inhalation of very small quantities of the gas produces a condition resembling that of a drunken man, with headache and vertigo which disappear again when the patient is brought into the open air.

Continuous inhalation of certain quantities of the gas (with sufficient oxygen present) induces a remarkable pathological condition characterised by debility, somnolence, heaviness in the head, buzzing in the ears; the clinical picture is similar to that of marked alcoholic intoxication, somnolence lasting for whole days, sometimes with loss of consciousness, amnesia, etc. In other cases there is a state of excitement progressing to a maniacal condition with delirium, hallucinations, muscular tremor, clonic spasms; sometimes neuritis, paraesthesia, difficult deglutition and speech, shooting pains in the neck and chest, fall in the body temperature especially in the peripheral parts, with cyanosis and sensation of cold, diminution in the respiratory rate and pulse. Loss of appetite, erections, vomiting and diarrhoea have been described. The conjunctiva becomes the seat of an irritation more or less severe with affection of the sight; the respiratory tract is also irritated (cough, crises of suffocation, bronchitis, etc.). Analogous symptoms have been observed from the use of lubricating oils, as a result of repeated inhalation of gas over a long period (chronic action).

**Diagnosis**

This turns on the history of the case, that is, on knowledge of the kind of work. In many cases the intense odour of the clothes and skin of the patient give the clue, a smell which persists even after repeated bathing. The stools, urine, and expired air also smell of petroleum for a long time. The varying clinical picture of the different skin lesions complicates the diagnosis. For paraffin workers particularly they are — comedones, epithelial proliferations, and pigmentation.

The general symptoms affect mainly the central nervous system; somnolence, cold extremities, and muscular contractions are those on which, together with the history, reliance is to be placed.
HYGIENE

First aid. — Cases of poisoning call for immediate removal from the place of work (the atmosphere containing the gas) to fresh air, and if necessary oxygen inhalation, baths, hot applications, stimulants (see article "First Aid"). Treatment of the skin affections follows that of the customary dermatological therapy. Severe cases call for suspension from work until a cure is effected. Growths must be promptly removed surgically.

Technical preventive measures are directed to substitution of machinery for hand labour, especially of closed and automatic apparatus. As the work at the filter presses exposes to greatest risk it would be well if some other process could replace it. Tanks which have contained petroleum, tank wagons and other closed receptacles should not be entered until they have been thoroughly ventilated; if this has not been done then the wearing of breathing apparatus is necessary, with some person keeping watch the while from the outside.

Further means of personal hygiene against contamination should be considered. The suggestion of protecting the face by means of a cap with large flaps and a covering over the neck has been made; and also the provision of large and impermeable aprons, wellington boots, thick gloves, zinc ointment, etc., for slight scratches has been suggested. Other measures should be observed: daily examination of the skin (especially of the exposed parts) of the workmen by trained medical men, instruction of the workmen as to precautions to be taken. Cloakrooms, washing and bathing accommodation, and arrangements to permit of change of overalls impregnated with oil should be in charge of a responsible person.

Cleaning the hands with benzine or sawdust impregnated with benzine is important and much resorted to; it, however, injures the skin as it removes the natural grease and makes it crack. Further, the skin of many persons is sensitive to benzine and reacts with symptoms of irritation. Rubbing the soiled skin after work is over with dry sawdust is useful, or washing the skin very rapidly in benzine and then in soap and water, followed by smearing slightly with lanoline and glycerine. It is essential that baths and means for cleanliness should be constantly available. Time devoted to cleansing purposes should be included in the hours of work. Working clothes and underclothing should be changed for homegoing ones after washing. Douche baths and rest-rooms should be installed. The ambulance room should keep in reserve a cylinder of oxygen, breathing apparatus, bandages, dressings for burns, etc.

LEGISLATION

No special Regulations are in force for petroleum refineries. In Great Britain, however, in 1919 a voluntary periodic medical examination of the persons employed in the green sheds (refinery) was arranged for with provisions including, among others, requirements on the following lines:

1. Paraffin workers to be provided with suitable working clothes, overalls or over-all suits. A complete suit to be provided once in every twelve months. In addition, suitable protective clothing to be provided for all scale (refinery) workers.

2. Shower or douche baths, with hot and cold water, suitable and sufficient washing accommodation with hot and cold water, and a sufficient supply of soap and towels for all the above workers. Suitable accommodation for clothing, with adequate arrangements for drying clothing if wet or damp. Messrooms, cloakrooms, bath and washing accommodation to be placed under the charge of a responsible person, and to be kept clean and adequately heated when necessary.

3. All workers in the green shed (refinery) department to be examined once at least in each quarter by the certifying factory surgeon, with power to suspend and to supervise the ambulance equipment and treatment.

4. The occupier to provide and maintain in good order an ambulance room. It shall contain among other things: (a) means for treating skin lesions (sterilised dressings, ointment, etc.); (b) a stretcher and breathing apparatus.

In Argentina women are excluded from work on distillation of tur products (paraffin, etc.).

Before the war the Austrian (Galician) Factory Inspectorate had arranged a monthly medical examination of all paraffin workers and the keeping of a register of such examinations. No data as to its application are available.

Every skin lesion, cancer, and ulceration of the cornea or conjunctivitis in persons employed in refining petroleum or tar or their derivatives must be notified in the Netherlands.

Epitheliomatosous ulceration of the skin or ulceration of the corneal surface of the eye has been made notifiable in Great Britain and Poland and is compensated as an industrial accident disease in Austria, Germany, Great Britain and the United States in the following states: Minnesota, New York and Ohio.

Compensation is afforded in Germany for cancerous dermatitis.

Paranitraniline

French: Paranthraniline. — German: Para-
nitranilin. — Italian and Spanish: Para-
nitranilina.

P.-nitraniline \([C, H, NH, NO_2 (1 : 4)]\) is
prepared by treating, at a temperature of
165° to 170° C., the p-chloronitrobenzene
with an excess of concentrated ammonia;
it is filtered, washed and dried. Starting
from acetanilide there is obtained after
nitration, at a temperature not exceeding
40-50° C., a mass which is then filtered.
The precipitate obtained is washed, com-
pressed, redistilled, with water, heated, and
neutralised by soda. In this way the impuri-
ties of the \(o\)-nitraniline are dissolu-
vved and there remains fairly pure
p-nitro-acetanilide which is collected on the
filter. The mass is taken up again with
water and caustic soda and brought to
boiling point. After being allowed to
stand, the mother liquors are drawn off
by syphon and the mixture is taken up
again with slightly alkaline boiling water.
It is then cooled, filtered, washed, dried,
and finally pulverised.

Pure p-nitraniline occurs in the form
of yellow crystals, which melt at 174° C.
It is very slightly soluble in water, slightly
soluble in alcohol and soluble in ether.
It is used in the dyestuffs industry.

Amongst the other nitro-derivatives of
aniline should be mentioned: m.-nitra-
tiline \([C, H, NH, NO_2 (1 : 3)]\) obtained
by reduction of \(m\)-dinitrobenzene. It takes
the form of inodorous yellow crystals
with a melting point of 114° C. It is soluble
in organic solvents and very slightly
soluble in water. It is used in the pre-
paration of alizerine yellow, dinetranil-
line, orange, etc.

The dinitranilines: only the isomere: 1:2:4
is of practical importance. It is obtained
by starting from 1:2:4 dinitro-chloroben-
zeine and concentrated ammonia. It is
employed in the preparation of violet
colouring matters for wool, fast red col-
ers, etc.

For tetranitraniline and tetranitromethyl-
aniline, see article "Explosives" § 3:
Nitromines.

TOXIC ACTION

The p-nitraniline is the most toxic
of the nitrated products of aniline.
Animal experiment has demonstrated
that it can be absorbed by the gen-
istive tract without serious harm
when the stomach is full. Doses of
0.3 to 0.5 grm. fed to cats under these
conditions have merely caused the
temporary presence of methaemoglobin
in the blood. On the contrary, in the
case of fasting animals, 0.2 to 0.3 grm.
may set up serious symptoms (tremb-
ling, paralytic and coma) followed
by death. Small doses (0.1 grm.)
distributed to a cat daily during
one month only caused very slight
troubles. Absorption by way of the
skin must be on a large scale to cause
fatal poisoning (Lehmann). Accord-
ing to Fischer, the paranitraniline
seems to possess a cumulative toxic
action, and in cases of resorption by
the skin the sub-cutaneous tissues act
as a reservoir. The toxic action is
exerted on the blood (formation of
methaemoglobin) and on the nervous
system (central paralysis of the heart).
Ischuria, haemoglobin and bilirubinuria
have also been reported (Bachfeld,
Lehmann, Lewin).

The toxic action of \(m\)-nitraniline
affects animals in the following de-
creasing order: dogs, cats, guinea pigs,
rabbits. A dog weighing 4 kg. died
in four hours as the result of an in-
tra-peritoneal injection of 15 cc. of
3.5 per cent. solution of \(m\)-nitraniline
in olive oil (or 0.07 grm. per kg.). Death
occurred after acute dyspnoea and con-
vulsions. At the autopsy the usual
lesions of asphyxia were found, but no
haemoglobin on spectroscopic examina-
tion. In the case of rabbits, poison-
ing which is not fatal may cause seri-
ous secondary anaemia. The urine of various poisoned animals showed a change in coloration (dark red brown), and there were found in it traces of albumen and sometimes a few red cells. There was never evidence of methaemoglobin. A second injection always caused less accentuated modifications whilst fatal doses set up anuria.

**Pathology**

In 1898, Bachfeld reported 9 cases, 4 of which were serious, of poisoning by p.-nitraniline. One case of aniline poisoning recorded in 1899 was attributed to inhalation of nitraniline dust (Rambousek). One case of an unusual disease resulting in death which occurred in 1909 in a nitraniline factory revived the question of the toxic action of this product. A worker aged thirty on arriving home one evening experienced a violent indisposition accompanied by a choking sensation, insatiable thirst, and a reddish violet coloration of the face. These symptoms continued into the night, but the next day the worker resumed his work. The foreman was only able to note the extreme pallor of his face, for, some seconds later, the patient died suddenly.

The autopsy revealed alteration of the coronary arteries, the presence of blood clots and, on spectroscopic examination of the blood, methaemoglobin. The victim had handled a considerable quantity of nitraniline either while sweeping dust which had fallen from receptacles being filled or while centrifuging the toxic product for hours at a time (Lewin).

Since then several cases of poisoning by p.-nitraniline have been reported: in Bavaria (1913) a case in which the symptoms recalled those of aniline poisoning and in Austria a case affecting a worker in a factory for printing cloth. In 1919 two cases occurred in the State of Hesse. In Great Britain, Henry reported in 1921 4 cases of poisoning affecting workers and one chemist engaged in sitting the product in question. In one of the cases the poisoning took a serious form, characterised by attacks of headache, nausea, vomiting, vertigo and obnubilation. The face and lips of the patient were yellowish-grey and the ears were cyanosed; he suffered from respiratory trouble, oppression with pain in the chest and cold in the extremities. In 1922, a fatal case occurred in Germany affecting a worker who had received splashes of the product while plunging an iron bar into a crust of p.-nitraniline under which there was water at a temperature of 95° C. There has been compulsory notification of cases of aniline poisoning in Great Britain since 1925; during the period 1926-1928 20 cases of poisoning due to p.-nitraniline dust were recorded.

Hamilton records the case of a worker of twenty-seven years of age who had been engaged for twelve days in the p.-nitraniline department. He had been poisoned by inhaling the product in powdered form which was accidentally liberated by the apparatus. He was sent to have a douche bathing and subsequently to the hospital, where twenty minutes later he fell into a state of unconsciousness and died in spite of the treatment applied. Death occurred two and a half hours after the accident.

An enquiry undertaken in 1928 by Jablokov, Sapojnikoff and Leites amongst workers in a Russian nitraniline factory revealed methaemoglobininaemia in 11 cases out of a total of 31 workers. The authors confirm the observations made by other experts and consider that acute poisoning by p.-nitraniline presents the same clinical symptoms as aniline poisoning; that rapid inhalation of p.-nitraniline exerts, in the first place, an action on the central nervous system and on the blood, in connection with which latter slight haemolysis is noted and the presence of a small quantity of methaemoglobin; that the nervous symptoms cannot be attributed to the formation of methaemoglobin in the blood; that the pallor of the skin finds its explanation not in the diminution of haemoglobin but is due to vascular spasm produced by the action of the p.-nitraniline on the vasomotor centres; that the symptoms of chronic poisoning consist in cephalalgia, pallor, vertigo, hypothyemia, tendencies to fatigue, circulatory derangement, inflammation of the liver, increased perspiration and slightly marked alteration of the blood count.

Finally, there is the irritant action on the eyes and the skin of workers exposed to powdered p.-nitraniline (Prosse-White).

Individual tolerance is rather variable and even a certain degree of immunity has been recognised among some workers in contact with this product.

Caubert (1904) had reported many cases of poisoning amongst workers engaged in dyeing articles red with p.-nitraniline. This product, wrongly designated in certain districts of France as "Russian red", was chiefly employed in dyeing thread intended for weaving cotton goods. There had
formerly been used "Turkey red" (alizarine) derived from madder root and in its turn replaced by artificial alizarine. The skin of cotton, mordanted by means of a solution containing β-naphotl and caustic soda, was subsequently wrung out, dried and immersed with a diazo solution, in which there occurs double decomposition between the β-naphotlate of soda of the fibre and the diazo chloride of the solution. The diazo dye of a beautiful red is then formed and fixed on the fibre. The solution for diazotization is prepared with p.-nitramine and hydrochloric acid.

Workers who had their hands constantly in the solutions (alkaline and diazo), who were in the habit of working bent over the vats, from which slight clouds of vapour were given off, and who wrung out the skeins with bare hands, complained of headaches, digestive derangement and especially a fairly serious form of eczema known as "purpurism". Localised on the hands, forearms and at times on the chest, this affection commenced with a slight swelling of the skin followed by the outbreak of numerous red spots accompanied by itching. If the worker left off work it healed at the end of four or five days; if not, the spots turned into pimples which finally dried up. Healing then took four or five weeks.

Caubert considers that the action of each of the two baths played a part in bringing about this effect and that neither would have sufficed to do so by itself. The injury was one which specially affected workers engaged in dyeing red with p.-nitramine. The use of gloves rapidly eliminated the "purpurism" and the introduction of a machine effecting mechanical impregnation and wringing of the cotton soon rendered all the operations in question quite harmless.

As regards human pathology due to m.-nitramine, Hamilton has reported a case of a young worker who had cleaned out a vat which had contained the product in question. Very shortly afterwards he complained of frontal headache, suffered from attacks of vomiting and lost consciousness. The hospital to which he was taken noted acceleration of the pulse and intense cyanosis, the lips and mucous membranes being almost black. Another case was reported by the New York Department of Labour of a worker who had cleaned out a receptacle which had contained m.-nitramine. The victim complained first of all of stomach trouble and nausea; the next day, shortly after resuming work, he was found lying on the ground uncon-
The addition of soda sulphite is said to attenuate the irritant effects of the substance. It is also used for dyeing hair and furs (ursol) and as a photographic developer with sulphites and alkaline liquids.

Certain organic substances used in the direct production of brown or black tints on hair or fur are known commercially under the name of "ursol".

The colouring medium is generally got by oxidation. Peroxide of hydrogen is at times used as oxidising agent, or chromates (bichromate of potassium) or quinone.

Dyeing may be effected directly or by means of mordants (iron, chrome, copper). P.-phenylenediamine is known commercially under the name of "ursol D", whilst hydrochloride of p.-aminophenol, etc., is designated "ursol P". In the different countries, however, these colouring agents are generally known under fancy names.

**TOXIC ACTION**

As regards the minimum fatal dose, these compounds may be classified in accordance with the experimental research effected by Hanzlik (1923), in the following descending order: dimethyl- and diethyl-p.-phenylenediamine; p.-phenylen diamine; m.-phenylen diamine.

The first two of the above are, in a basic form, capable of absorption by the intact skin on account of their volatility and their liposoluble property. Their fumes are also toxic. Poisoning is characterised by acute symptoms with fatal evolution. Locally these two substances exercise an irritant action (dermatitis) which is not caused by their salts.

The p.- and m.-phenylen diamine are very slightly or slightly irritant, but their effects vary in accordance with the conditions under which the experiment is carried out. They both give rise to identical symptoms: cardiac and respiratory excitement, fall in the temperature, trembling, convulsions, coma, death.

Medical experts engaged in investigating injuries due to ursol have undertaken research with a view to determining the pathogenesis of the poisoning. Prosser White has been able to establish the fact that after the second day the cutaneous region in permanent contact with a fur dyed with a solution of p.-phenylenediamine showed considerable irritation, which after a lapse of less than four days developed into papulæ. As a counter-test, a high-class dyed skin applied under the same conditions to the skin gave rise to no trouble of any kind. Experiments of the same nature were engaged in by Semon, who remarked the outbreak of a form of dermatitis after the first twenty-four hours. The fur used showed a slight acid reaction and left traces of a reddish colour on paper. No oxalates, chlorides or chromates were found, but small traces of arsenic. A systematic study of the toxic action of the products in question, namely, of those that Hanzlik has demonstrated that p-phenylenediamine in the dry state or in a 10 per cent. alcoholic solution was only relatively slightly absorbable and merely caused slight irritation of the skin. In solution with water, on the other hand, its harmful action was considerable and almost as intense as that of quinone. Hanzlik was of the opinion that these compounds are definitely toxic and that asthma and respiratory troubles noted amongst furriers are due particularly to direct irritation of the smooth muscular system of the bronchi rather than to anaphylactic action.

According to Mayer, 1929, individual reaction is said to give rise to asthma or eczema in accordance with the point at which the injury occurs. He therefore supports the opinion of von Criege, of Curschmann and those medical experts who ascribe these injuries to an allergic phenomenon connected with ursol or its oxidation products (quinonedi amines), which holds good of all bodies having a quinonic structure. A similar opinion has been expressed by Buschke and Ollendorf, R. Ledermann and R. L. Mayer in regard to forms of dermatitis. Prosser White considers that in this case it is a question of irritant action caused by products of oxidation. There has, however, been noted a special effect on the part of certain p-phenylen diaminic derivatives to the exclusion of certain others.

Observations relative to dangers connected with ursol are very numerous. An enquiry into the subject undertaken in December 1928 at Leipzig has enabled Mayer and Förster to study troubles caused by use of p-phenylen diamine and its derivatives in the case of 181 workers engaged in the fur industry. They found that out of 111 workers suffering from asthma or eczema of occupational origin 78 regarded ursol as the cause of their troubles, 21 ascribed symptoms to ursol in accordance with the diagnosis of their doctor; whilst the remaining workers attributed their illness to different substances: chlorine, ammonia, dust, etc. The illnesses noted were distributed as follows: eczema, 50 cases (45.0 per cent.); asthma, 43 cases.
PARA-PHENYLENDIAMINE

(38.7 per cent.); asthma and eczema combined, 18 cases (16.2 per cent.).

In 49 of these cases there was noted hypersensibility to the effects of ursol. This reaction was encountered in 46 per cent. of those suffering from eczema, in 30.2 of the asthmatic subjects and in 72.2 of the patients suffering from both diseases.

PATHOLOGY

Since the first industrial utilisation of ursol pathological disturbances have been noted in connection therewith (forms of dermatitis, Carozzi; asthma, von Criegern), especially amongst workers in the fur industry. It has even been found that persons wearing furs dyed with ursol suffer from more or less serious effects and, finally, serious cases have been met with amongst persons whose hair was dyed with dyes having an ursol basis. Injuries caused at the outset amongst workers in the fur trade were fairly numerous and Lehmann has reported in one single year for Leipzig 187 cases of poisoning.

According to the observations of Prosser White, cutaneous troubles are encountered chiefly amongst the workers who handle liquid colouring agents. The quinonic fumes which are liberated at the moment of oxidation in production of black colours have, however, an irritant action on the mucous membrane of the nose and eyes. The eruption affects generally the face (corners of the mouth, pupils, nostrils), the back of the neck, the fore-arms and particularly the dorsal region. The parts of the body protected by clothing are not affected and likewise the anterior part of the arm escapes. The hands are strongly discoloured with a blackish brown colouring. Localisation is explained by the fact that certain cutaneous regions and damp mucous membranes favour adhesion of dust particles. Cutaneous lesions which are small and superficial at the outset take the form of small round papulae surrounded by a red zone which becomes partly covered with yellow crusts and may even undergo ulceration.

Prosser White remarks that none of the patients examined by him showed any tendency to seborrhoea or to soda- tion which would render the skin more liable to the development of dermatosis.

Besides 4 cases of eczema, examination of 25 workers in the "Proletarski Troud" Fur-Dyeing Works, of Moscow, revealed 12 cases of hypertrophic rhinitis; pharyngitis in the case of 9 workers; and chronic bronchitis in the case of 6 other workers; 9 were subject to violent fits of coughing, which however ceased as soon as they left off work. The hands of the workers in question were quite black. The workers complained of difficulty of respiration, spasms of the throat with a sensation of dryness and a special taste in the mouth, watering of the eyes, etc. The furs which had given rise to these symptoms in the case of the workers were also responsible for setting up dermatitis amongst people who wore them later and at times customers returned their purchases, lodging complaints and demanding damage.

In France, Thibierge and Lacassagne engaged in a study of eczematous dermatitis due to the wearing of dyed furs (1926).

Gougerot, Barthélemy and Cohen published in 1930 particulars of a case of dermatitis affecting the face and hands of a woman who had worked for six months in a rabbit skin factory.

Atmospheric humidity, perspiration, the more or less careful methods employed for dyeing, washing and freeing from grease the furs in question, all play a part in the development of these forms of dermatitis. It is necessary to consider in conjunction with these the role played by the constitution, the frequent incidence of endocrine troubles in the case of these patients being well known (Babalian).

The other typical symptom represented by asthma is attributed to the use of certain products of the aromatic series (p-phenylenediamine; o- and p-amino-phenol; p-aminophenylamine; p-amidopara-nitratiniline; p-aminophenylamine; p-totuylendiamine, etc.).

The troubles caused by colouring matters in the French industry for the production of cheap furs — generally rabbit — have been described in 1930 by Babalian and Reitlinger. These colouring agents were used with a view to imparting to the fur the appearance of expensive furs.

Ursol disease would appear, according to the experts, not to consist of an allergic reaction but of a purely local reaction of the skin and respiratory passages.

The cutaneous reactions which characterise them are of the eczematous or prurigo type. Those affecting the respiratory apparatus are grouped under the name of ursol asthma and involve a series of asthmatic troubles of the upper and lower respiratory
passages. These reactions occur preferably amongst subjects showing predisposition following the slightest irritation.

General poisoning due to p-phenylenendiamine has been observed by H. W. Nott in the case of a hairdresser who for three years had utilised this product in dyeing hair. He suffered from sudden fits of illness characterised by the following symptoms: palpitation, feeling of weakness and fear of immediate death, at times followed by loss of consciousness, greyish cyanosis of the face, anxious expression, moisture of the eyes, swollen conjunctivae, oedema of the eyelids, gums and tongue.

DETECTION

With a view to rapid research for p-phenylenendiamine in a liquid, it should be alkalised where necessary, extracted with ether, decanted, and the ether solution taken up with acidulated water (hydrochloric acid). It should then be shaken, decanted afresh, and the phenylendiamine detected in the watery solution by means of perchloride of iron.

Shitkowa (1929) has suggested two methods of detecting with adequate precision small quantities of p-phenylenendiamine. In the use of the titrimetric method he determined the presence of p-phenylenendiamine by oxidation by means of hypochlorite of soda; in the case of the colorimetric method he utilised an indamine reaction (FeCl3 and aniline), which permits of titration of 0.002 mg. of p-phenylenendiamine. This product can be extracted from dust or hair by means of hot water.

Shitkowa again has been able in this manner to titrate 0.004 per cent. in dust which contaminated the working benches and 0.006 mg. in dust contained in a litre of air in a Russian factory. The product in question was non-oxidised p-phenylenendiamine.

In another Russian factory for fur-dyeing Schliffmann (1929) found 0.0029 to 0.0014 mg. per litre in air of a Russian factory. These反应s were, however, without any means of ventilation.

HYGIENE

The aqueous solutions of phenylenendiamine and toluylenendiamine are highly toxic. Dilute solutions seem to exercise an action on the skin. There should therefore be taken, in regard to these solutions, precautions similar to those prescribed for the products themselves.

The phenylenendiamines and toluylendiamines are less volatile than aniline. Diluted, cold aqueous solutions containing less than 10 per cent. of these products may be stored, transported and decanted in apparatus or receptacles which are not hermetically closed. Practice has proved that this procedure is without harmful consequences.

For measures of general and special hygiene, see articles "Aniline", "Chemical Trades" and "Nitro and Amido Derivatives".

As regards the protection of workers engaged in dyeing with colouring media with a phenylenendiamine basis, rubber gloves, adequate means for washing the hands and headgear should be provided. Workers should not have beards or moustaches.

Increasing use should be made of substitutes for colouring media with a phenylenendiamine basis. The processes of fur-dyeing should be closely supervised when the products in question are manipulated. There have been recommended the use of the most dilute solutions possible and the restriction of the utilisation of the mordant until the very moment at which the furs are dipped. Coloured skins should be thoroughly washed in running water, dried, and thoroughly beaten for several hours in a revolving drum containing sawdust or some other similar substance.

LEGISLATION

See articles "Aniline", "Chemical Trades" and "Nitro and Amido Derivatives".

Parasites

Under the name of parasitic diseases are designated those disease forms caused by animal parasites either Protozoa or Metazoa (worms, acari, insects).

Like agents of infection, parasites under special working conditions may give rise to occupational diseases, certain of which are, however, more frequent in certain tropical countries.

Reference should be made to the article "Infectious Diseases" for general considerations. Here it will suffice to recall that, besides the direct effect which they exercise, parasites also play a part in the transmission of certain infectious diseases.

To avoid passing in review the whole human parasitology, this article will be confined to enumerating the parasitic diseases reported by various authors as having been at times of occupational origin, giving a very short account of these since fuller details will be found in treatises on special pathology. (See also articles "Ankylostomiasis", "Anguillulosis" and "Infectious Diseases", in which certain parasitic affections have already been dealt with.)

ASCARIASIS. — This disease is due to a nematode worm (Nematelminia), the *Ascaris lumbricoides*, an intestinal parasite peculiar to man which transmits infection by accidental ingestion of eggs. Workers digging the soil, engaged in cultivation, and miners are particularly exposed. The presence of merely one infected and dirty individual disregarding all hygienic precautions is sufficient to give rise to veritable epidemics of ascariasis (Brumpt).

BALANTIDIOSIS (Balantidium dysentery). — A disease due to *Balantidium coli*, an infusorian parasite of the intestine, the host in general being the pig. In numerous cases persons in contact with this animal become contaminated (pig-farm attendants, workers in pork butchers' shops). The disease is likely to be confused, in regard to its symptomology, with amoebian dysentery.

BOTHRIOCEPHALOSIS. — Disease caused by the "*Botrichcephalus latus*" a broad tape-worm, the larvae of which are often found in lake fish; and are considered by some authorities as an occupational disease of fishermen (Quarelli), who become contaminated during manipulation (gutting fish) or by ingestion.

CYSTICERCUS DISEASE. — An affection produced by the larvae (*Cysticercus cellulosae*) of a tape-worm (*Platyhelminia*), the *Taenia Solium*, the usual parasite of the pig, also known as "hyatid" or "pork measles". Certain social conditions may favour contact with faecal matter or soiled objects (rag-sorters) or infestation by *T. Solium* (butchers, pork butchers). Man becomes infested by absorption of the eggs in carrying these to the mouth on soiled hands. In the stomach the eggs give birth to embryos which are thereafter distributed through the whole circulation of the system and become the centre of cysts which give rise to varying symptoms according to their localisation (brain, eye, muscles, cellular tissue, heart, etc.).

DIPYLIUMASIS. — According to Guer-rini, this is the only infection by *Cestoda* which may assume an occupational character. The disease is due to the *Dipylium Caninum*, a parasitic worm peculiar to the dog and at times the cat. This disease affects especially those in contact with the animals in question (keepers, trainers, dog-shearers, poachers, dog-catchers).

The most usual intermediate host is the dog flea (*Ctenocephalus Canis*) and even the human flea (*Pulex irritans*) in its adult state. Man becomes infested by caressing animals or through swallowing the parasitic flea.

INTESTINAL DISTOMATOSIS. — Affection due to *Fasciolopsis buski*, a fluke which chiefly affects agricultural populations. The disease is characterised by a more or less lengthy latent period (sometimes several years), followed by diarrhoea (yellowish fetid excreta), which may last several months, and then by a terminal period of oedema of the abdomen and lower limbs. Prognosis is serious only in advanced cases complicated by oedema and intense anaemia.

PULMONARY DISTOMATOSIS. — See Paragonimiasis.

ECHINOCOCUS DISEASE. — Disease due to the larvae of the *Taenia Echinococcus*, a flat worm habitually a parasite of the dog and especially affecting persons in contact with this animal (those engaged in cultivation, shepherds, butchers, pork butchers). Man becomes infested by ingestion of the eggs: food soiled by infected excreta of the dog, intimate contact with dogs having their mouths or tongues contaminated by eggs. Cases have been reported as affecting women in Iceland engaged in milking ewes contaminated with the excreta of sheep dogs (M. Einarsson). The eggs swallowed lib-
erate hexacanth embryos in the stomach which become distributed throughout the system by the circulation and form the centre of cysts giving rise to various symptoms dependent on their localisation (liver, kidneys, abdominal cavity, lungs, etc.).

FORMS OF ITCH. — Forms of itch are cutaneous lesions caused by acari which live either on animals or on vegetables. There are also designated by this name the various types of dermatitis due to acari.

In addition to human itch due to the *Sarcopes scabiei* or itch mites, which may affect those persons coming in contact with dirty individuals or soiled clothing (nurses, rag sorters, etc.), there exists a whole series of animal itchies due to the habitual parasites of a large number of irritants. These forms of itch are almost always without furrows, assuming the aspect of millinary or polymorphous eruptions of a diffuse and pruriginous type, yielding easily to treatment, and healing.

Brumpt reports cases of transmission to man by the following animals: horse, donkey, mule (keepers, coaches, stable boys, veterinary surgeons, etc.); goat, sheep, pig (agricultural workers, shepherds); cat, dog, rabbit, ferret fox, (for instance, one case affecting a hunter who had skinned a contaminated fox), llama, camel (keepers: Cross); staff in menageries, amongst whom camel itch takes a fairly serious form (Brumpt).

*Trombidiosis* should be mentioned here (due to *Microtrombidium pusillum*, a type of harvest bug, the larvae of which infest chickens and various small wild animals (mole, hedgehog) and may attack man). They climb up the legs and accumulate at the level of any clothing which bars their progress (garters, suspenders, belts) causing pruriginous papules which at times set up fever and insomnia and may give rise to extensive erythema (autumn erythema). Agricultural workers and poultry breeders, gamekeepers and haymakers are often affected (Guerrini) and the condition is very prevalent in the Southern States of America.

*Ticks* (*Ixodes Ricinus*), the adult female of which lives on the skin of animals (dogs, cattle, sheep, horses, etc.), affixing itself by its rostrum, causes in man at the point of fixation a red oreole with a fair amount of itching and a small tumour when there is penetration under the skin (Blanchard, Mégnin). There are no further symptoms unless the animal, being removed roughly, leaves its rostrum in the skin, or unless there is inoculation by septic germs (*bacillus anthracis*: Calandruccio). Salamanque has described (1892) under the name of "ixodiasis" symptoms noted among Spanish peasants during haymaking, characterised by vomiting, urticaria, and diverse disturbances of a local and general order.

Other acari again alive on birds: pigeons (*Argas reflexus*), chickens (*Dermanusius avium* or *B. Gallinae*), and may affect persons engaged in rearing these animals. According to Guerrini, poultry breeders' itch is a form of dermatitis which is at first erythematous, then papular, eczematous, pustular, and highly pruriginous with lesions due to scratching caused by the bite of the parasite, the saliva of which is hemolytic and irritant.

A whole series of sarcopitidae live on grain and fruit or on the insect parasites inhabiting grain and fruit and may cause in man eruptions which are likewise pruriginous but disappear rapidly after some days. General manifestations are rare when these exist are due to toxines (Bernstein).

The chief form of dermatitis of this kind noted during manipulation of wheat is due to *Pediculoides Ventricosus acarus*, which is a parasite of the larvae and nymph of a type of lepidoptera (wheat linea or moth). It causes in man a polymorphous, papular or papular-vesicular erythema accompanied by very violent itching and sometimes fever (temperature 39-40° C.; grain fever: Guerrini). This disease occurs amongst agricultural workers, sorters and cleaners of grain, millers or carriers engaged in transport of grain, carters, railway workers, but chiefly amongst dockers, amongst whom veritable epidemics have been reported on several occasions in different countries (see article "Dock Labourers").

Analogous forms of dermatitis have been noted during manipulation of cotton (London dockers engaged in transport of cotton seeds (O'Conner, 1913), dried peas (Macri, 1915; Nixon, 1916), straw, cereals (Sachs, Schamburg, Sberna), barley (Hodara, Behrdjet, Sureva), and amongst warehouse workers (Blaschko, etc.).

Other forms of dermatitis are due to the *sarcopitidae* (*Tyroglyphus longior*) found on coconuts. Castellani has described "copra itch" amongst workers handling coconuts in the country of origin, and also amongst workers unloading these in ports.

The same author has described "pineapple estate pyosis" amongst planters of pineapples in Central America,
characterised by pustulae and ulcerations located on the arms and legs and which he attributes to the action of arcari, though he was not able to prove this.

Other analogous forms of dermatitis have been noted amongst workers in tea plantations in India (for example, *Rhizoglyphus Paraticus*, a cutaneous eruption commencing between the toes and spreading to the ankle-bone: Dalgetty), amongst workers handling vanilla pods containing moths or moulds (*Tyroglyphus Siro*). (See articles "Perfumes" and "Skin Diseases").

There has likewise been reported a form of itch affecting grocers (Murray) due to *Glycyphagus domesticus*, characterised by a violent eruption of the skin which is, however, transient, similar to itch due to *Tyroglyphus point豇豆* caused by wheat from certain districts (Moniez).

The title of this article is extended to cover bites and forms of dermatitis due to certain insects, among which may be mentioned mosquitoes (Oxitec pipiens, *culex anulatus*, etc.), anopheles mosquitoes, which bite workers in forests and fields and set up forms of urticaria and eczema at times complicated by lesions due to scratching.

Brumpt has noted amongst market workers engaged in the sale and transport of large game bites due to lipoptene (*Lipoptene cervi*), which live in the month of September on large game (deer, roe deer, wild boar) and set up analogous lesions (leaving no immediate visible lesion), a hard pruriginous papula which sometimes persists for fifteen days. Brumpt refers also to analogous lesions (invisible bite with appearance on the following day of a slightly pruriginous papula) due to an insect *Melophagus ovinus*, which lives in the fleece of sheep and often bites workers during shearing.

**MYIASIS. —** Under this name are designated certain skin affections due to insect larvae (*Diptera brachycera*). The larvae which are essentially parasitic cause cutaneous myiasis (sub-cutaneous spreading myiasis, sub-cutaneous myiasis with creeping tumours, myiasis accompanied by carbuncles): the larvae which, on the other hand, are free living, i.e. not essentially parasitic, set up myiasis in the body cavities and intestinal myiasis.

Creeping myiasis starts with an extremely painful sub-cutaneous spot and spreads in a cutaneous manner, its progress being traced by a red ecchymotic line, which is effaced in several days. When the larva accomplishes its exit, the pain remains stationary and a small tumour develops at the spot, the apex of which becomes perforated, permitting the exit of the larva and at the same time of a seropurulent liquid. Amongst the larvae may be mentioned those of *Cochliomyia macellaria*, which at times gives rise to serious symptoms among breeders of domestic animals (Brumpt): of *Phormia regina*; and of *Gastrophilus intestinalis*, a case of spreading sub-cutaneous myiasis being recorded as having been caused by the latter and affecting a groom at Saskatchewan, Canada (case recorded by S. and L. Corrigan in 1925).

Sub-cutaneous myiasis, accompanied by spreading tumours characterised by a type of carbuncle occurring at the moment of exit of the larva, is well known amongst peasants in Norway (Hoegh), Ireland and Scotland (Whitaker, McCalman) and in Brittany, etc.

Myiasis of the cavities is due to the development of larvae of the dyptera in the natural cavities of the body (nasal fossae, orbit of the eye, external auditory meatus, genital and urinary passages and wounds, etc.). There have been recorded cases of ocular myiasis amongst shepherds (Galvagni, 1845), cases of myiasis of all the natural cavities of the body amongst arab shepherds in Algeria due to *Oestrus ovis*, and cases of vulvitis and vaginitis caused by myiasis amongst field workers (Jarisch).

An affection which resembles forms of myiasis is "cheese workers’ itch" (Guerrini), affecting persons engaged in the cheese industry, especially those who handle milk; shop assistants and those engaged in the transport of cheese are also affected. It is due to *Piophila casei*, a cheese maggot which lays its eggs in cheeses and on the residual products of fermentation. The larvae having once developed, may settle in the inter-digital spaces, on the back of the hand and forearm, setting up punctiform and linear lesions with a pigmented base, raised and hyperaemic edges accompanied by pruritis and aggravated by lesions due to scratching (Guerrini).

**ONCHOERCOSIS (VOLVULOSIS).** African onchoercosis is a cutaneous disease due to a thread worm *Onchocerca Volvulus*. According to Brumpt, in the Belgian Congo 5 per cent. of the peasants are affected by this disease, which is characterised by a papulopustulous and very pruriginous eruption or by lichenification of the skin and elephantiasis.
American onchocercosis is due to *Oncocerca Caecutiens* and consists in cutaneous lesions accompanied by general symptoms (erysipelas of the Guatemalan coast), encountered chiefly amongst workers on the plantations (Joyeux).

**Oxyuros.** — A disease due to a round worm (*Nemathelminia*, *Oxyurus Vermicularis*), a parasite peculiar to man and inhabiting the large intestine.

Infection occurs by accidental ingestion of the eggs. Social conditions are only an influence in so far as they multiply opportunities of contact between infected individuals and healthy individuals or between the latter and the excreta of the former (soldiers, miners, cesspool workers, etc.: Brumpt). Guerrini has recorded cases of this disease characterised by anal vesperal pruritis amongst laundry-women engaged in washing clothes by old methods, infection occurred by accidental ingestion of faecal matter from the soiled clothing. Those most liable to infection are the workers who collect and sort the linen rather than those actually engaged in washing and drying.

**Paragonimosis.** — This disease, well known as "pulmonary distomiasis" or "parasitic haemoptysis", is due to a flat worm, the *Paragonimus Westermani*, a habitual parasite of domestic animals.

It is characterised in its most usual pulmonary form by coughing, blood-stained sputa and at times general benign haemoptysis, which may, however, endanger life.

The cerebral form, which is a complication of the above, is characterised by headache, vertigo and epileptiform attacks.

According to Guerrini, the disease in question is chiefly an affection occurring in mountainous regions and affecting particularly quarrymen, stoneworkers and workers in marble quarries.

**Pediculosis.** — In its three forms — pediculosis of the head (Pediculus capitis), pediculosis of the body (Pediculus vestimenti) and pediculosis of the pubis (Phthiriusinguinalis) — this disease is met with amongst individuals (nurses, rag merchants, etc.) coming in contact with contaminated persons or material.

**Sarcopsylliasis.** — Disease due to the *Sarcoptes ou pulex penetrans* or jigger, an exotic insect (tropical America, Africa). The female, after fertilisation, penetrates under the skin of warm-blooded animals or man (feet and legs). Native porters are very often affected (Brumpt).

**Trycocephalosis.** — A parasitic disease due to a nematoid worm, the *Trycocephalus hominis* or *Trichurus Trichiura*, a parasite known as the whipworm, peculiar to man, the infection being caused by swallowing eggs in the embryonic state. These live in water and in the ground, and are resistant to heat, cold and putrefaction. Eggs may be ingested with drink or food in the raw state or may be carried to the mouth by dirty hands (miners, farm workers).

The symptoms consist in nervous and digestive troubles and at times pernicious anaemia.

**Pearls (Artificial)**

**French:** *Perles artificielles (fabrication des)*. — German: *Fabrikation unechter Perlen*. — Italian: *Fabbicazione di perte artificiali*. — Spanish: *Perlas artificiales (fabricacion de)*.

**Technical Data**

The first artificial pearls made were hollow. Though at the present time solid pearls are the fashion, hollow
Pearls (Artificial)

Pearls are still manufactured in large quantities and for a number of special purposes: for trimming dresses, for large earrings, etc. Hollow pearls are essentially transparent beads made of blown glass, the interior wall of which is coated with a nacreous lustre. This lustre is obtained by injecting into the glass bead a mixture formed of gelatine and a product known as essence d’Orient. Except in the case of very high class pearls, this mixture is introduced mechanically into the bead. After filling, the pearl is emptied, leaving only a thin layer giving the nacreous shading. For this purpose the pearl is slightly heated and then allowed to dry. Finally, in order to give it weight, it is once again filled with white wax which is injected by blowing by the mouth or mechanically, a vacuum being created under the tables of a pneumatic machine. The pearl is again dried, then washed to remove external soiling.

Pearls made in this way conserve their appearance perfectly as long as they are not washed in hot water or brought into contact with alcohol solutions.

Contact with the skin has no effect on these pearls since they are coloured internally. The colouring process is practically the same for all colours and consists in the addition of colouring matters to the solution used for imparting the nacreous lustre. The hollow pearls are sometimes rendered iridescent. In this case it is the outside of the bead which is iridesced by applying salts of titanium in a hot state. The manufacture of these pearls does not, in short, involve the use of any toxic product. Complaints have been made in regard to the operation of blowing glass beads by the mouth. This operation, effected by women, consists of blowing into the inside of the bead the mixture of essence d’Orient and gelatine. Continual repetition makes it a tiring process, but there is no further inconvenience. It has been alleged, without proof, that tuberculosis was of frequent occurrence amongst these women workers. In fact, only the manufacture of the small hollow glass beads is trying and may cause chronic poisoning by reason of the combustion gases liberated in the overheated and badly ventilated workshops in which the women are engaged.

For the last ten years the manufacture of “solid pearls” has been carried on on a very large scale. It is totally different from the preceding process; the principal operations are as follows:

The small solid bead is made of a milky enamel which is caused to adhere in a molten state to a hollow copper wire by means of a blowpipe. Women and young girls do this work by hand. Beads are then detached by plunging the wire, which serves as their support, into nitric acid, which dissolves the copper. The beads thus prepared are stuck on to iron or wooden supports fixed on a wooden board covered with plastic material. The operation of imparting a nacreous lustre then follows. The solution employed for this purpose consists of an alcohol-ether collodion which is mixed with essence d’Orient. A series of processes consisting of dipping and drying then follows, terminating with dipping in an anyl acetate collodion.

About five years ago certain manufacturers, instead of following the above process, commenced to use a collodion consisting of tetrachlorethane. This collodion possessed the advantage of not being inflammable and of providing a more solid coating substance. Its use has, however, been given up for reasons which will be mentioned later, and consequently there are no more serious cases of tetrachlorethane poisoning to deplore. Pearl manufacturers no longer use this product unless for the manufacture or iridescent pearls, and therefore in very small quantities.

An iridescent aspect may also be obtained by the use of bismuth oxychloride.

For setting, a white lead paste is often used.

Pathology

The workers engaged in the artificial pearl industry are subjected to various kinds of poisoning more or less serious in character. The manufacture of beads involves exposure to slow poisoning due to liberation of volatile products in the incomplete combustion of the gas, carbon monoxide being present. The melting of the copper wire in nitric acid gives rise to intense liberation of nitrous fumes, which constitute grave danger for the respiratory passages.

Amongst the products employed in imparting a nacreous lustre to the
pears is amyl acetate, which though not very poisonous may cause transitory symptoms: vertigo, headache. At the end of eight or ten days, the majority of women workers no longer feel the effects of this solvent, which has a characteristic smell noticeable at some distance.

On the other hand, tetrachlorethane has been the cause of serious cases, some of them fatal. In France, Frois has reported three cases of this type. The victims, three women, were employed in dipping the pearls. All three died of toxic jaundice due certainly to tetrachlorethane fumes. Frois made an investigation in the factories in which these women workers were engaged, and in a paper read to the Academy of Medicine on 11 July 1922, called the attention of the medical authorities to the dangers attending the use of tetrachlorethane in pearl factories.

Clinical observations made in this connection date from the same time. In 1922, Leri and Breitel described two interesting cases met with amongst pearl makers who suffered from polyneuritis with anaesthesia and paralysis of the fingers and toes, accompanied by interosseous atrophy. They also found symptoms affecting the central nervous system, with loss of deep tendon reflexes, ataxia in walking, cramp, heaviness of the limbs, but no pain. The tendinous reflexes may be entirely abolished; the pharyngeal reflex and the soft palate are affected at an early stage. Recovery was very slow. The two workers in question had been engaged in dipping the pearls and exposed to toxic fumes during ten hours per day. Before using the coating material they filtered it under pressure through a cloth, and so had their hands covered with it. These authors admit of two paths of absorption of the toxic product — by way of the respiratory passages and by way of the skin — with a possible third entry by way of the digestive tract.

At the sitting held on 15 January 1923 of the Forensic Medicine Association of Paris, Leri cited the case of a woman worker employed in the manufacture of artificial pearls who showed the following main symptoms: jaundice and, as regards the nervous system, also symptoms resembling drunkenness, ataxia in walking with paralytic phenomena affecting the extensors and interosseous muscles. There was loss of the tendinous reflexes, of the pharyngeal reflex with anaesthesia at the level of the toes and retarded response to electric stimuli. Similar symptoms appeared in the case of a woman worker who had preceded the patient on the same work.

Fiesinger, Brodin and Wolf have related two cases, one a young girl employed in drying pearls who at the end of three weeks' exposure to tetrachlorethane fumes suffered, after a short phase of digestive trouble, from benign jaundice with transitory amenorrhoea. The second case, one of those referred to by Frois, had fatal consequences: a woman aged forty-six lost, followed by alcoholic excess, who suffered at first from benign jaundice complicated later by other symptoms. After a rest she returned to the factory, but developed severe jaundice which ended fatally.

The two other fatal cases of jaundice quoted by Frois occurred in a different factory. They have been described by Charbonnier in his thesis. The victims were two young girls engaged in dipping pearls in a badly ventilated factory. They suffered from digestive troubles, anorexia and vomiting, followed by jaundice of a toxic character which was not immediately diagnosed.

A Russian study dated 1930 deals with working conditions in a factory making artificial pearls and the paste for them. The chief source of injury resided in the use of amyl acetate and ether (solution of nitrocellulose in allyl alcohol). The women workers inspected complained of nervous troubles, headaches and fatigue. The liver was distended and painful under palpation. Examination of the blood revealed irritation of the haematopoietic organs (S. Frumkina).

**HYGIENE**

The workshops in which beads are made by blowpipe should be spacious with high roofs and well ventilated from the upper part. It is difficult to install ventilators with a big drop in pressure, for the work cannot be carried on effectively in a draught, since the flame from the blowpipe must remain upright in order to melt the enamel in a satisfactory manner.

Dipping in nitric acid should be effected under an exhaust hood provided with a chimney which draws well. This process was, a matter of fact, given up some time ago. Instead of making the bead by hand on a hollow copper wire, the enamel is now attached by the blowpipe to a solid copper wire stretched between two supports. To remove the beads it is only necessary to withdraw the wire.
Hygienic conditions are much more satisfactory where this method, which is patented, has been adopted.

Imparting a nacreous lustre to the pearls may perfectly well be effected with alcohol-ether and amyl-acetate collodions, and the use of tetrachlorethane colloid should be forbidden, at least for this purpose. In France the majority of manufacturers have already been requested to abolish its use. They have, moreover, admitted that pearls made in this way are apt to have a rather indefinite smell, recalling that of chloroform. With the elimination of tetrachlorethane colloid in coating the pearls the serious toxic accidents referred to above have disappeared.

For the making of iridescent pearls tetrachlorethane is frequently used, but only in exceedingly small quantities.

All the above operations, whether dipping, coating or rendering iridescent, should be effected inside glass cages, provided with holes through which the arms of the workers are passed, and at the bottom of these cages there should be installed a pipe communicating with an exhaust duct, creating a slight drop in pressure and removing the toxic fumes.

As a general rule, workrooms where these operations are effected should be spacious, well aired and well lighted.

Special precautions require to be taken for the safety of the staff since the products manipulated are particularly inflammable.

Though the use of tetrachlorethane is at present limited, periodical medical supervision is advisable, as early diagnosis would permit of the withdrawal of women workers in danger of developing poisoning.

Also, it is advisable to exclude from this work women suffering from any kidney or liver trouble. It should be noted particularly that relapses are extremely serious, if not fatal, in the case of the poisoning in question.

On account of possible absorption of the toxic product by way of the skin or digestive passages, strict personal cleanliness should be demanded on the part of the women workers. Cloakrooms and adequate washing accommodation should be available. After several months a rest of two or three weeks and change of work is advisable for women engaged in the manipulation of the toxic products in question.

For compensation in the case of injuries due to tetrachlorethane, see that article.

**Perfume and Essence Industry**

Under the name of perfumes are designated a large number of natural or artificial products of complex composition characterised by their smell. The majority of natural perfumes come from plants in which they are found in a state of essential volatile oils. According to the plant in question these essential volatile oils are contained in different parts: root, underground stalk, wood, bark, leaf, flower, fruit or seed. Some plants furnish besides several characteristic perfumes varying with the part from which they have been extracted: anise, bergamot, lemon, iris, lavender, jasmine, neroli or orange flower oil, origanum, geranium, etc.

The essential oils are generally present in the form of volatile odoriferous liquids capable of distillation without being subjected to decomposition and are composed of different constituents, in one or several of which is concentrated the characteristic aroma of the essential oil. These oils are generally soluble in absolute alcohol, ether, carbon bisulphide, petrol and numerous other organic solvents.

The properties and composition of the various essential oils differ greatly. The isolated compounds of these oils are generally hydro-carbides of the terpene series, alcohol ethers, especially ketones of the terpene series, or alcohols of the geraniol or citronellol type, phenols and their derivatives (etherophenols), substances of the alkaliphatic series, acid and ether compounds, lactones and oxides, nitrated or sulphurated compounds.
Perfumes of animal origin are the product of secretions or excretions. Amongst the principal of these may be mentioned musk, civet, ambergris, castoreum.

Artificial perfumes do not generally possess such a fine odour as these natural products, but have the advantage of being usually much cheaper. Certain perfumes are the synthetic reproduction of the odoriferous principles of natural perfumes. Others are new odoriferous products having the same odours as the preceding ones but not their chemical constitution; others again are entirely new perfumes. Certain substances, moreover, though having a similar odour to that of natural products, are not found in nature.

It was a synthetic production of vanillin by Tiemann and Haarmann which marked the rise of the artificial perfume industry, which is now steadily developing. Amongst the substances which are used for artificial reproduction of some elements constituting the characteristic perfumes of natural products may be mentioned acetate of lynal (bergamot essence), benzoic aldehyde (essence of bitter almonds), methyl salicylate (essence of gaultheria), coumarin (tonka beans), as well as a number of other products: terpineol (essence of cardamom, marjoram), borneol (aspic, lavender, rosemary, marjoram), etc.

It is absolutely impossible to cite all the substances possessing an odour similar to these natural products or perfumes. It must suffice here to recall the following: beta-naphthol ether (acccia), nitro-benzene (bitter almonds), acetophenone (various aromatic odours), anisic aldehyde (new mown hay, hawthorn, or May blossom), benzilidine acetone (coumarin, sweet pea), salicylic aldehyde (“queen of the meadow” essence), amyl acetate, ethyl acetate, iso-benzylidene acetone (“enfleurage” concrete from which the essential oil is separated by extraction with alcohol).

It is absolutely impossible to cite all the substances possessing an odour similar to these natural products or perfumes. It must suffice here to recall the following: beta-naphthol ether (acccia), nitro-benzene (bitter almonds), acetophenone (various aromatic odours), anisic aldehyde (new mown hay, hawthorn, or May blossom), benzilidine acetone (coumarin, sweet pea), salicylic aldehyde (“queen of the meadow” essence), amyl acetate, ethyl acetate, iso-benzylidene acetone (“enfleurage” concrete from which the essential oil is separated by extraction with alcohol).

Industrial Operations

A. — Preparation of Essential Oils

This is done by means of different processes varying in accordance with the kind of essential oil to be obtained.

(1) Extraction by hydraulic press (for substances rich in volatile oils: orange juice, lemon juice, etc.). — The oils obtained are separated from the aqueous liquids by means of decantation and filtration.

(2) Distillation (in the case of certain flowers containing odoriferous substances in almost complete form). The products are generally distilled in a fresh condition but sometimes after drying or conservation in salt water. Where the products in question consist of seeds, wood or roots, they are shredded or grated prior to distillation; others are submitted to fermentation by simple maceration in water in order that the fermenters and enzymes may liberate essential oils fixed in the plant in the form of glucosides or other combinations.

Distillation may be effected by water or by steam (sub-pressure, reduced pressure, vacuum). The essences and perfumed waters are obtained directly and collected in suitable recipients.

(3) Extraction by use of a volatile solvent (for delicate flowers poor in essence, or for certain other products: sandalwood, cedarwood, rhizomes of the iris plant, vanilla, etc.). — Alcohol, petrol ether, ether, chloroform, carbon bisulphide and benzine are the chief solvents used. A compact mass formed of essential oils mixed with wax, fatty and resinous substances is formed, these substances being the “concretes” from which the essential oil is separated by extraction with alcohol.

(4) By means of non-volatile solvents (“enfleurage” by a cold process or by absorption”). — On each side of a glass placed in a wooden frame or “chassis” a layer of fat is spread (beef, pork or mutton) which has been purified, and on to this the flowers are spread and left for a period varying in each particular case. The frames are piled one on top of the other and the plant continues in flower, which usually involves a period of two to three months, this process being continued until the fat is completely saturated with perfume. In enfleurage by the hot process, or by maceration, the flowers are thrown into the melted fat, which is steam-heated in a double recipient, and when the flowers are used up they are removed and replaced by others until the point of saturation of the fat is reached.

At times solid fatty substances are replaced by olive oil, or better still by vaseline or paraffin, which possess the advantage of not turning rancid. In the first case, material spread on frames is impregnated with olive oil and the process is effected as described
above in enfleurage by the cold process. The material used is then subjected to pressure for extraction of the perfumed oil. In extraction with vaseline the flowers are placed between the plates of a filter press heated to 50° C., which removes the molten vaseline.

The fatty substances charged with perfume constitute a kind of wax which, subjected to suitable treatment, provides essential oils. The latter are thereafter freed from their insoluble impurities (water, pectic and mucilaginous substances) by allowing them to stand for a certain time, by decantation and filtration; and from soluble impurities (varieties of waxes, fats, resins, colouring matters), by means of distillation and rectification.

The essences are mostly subjected to a process of determinisation with a view to ridding them of inodorous or slightly odorous compounds (terpenes and sesquiterpenes), thus increasing the strength of the perfume and rendering them more soluble in dilute alcohol, and at the same time assuring better conservation.

The final products obtained constitute concentrated soluble essential oils (deterpine essences, quintessences and absolute essences). Their solutions in alcohol constitute the flower “extracts”, which after removal of the alcohol by distillation in vacuo give the “absolute flower oils”.

B. — Manufacture of Artificial Perfumes

This is highly important, since the majority of natural perfumes have been reproduced by synthetic processes, but many are still extracted from low-priced natural essential oils, either by fractional distillation or by other mechanical operations. The most important are perhaps ionone (violet odour) and vanillin (odour of vanilla).

Recent developments in the technique of the manufacture of artificial perfumes consist in the discovery of juperitone and synthetic thymol, and especially in the perfectionment demanded by fashion which singles out a particular perfume. There should be mentioned also the synthetic preparation of borneol, connected with that of camphor and terpinol. The synthetic preparation of thymol by simple hydrogenation gives menthol, and that of menthol — which can also be produced by reduction of piperitone — gives vanillin or hydroxycitronellol.

C. — Preparation of Various Perfumery Products

Essential oils and artificial perfumes are employed in the manufacture of a large number of well-known toilet preparations in liquid, solid, paste or powdered form. Certain essential oils or certain synthetic perfumes are used in the manufacture of artificial aroma for wines, liqueurs, confectionery, and in the food, pharmaceutical, paint and varnish, etc., industries. Besides extricents which receive the perfume there are often added fixing agents designed to retain the transient odours as long as possible. These are either substances with their own very durable perfume; or inodorous substances capable in a high degree of holding the very volatile essential oils, or again they may be absolute essences (of flowers), resinous substances, oleo resins, or finally compound fixing agents. The fixing agents chiefly employed are amber, musk, civet, ambrette, benzoin, storax, Peru balsam, balm of tolou, incense, myrrh, etc. Amongst the artificial products may be mentioned the ethers of formic acid and of benzyl (acetate, benzoate, salicylate).

Natural colouring agents are used for colouring perfumery products (saffron, false saffron, caramel, cocheinal, campeachy wood, sorrel, etc.), and more commonly artificial colouring agents.

After preparation the perfumes are kept until the various products they contain have become thoroughly homogeneous.

TOXIC ACTION

Injuries met with amongst workers in factories for the manufacture of perfumes or perfumery products have been related either to the harmful action of the products manufactured or handled, or to the action of the odours involved.

The disinfectant and narcotic effect of ethereal oils is known (Geinitz, 1912); likewise, that of thuyone of myristicine, of nutmeg, of wallflower (Jürso), of safrone and isosafrole (oil of saxifrage) (Heffter and Waldvogel), of coumarin, of essence of odoriferous asparagus, and of clover (Rober). In guinea pigs the fumes of essence of anise (Albein, Meunier and Cadéac) immediately cause excitement, violent irritation of the nasal and mucous membrane, spasmodic movement and fibrillary trembling recurring every five to six seconds. The animals thereafter show signs of inebriety and somnolence, which lasts for a long time.
With slight doses the effects are less intense and more transient. Similar symptoms have been noted in experiments on frogs. In 1879 Masoin and Bruyland caused convulsions, somnolence and trembling in pigeons and rabbits. The most toxic of the essences utilised was that of rosemary, followed by thyme and lavender; essence of marjoram was almost without effect. These essences have been considered as likely to give rise to convulsions on account of their terpene content.

Here (1893) brought about retarded development, miscarriage, and production of monsters by submitting eggs to the action of anise, wallflower and lavender.

In a general manner it may be said that the injuries due to essential oils are analogous to those caused by ethers, hydrocarbides and aldehydes. Still more serious lesions have been noted (nephritis), and even tumours (see article “Occupational Diseases: Urogenital System”). Apart from a general toxic action in the strict sense essential oils may affect the mucous membranes (eyes, nose) or the skin, causing localised irritation related partly to the phenomena of ana-phyllaxis, and interpreted most commonly as resulting from individual constitution. Other sources of danger are represented by solvents used for the extraction of the perfumes. Hayhurst has reported a case of acute poisoning due to ether.

As regards odours (see that article), it must be stated, on the one hand, that the majority of workers usually become accustomed to the odours connected with their occupation, and, on the other hand, that concentrated essential oils have in any case very little odour. At high concentration has such a feeble smell that the first person who succeeded in manufacturing it did not recognise its value as an odoriferous product. It is in fact only by means of dilution that these products acquire value as perfumes.

STATISTICS

Statistical data are very scarce. Reference may be made to a health enquiry made by the New York Bureau of Women in Industry (1928) which, for a period of three months, collected medical statistics concerning three factories employing a total number of 1,757 workers. The majority of the operations were dusty, and consequently the chief disorders found were irritation and diseases of the upper respiratory passages. In one factory employing 660 women, there were 526 cases of disease, of which 26.2 per cent. were respiratory; in the second employing 388 women, 554 cases of disease, of which 46 per cent. were respiratory; and in the third employing 708 women, 2,411 cases of disease, of which 34.4 per cent. affected the respiratory system.

This enquiry revealed the importance of hygienic working conditions. In fact, the factory which had the most defective conditions from this point of view had an average of 3.45 cases of sickness per employee, whilst in another — in which greater attention was bestowed on hygiene — the average fell to a little below one case per employee.

PATHOLOGY

The manufacture of odoriferous oils and essences is likely to give rise to similar accidents to those met with amongst workers exposed to alcohol ether fumes. The more marked convulsive phenomena noted are to be explained by the greater toxicity of the fume.

Certain authors have asserted that inhalation of perfumes handled (workers in the perfumery industry, bottling, retailing of volatile essences) may give rise to all the evil effects of aroma poisoning. According to Imbert-Guerbeyre, Lanceraux and others, staying in an over-perfumed atmosphere tends to cause acute and chronic symptoms characterised by headache, vertigo and neuralgia (of the head), especially amongst new workers. Perfumes or essences of hyacinth, heliotrope, jasmine, tuberose, musk and patchouli are said to cause violent headache rather easily (Layet). They are colloquially called “heady” perfumes. Other symptoms noted are a state of general discomfort accompanied by sweating, nausea, cardiac oppression, vomiting, muscular and articular pains, nervous and digestive troubles, and general weakness. According to Layet, certain perfumes are said to be more likely than others to cause discomfort amongst those obliged to manipulate them, and he noted in particular the perfumes or essence of almonds, which enters into many perfume preparations; the perfumes or oils of citron (Citrus medica genuina), bitter oranges, bergamot and lemon give rise to nervous disturbances and are fairly characteristic amongst the workers who grate the rind of the fruit.

Injuries vary according to the process of preparation followed. Layet noted that in his time workers engaged on distillation were more frequently attacked, and that nervous disorders of a complex nature were very frequent amongst workers engaged on extraction of perfumes by means of ether
and carbon bisulphide. Diseases of the respiratory system were likewise of not infrequent occurrence.

Lehmann, however, states, on the evidence of a large German factory for the production of essences and perfumes, that at the present time there may hardly be said to be any specific diseases affecting workers engaged in the manufacture and mixing of ethereal oils. In drawing attention to the fact that medical literature contains accounts of numerous cases of persons who had developed illnesses as the result of having inhaled the perfumes of large quantities of oranges and of flowers, Lehmann considers that the individuals in question must have been particularly sensitive, and that it would be hard to determine whether the diseases noted were entirely caused by the perfumes inhaled. It is, however, certain that perfume workers are hardly ever, if at all, inconvenienced by their work, for according to certain authorities the sensorial terminations of the olfactory organ are quickly dulled by odorous substances when the latter are present in an unduly large quantity. Whilst, however, tolerance seems to be the rule, there are nevertheless certain susceptible individuals and particular idiosyncrasies, notably as regards certain substances (for instance, phenyl-acetaldehyde and indol).

Amongst local injuries there have been noted cases of acute rhinitis and epistaxis, as a reaction to stimulation of the mucous membrane amongst hunters of musk-deer. There have likewise been noted various olfactory developments at times; there occurs a persistent sensation of the odour noticed during work (chiefly at meal times): at times there is attenuation and tolerance with marked exhaustion of the olfactory sense.

Forms of conjunctivitis are frequent, as well as styes, and sometimes even lesions due to foreign matter (dust, etc.). Dermatitis and lesions of the nails, especially discoloration of the nails, are also common.

In the American enquiry referred to above, lesions of the latter type were of higher incidence than amongst workers engaged in a candy factory and much higher than the general figure for occupational dermatitis. The lesions generally consist of boils on the hands, and more especially on the face and neck.

A woman worker engaged in dipping toothpicks in cassia oil (a type of acacia plant), to give them an agreeable odour, suffered from dermatitis of the hands with vesicular eruptions, redness and spots on the face and abdomen. This oil was a cheap substitute for cinnamon oil (Prosser White). Eruptions with erythema, papules and vesicles situated chiefly on the hands are caused by essential oils of orange (Kober and Hanson). Serious and obstinate cases of dermatitis have been noted amongst perfume makers and workers engaged in the preparation of hair lotions (Sachs). Particular symptoms are also reported as occurring in consequence of manipulation of distillates of copaiba balm. The urine had a violet odour similar to that caused by turpentine essence.

Similar accidents have arisen from manipulation of vanilla. As far back as 1883, Layet referred to lesions frequently encountered at Bordeaux, at which port 23,000 kg. of vanilla are unloaded per annum. The work in the warehouse was distributed as follows: sorting with a view to separating vanilla in good condition from vanilla containing moths or moulds, brushing to remove the moths and moulds from the pods, repacking or boxing the pods.

Verdalle found a case of vanillism affecting a worker engaged in a liqueur factory in cutting the pods into small pieces. Other cases of vanillism have been studied by Hutchinson (London) and Schultz (Wurzburg) in 1892; by J. C. White in 1893 and by Guérin (Paris) in 1895, who noted erosions and superficial excoriation of the eyelid due to the oil contained in the pods, conjunctivitis at times simple and at times accompanied by ulceration, painful tension and heaviness of the eyes, progressive weakness of sight which in certain cases amounted to amaurosis; by Gieseler (Bonn thesis, 1896), Harning (Berlin, 1897), Audéoud (Geneva, 1899), Brock and Fage (1906), Haley (1906), etc. The causes of this disease have been the subject of much discussion. According to certain authors, the injuries are said to be due to a parasite closely related to the acarus (Valin, 1897). Others attribute the affection to the action of moulds, and others, again, to a substance used in preparing or reproducing vanilla. It must however be taken into account that even vanillas which have not undergone manipulation — in fact, the whole vanilla plant — are toxic (Claverie). It is for this reason that it has been thought that the harmful principle is contained in the oily juice which escapes from the pods, and that its action is aggravated by other factors (particular susceptibility, other irritant substances present, etc.).
In 1803 P. White noted cases of acute dermatitis which he attributed to the action of cardol (oil) rather than to that of an acarus from the pod.

According to observations of Brock and Page and others in cases of blepharitis and conjunctivitis amongst persons coming into contact with vanilla dust, the injury has again been attributed to an acarus or mould. Other authorities, again, have attributed the trouble to catechu colouring matter used for colouring the sticks of vanilla.

The sticks of vanilla are often placed in recipients containing alcohol. Splashes of this liquid may induce redness and dermatitis of the forehead, face, etc., amongst sensitive workers.

While studying a case of vanillinism, Lortat-Jacob and Solente (1929) were able to determine that the cause of the injuries was proteins present in the pod rather than the vanilla. The benzoic acid crystals found in the shape of a crystalline efflorescence consisted of a vanillin known as "givre", on the surface of the vanilla have also been blamed, since they constitute an irritant and cause a burning sensation.

Vanillinism is a disease at once general and local.

The general phenomena are represented by headache, vertigo, somnolence, singing in the ears, forms of neuralgia, cramp, insomnia, muscular pains and vesicular irritation. In the more or less serious cases studied by Audouëd cutaneous and nervous troubles were complicated by affections of the genital organs: genitic stimulation, lassitude, muscular pains, etc.)

Nervous symptoms (headache, giddiness, lassitude, muscular pains, vesicular irritation, etc.) have been attributed to the odoriferous emanations, and are met with especially amongst workers and chemists engaged in the manufacture of vanillin.

Cutaneous manifestations consist of papulo-erythematous eruptions on the hands, neck and face of a highly pruriginous type accompanied by oedema resulting very closely a form of erysipelas. The eyelids also are affected with oedema. Brock described a case of transitory alopecia of the eyebrows very shortly after the outbreak of the eruption. Furfuraceous desquamation of an intense type was present. The hair of the head remained unaffected.

In the slight form there has been noted papulo-erythematous and pruriginous eruption confined to the hands and certain parts of the body, together with headaches.

The recurring phenomena are chiefly the following: generalised eruption as soon as the worker enters the factory. Such workers are soon driven from the work. When this form of the disease is confined to small outbreaks of papulæ the patients may resume the occupation, though from time to time they suffer from more marked attacks. In a third series of cases the cutaneous symptoms are not very intense, and in a fourth absolute tolerance sets in. The cutaneous troubles are more or less marked during several years and finally they become quite mild.

There should finally be mentioned certain cutaneous symptoms described by Loriga, Sutherland-Campbell, Shapiro, Horner, etc., amongst workers engaged in peeling and squeezing lemons and oranges for the juice. According to Sutherland-Campbell, the complaint in question is a paronychia caused by a mould peculiar to the oranges which rapidly attacks the pulp of the fruit. In the case of the worker affected, the skin of the fingers in contact with the juice or the pulp is rapidly infected, and there is erosion of the nails with collection of pus underneath.

Loriga (1927) has studied cases of dermatitis caused by juice and essence of lemon. In general it is the left hand that is affected, more rarely the right. The skin assumes a whitish, pale colour, and dermatitis of a painful type, especially in cold weather, attacks the interdigital spaces and in the folds of the fingers, the nails travel up the arm and the worker suffers from nervous symptoms.

The nails are also affected, and a lesion of the periungal groove leads to the loss of the nail. If the worker suffers from warts these often become a central point of necrosis.

Mechanical work, which is steadily ousting manual work will soon succeed in eliminating this cutaneous disease.

The German factory inspectors, in their report for 1920, refer to a case of dermatitis affecting a worker who had manipulated lemon wood. It is possible that the lesion in question was due to the oil contained in the wood.

Hygiene

Perfume and essence factories are only included among scheduled trades by reason of certain dangerous features (smells, danger of fire where volatile solvents are handled, etc.). On this account they are
subject to certain regulations which will be found detailed in the articles "Odours", "Chemical Trades", and in the articles dealing with the products in question. Where the odour given off is faint and such that it does not constitute a nuisance for the neighbourhood, the workshops may simply be provided with a louver having blade shutters or small chimney stacks raised above the roof. It is, however, advisable that such chimneys should be brought to a sufficient height and turned so as to avoid inconvenience for the neighbourhood and for the factory workers (re-entry of the emanations by windows and doors, etc.). Treating the materials which liberate odours should be effected in closed vessels. It would also be advisable to have the apparatus covered with hoods connected up to a system of localised ventilation in order to remove the fumes. Very often there is every advantage in collecting and recovery of these products (solvents).

The same holds good of operations which involve manipulation of dusty materials or powder.

Cleanliness of workshops and tools should be observed. The workrooms should have impermeable flooring with tiled or cemented yards. Withdrawal of liquids from the workrooms should be effected in waterlight and subterranean piping leading directly to the drains or, where necessary, into vats for treatment. In the absence of drains in the neighbourhood, the liquids should be collected in waterlight vats where they can be neutralised and freed from odours. They should be evacuated as often as possible.

Wherever necessary there should be a provision of water under pressure and facilities for attaching flexible hose to the pipes.

Openings giving on to public highways or neighbouring property should be kept closed.

Measures of personal hygiene are necessary. Certain authorities insist on the necessity of organising a medical service in establishments for the production of artificial perfumes, with compulsory notification of all cases of sickness, even slight. The American enquiry has revealed the importance of medical examination on engagement with a view to elimination of workers affected with certain symptoms or diseases. This is reflected in a notable diminution of the sickness rate of the worker.

Legislation

In Belgium young persons under sixteen years of age are excluded from the manufacture of eau de Cologne and similar products obtained by distillation. For legislative provisions see articles quoted above under Hygiene. See also articles dealing with compensation of injuries due to products manipulated. In Italy compensation is provided in the perfume industry for injuries caused by benzene and its homologues.

See quarterly publication of the International Labour Office: Bibliography of Industrial Hygiene.

Personal Hygiene

The Workers' Health

It is true that factory work is regulated by laws, orders and regulations; but there is no doubt that an understanding based on co-operation and mutual confidence between employer and workman will make this work profitable, remunerative and as agreeable as possible. A factory owner should make a point of introducing all improvements required to ensure both the smooth working and efficiency of his undertaking and for the well-being of his personnel. In this connection it is important to note how anything which contributes to make time spent at the factory agreeable, or which makes the work easier in one way or another, exercises a beneficial influence on the moral of the workman and on output.

The workman feels more at ease and works better in a clean place, well-equipped, spacious and well-lit. For this reason, therefore, it is essential to take special care with the upkeep of the works. It is not enough for the various installations prescribed by regulations to be provided; they must also be maintained in perfect working order. In large works the maintenance, supervision and control of hygienic arrangements should be entrusted to responsible persons.

The workman on his part should feel that some interest is being taken in him; this will encourage him to work. The employer should not strictly confine his solicitude to the works; he should turn his attention to the problems which particularly interest his workmen, and should interest himself in their homes, diet, leisure, children's education, etc. (see article "Welfare").

The formation of joint committees which include representatives of the employers and workmen will do much to bring them
closer to each other in this way, and also to smooth over many differences.

As regards medical examination, see article "Factory Surgeons." The workman must be convinced that all hygienic measures are intended to promote his well-being and efficiency, and that therefore it is entirely to his interest to comply with them.

The buildings should be plain, in good taste, but free from any useless display, as the workman who is obliged to live in modest conditions in his home, does not as a rule like the sanitary accommodation at the works to be on too luxurious a scale.

**DRINKING WATER AND BEVERAGES IN THE WORKSHOP**

Every industrial concern must supply drinking water of good quality and in sufficient quantity for the use of the personnel. The supply of water and its distribution, being a matter of the highest importance, should be considered before the opening of the works.

The drinking water should satisfy certain physical, chemical and bacteriological conditions, which are laid down in each country by the competent authorities.

It must be limpid, colourless, fresh, odourless, tasteless, and not liable to putrescence; it must contain air in solution, and a certain proportion of salts, but must not contain pathogenic micro-organisms.

Water of which the supply is not controlled by some responsible public health service must never be used. Special precautions must be taken in the case of well water, especially in the case of shallow wells. The most scrupulous care must be taken with their construction, so as to ensure purity of the water. All wells must be completely covered and supplied with a fixed device (pump) for raising the water, or with a delivery apparatus which cannot be contaminated.

If the factory must use rain water, collected in cisterns, care must be taken that it does not contain dust, organic matter or dissolved substances coming from zinc or lead roofing. Cisterns must be constructed of water-tight masonry, or of such metal as cast-iron, protected by a paint based on a harmless pigment.

The water supply is sometimes undertaken by the town and sometimes by authorised companies. In order that there may be sufficient pressure, the water is often collected in tanks placed on columns, or on other constructions; in such cases the precautions mentioned above for reservoirs must be observed.

Taps should be placed near the lavatories, and at various points in the workshops to which workers can easily have access, without interfering with their comrades or the general work.

It is also important to put up notices over the water taps, "drinking water" or "washing water not drinkable." Each place for drinking water should be provided with a tap. It is usual to place a metal cup, attached by a chain by the side of the taps; but this custom should be prohibited since it is well known that workers have some repugnance to using the same vessel. Taps and outlets should be so arranged that workmen cannot drink from the spout. Hence the type of fountain with a rising jet is growing in popularity.

Practice has shown the advantage of fountains in which the jet of water is directed from below upwards with a slight inclination towards the front. In this way the water is not contaminated by the drinker who can imbibe it without touching the apparatus. Sometimes a lever enables the height of the jet to be regulated (figs 57 and 58).

Care should be taken to ensure that the water always has a constant temperature, neither too hot to be unpalatable, nor cold enough to cause colic and cramp of the stomach.

No reservoir or receptacle so placed in a workshop that it may be contaminated by dust or fumes should be allowed. When the water which the firm provides does not come up to the desired standard, recourse must be had to purification. Water which is purified artificially should be submitted to constant testing; but a supply of water from an irreprouachable or fixed source is naturally preferable to a suspected supply which has to be purified.

**Methods of Purification**

Among the methods of purification used at the present time are boiling, filtration and chemical processes. Boiling is a process of very limited application; boiled water is free of pathogenic micro-organisms, but it is flat. Neither does filtration represent an ideal and safe process. A bacterial filter abstracts impurities and micro-organisms from water for a certain time, which varies in length according to the kind of filter and the quality of the water; but after this the filter does not function and has to be renewed or cleaned. The best chemical disinfectant in use at the present time is chlorine, which is used in the form of cylinders of liquefied gas, or of hypochlorite of lime, or of other chlorated preparations which give off
chlorine in the nascent state. The bacteriocidal effect of chlorine is very powerful: 1 mg. and even less is sufficient to purify a litre of filtered water after contact in half an hour. If the water is turbid, the quantity of chlorine must be increased.

This method of purification, which is already very extensively used in America, can be used when good drinking water is not available. A good practical means of making drinking water safe without altering the taste is by the use of chloramine. The ozone apparatus should also be mentioned, which, if well constructed, is excellent for purifying water. But very strict supervision is required and the water does not become clear. For this reason the water should be subsequently filtered in order to deliver it pure and clear.

Sterilisation by ultra-violet rays is simple, not costly, and represents the method of the future. However, the sterilisation of large volumes of water has not yet been technically perfected.

**Beverages in the Workshops**

Workmen in general and particularly those in certain industries, such as dusty occupations, those involving exhausting work and work in overheated places, consume, sometimes to excess, drinks such as wine, beer, cider, infusions and coffee, rather than fresh water.

In some occupations, for example in the erection of Flemish furnaces, according to Bargeron, a litre of gin a day at 50° was supplied by contract, and the workmen imbibe it without any drunkenness occurring, though a normal individual employed on less arduous work could not take such an amount without ill-effects.

The fight against alcoholism (see article "Alcohol: Intoxication by") should be carried on with a defined objective; fermented or alcoholic drinks should be replaced by other beverages, non-alcoholic and cheap. Some managements provide tea or coffee gratuitously for their personnel. In other works fruit syrup drinks, milk or lemonade are brought round at fixed hours; for these the workman pays by a check which he buys cheaply at the canteen (see also article "Welfare Workers").

Thus it is seen that a good method of fighting alcoholism, and one worth imitating, is to provide workmen with beverages in the workshop, especially during the summer.

Among these beverages should be mentioned weak cocoa, lemon juice, extract of liquorice, an infusion of the dried leaves of the ash tree, which coloured with caramel and with a little tartaric acid added gives, according to Bargeron, excellent results. A fermentable sweet wort can be made by using ordinary sugar, in an amount varying according to the degree of alcohol to be obtained (18 grm. per litre and per degree) which is started to ferment by means of a few hundred grammes of good yeast.

In Germany efforts are confined to aerating water by means of an apparatus similar to that used for preparing aerated lemonade.

**Legislation**

All laws on the hygiene and safety of workmen call for the provision of drinking water at the place of work. Apart from general regulations and by way of illustration, it may be men...
in Germany, 1911, Belgium and Denmark, 1912, Great Britain, 1911, and the Netherlands, 1906; for building yards in Austria, 1909, and Italy and Switzerland; in the painting, lacquering and decorating trades in Austria, 1908, Belgium, 1910, Great Britain and Russia; in the polygraphic industries of Austria, 1911, and Denmark, 1908; in boot factories in Denmark, 1906; and in bakehouses in Denmark, 1912.

Many Governments have prohibited the introduction and use of fermented and alcoholic drinks in workshops and factories, especially when the workmen are exposed to risks from poisoning. This prohibition, conceived in the interests of the worker's health, as well as in the interests of the employer, has been laid down either by general regulations or by regulations relating to particular industries as follows: in Germany, for the tinning of metals in 1909, enamelling on metal and glass, in the factories of nitro and amino derivatives, and in the pottery trade in 1913; in Italy, in all industrial concerns (section 23 of the General Regulations on Factory Hygiene of 1957); in the Netherlands in compressed air works and in match factories in 1919; in Switzerland by the Federal Act on work in factories in 1914; similarly by the Decree of Luxembourg respecting the health of workers; and in Belgium the Regulations of 1905 concerning the health of workmen.

**PERSONAL CLEANLINESS**

Cleanliness is the basis of hygiene at home, at school and in the workshop.

Fig. 59. — Wash basins in a British factory (Scottish Shale Oil Company, Broxburn).
presides over most organic exchanges; especially if one remembers that a dirty skin may be the starting point of infections and even of serious diseases.

**Lavatories**

Lavatories always include a basin and a tap supplying clean water. Basins in a general lavatory are replaced by a fairly large trough which collects the dirty water after men have washed under a running tap. The dirty water is conveyed outside by suitable pipes.

Tip-up basins that enable the dirty water to be emptied into a trough, are easier to clean than fixed ones.

However, in actual industrial practice troughs or basins are preferred without plugs. In this way the dirty water cannot collect in the basin.

Ordinary buckets or basins without supply taps and without waste pipes should not be regarded as washing places.

The number of taps should be in proportion to the number of persons who have to use them, so as to enable the workers to wash quickly without waiting too long.

The proportion generally adopted is 1 to 5, but this proportion means that only 20 per cent. of the workers can make use of the lavatories at any one time. This proportion is insufficient and a tap for each individual should be aimed at.

A suitable washing place should consist of a basin measuring 50 by 30 by 10 cm., above which, at the level of the hands, is a tap giving a continuous flow of water. The basin should be provided with a waste pipe which cannot be closed (figs. 59, 60 and 61).

If a general lavatory is adopted, each basin should be assigned to definite workers, always the same, so that they wash in turn at the end of each period of work, the time for this being allowed.

The assigning to each worker of a numbered washing place has given very favourable results in practice.

As regards the shape of the basin, there are no rules. It depends on the nature of the work and the local conditions. Generally a basin or deep trough, wide in front is used to enable the upper part of the body to be washed easily, which is very desirable for workers in dusty occupations.

To induce the workers to use the lavatories regularly they should be placed near the workshop, carefully arranged and kept in a clean state. They should be either in the workshop itself or in a place close at hand and should be well lighted, ventilated and warmed in winter, and there should be separate accommodation for the two sexes. If natural lighting is insufficient recourse must be had to artificial light.

The floor should be watertight, of asphalt, flagstones, concrete, or preferably of impregnated wood.

Hot water should also be supplied for the worker, especially if he handles greasy materials, varnishes, fine and adhesive dust, or poisonous materials.

The soap should be supplied by the works; it may be in pieces, or soft or liquid soap, or even soda, pumice-stone, sand, or sawdust. But care should always be taken not to supply soap which is too caustic for workers whose skin has been already irritated by the products handled. In this case recourse should be had to very fat soaps or to other products, such as grease or vaseline.

Each lavatory should be provided with an adequate number of nail brushes, especially in works where there is a risk of poisoning. Some experts also recommend the use of files for the nails.

A towel, used by all and sundry, is not inviting. A separate towel being certainly preferable; but it is costly and has disadvantages. One might even say that supplying individual towels is not, as a rule, indispensable, except in the case of industries with special dangers where personal cleanliness is of fundamental importance.

It has been found at factories where a separate washing-place is provided for each workman, that many make a habit of bringing each Monday, not only their own clean towel, but also a piece of soap.

When lavatories are intended for women it is a good thing to provide looking-glasses. This addition is most acceptable; and it encourages the women to use the lavatory. If no looking-glass is provided it is usual to see women bring little hand mirrors. The toilet is most often made some minutes before the end of work, when supervision is usually relaxed. The woman tidies her hair and powders her face; she ceases work and does not realise that this toilet, done on the quiet and hastily, close to the running machines, may have very serious consequences — as when a scalp is torn off owing to hair getting caught in moving gear.

Bodily hygiene should also include care of the mouth, teeth and nose.

The hygiene of the mouth leaves much to be desired. The article dealing with the teeth and buccal cavity mentions
the occupational injuries caused by vapours and deleterious dust. In some concerns a dental service has been organised (see article "Factory Surgeons"), which is provided by a dentist whose duty it is to inspect the teeth and buccal cavity of each worker at regular intervals. This service is even compulsory for workers employed in certain unhealthy occupations, such as manipulating phosphorus, radium and mesothorium. Many sickness insurance societies include care of the teeth of the insured in their benefits. Inspection by the dentist attached to a factory is essentially of a prophylactic nature, as in the case of the doctor.

**Legislation**

The provision for workers of lavatories in sufficient number in a part of the factory sheltered from dust is laid down: by the German Government in the Factory Code, which also prescribes the provision for workers of nail brushes, soap and hand towels, in lead and zinc foundries, accumulator works, paint works, in works for vulcanising india-rubber articles, for making cigars, alkaline chromates, basic slag, and printing type; by the Austrian Government in the Order of 23 November 1905; by the Belgian Government in the General Regulations for the protection of the health of workers, 1905; by the Danish Government, as regards boot factories, bakeries, printing works, iron foundries and laundries; by the French Government in the Factory Act and Regulations for operations of combing and carding wool, hair, bristles and Indian wool, for white lead works, works for the manufacture of lead compounds and the vulcanisation of india-rubber, for brass foundries, file works, and works for enamelling on metals, for pottery works and chromate works (generally the requirements on this matter are very detailed); by the Italian Government in sections 19-20 of the Regulations for the health of workers of 1927; by the Governments of the Netherlands, Sweden, and Yugoslavia in the Regulations of 1921.

**Douche Baths**

Men and women employed at factory work require baths, and the more so in proportion as their work calls for great muscular exertion, or as it is carried on under unfavourable conditions of heat and dust. The lavatories provided in some industries do not allow the workers to pay sufficient attention to their personal hygiene; hence it would be well if most, or better still if all, industries provided douche baths. The simple douche is to be preferred to the bath-tub; it is much cheaper and requires less maintenance. In some firms both systems are put in; and the worker has a right to three douches a week and to a full bath each month. For certain classes of workers who are employed at furnaces or in overheated places, or who handle poisonous materials, a daily douche at the end of each day's work is necessary. Douche baths should supply cold water (18° to 24° C.), tepid (25° to 30° C.) and warm (30° to 35° C.) for the different requirements.

The simple douche is to be preferred to the bath-tub; it is much cheaper and requires less maintenance. In some firms both systems are put in; and the worker has a right to three douches a week and to a full bath each month. For certain classes of workers who are employed at furnaces or in overheated places, or who handle poisonous materials, a daily douche at the end of each day's work is necessary.

Douche baths should supply cold water (18° to 24° C.), tepid (25° to 30° C.) and warm (30° to 35° C.) for the different requirements.

Compartments of 1 by 1.20 m. or less should have walls covered with a layer of very smooth impermeable cement;
the floor should be slightly on the slope and impermeable; some pegs for hanging clothes should be fixed at the door and a seat of hard wood provided. These places should be well ventilated and lighted and heated in cold weather (fig. 17).

Douches and baths should be placed in separate compartments, divided by thin metal partitions 2 m. high. For douches the compartment should be divided into two by a partition so that the clothes are not splashed by the water. If natural lighting is not sufficient a good lamp should be put in, which will light both parts of the compartment.

A certain number of bath tubs should also be provided for cleansing purposes. Such a room should have a minimum area of 2 by 1.40 m. The waste pipe of the bath-tub should be connected by a water seal or trap with the collecting pipes. The bath-tub should be well made in white enamelled iron so that it can be easily kept clean. One or two baths should also be attached to the works ambulance room.

For most workers douche baths are sufficient to ensure personal cleanliness.

A rose sending out tepid water should be used, the flow of which can be stopped at will by the person using it.

The flow from the douche should fall in a fine spray which is slightly slanted. For women a waterproof cap will protect the hair. But the rose may be replaced by a metal ring pierced with small holes and connected with the tap by a flexible tube. The ring makes it possible to spray the body without wetting the hair.

The bather should bring his soap and towel; but on premises where serious occupational risks exist, they should be supplied gratuitously by the firm.

The douche bath allows not only thorough soaping, but also a perfect rinsing with clean water.

Douche baths are generally put in by the firm, and, while some employers make a small charge to cover part of the expenses of maintenance, others not only provide them free, but award prizes to the workers who take the greatest number of baths during the year. In unhealthy industries the time taken for the douche or bath is included in the working time, and is paid for as ordinary work. Outside working hours, if the situation of the baths allows, it is good practice to place them at the disposal of the workers’ families.

During the summer, where it is possible, douches should be replaced by bathing in the running water of a lake or river.

As regards the provision of covered swimming baths, see article “Welfare”.

Legislation

The same rules requiring the provision of lavatories for workers as a rule also require the provision of douche baths with soap and towels. Sometimes, even the intervals at which baths are to be taken are fixed for persons employed in particularly injurious processes.

Douche baths are required to be provided by the following Governments: in Germany by the Regulations relating to the industries dealing with leather, hair, brushes and hair pencils (1905: twice a week), for lead foundries (1905: daily for certain classes of workers, weekly for others), for accumulator factories (1908: weekly), for lead colour works (daily), for alkaline chromate works (1907: weekly), and for basic slag and nitro and amino compounds works; in Austria for lead and zinc foundries, sugar refineries and paper works; in Belgium for works producing white lead and other lead compounds (1910: a douche bath for every five workmen); in Denmark for bakers and confectioners (1912); in Great Britain in white lead works (1899: daily), accumu
lator works (1903), in lead smelting and the manufacture of red lead and litharge (1911), and nitro and amino derivatives works; in Italy (1927) for works with more than twenty workers when the work is dusty or gives off fumes or foul vapours, or when poisonous materials are handled; in the Netherlands, for mines (1906) on leaving the mine; and also in Belgium, in Hungary for the preparation of hair (1905: weekly); in Yugoslavia (Regulation of 1921, section 17). In Great Britain, douche baths at coal mines are being constructed out of a special levy imposed by Parliament.

Clothing, Head Coverings, Gloves and Boots

For most industrial processes the use of such working clothes as blouses, aprons and overalls is advisable. This measure is essential in all works where clothing is exposed to contamination or spoiling by grease, colours or dust, and especially when poisonous substances and dust are manipulated.

Working clothes may be brought by the workman or supplied by the factory. But gratuitous provision to the workers has its disadvantage; a worker who has no direct interest at stake is too ready to neglect what is offered to him; whilst if he is required to pay even a very small part of the cost of purchase and of maintenance, he is more careful. On the other hand, inspection and maintenance are easier if the factory has charge of the provision.

Light colours are to be preferred for working clothes, because the state of cleanliness is then apparent. For women, aprons with sleeves, but without frills or ornamentation, should be chosen. Loose strings and ribbons must be avoided. In factories with motors and driving belts, button-holes should be put on the side or covered in such a way as to avoid accidents. Further, skirts should be replaced by trousers, wherever the wearing of skirts presents a danger from moving machinery, and especially in places where dust, irritating vapours, or clouds of steam are given off. In these cases working clothes should fit close about the neck, wrists and legs (gaiters); the hair should be protected by means of head covers or washable caps. The use of special coverings for the head is most necessary when toxic dust is present.

No clothing or equipment in celluloid or other highly inflammable substances should be allowed in undertakings where there are fire risks.

The Moscow Institute for the Protection of Labour has since 1926 studied the principles of suitable working clothes, taking into account both the injurious nature of the occupation and the hygienic properties of the materials used. Up to the present, investigations have been made concerning woolen, linen and cotton materials, and india-rubber used to waterproof stuffs, materials used for gloves, leather, etc., for working boots. Naturally, consideration has been given to the weight, thickness, porosity, permeability to water, conductivity and loss of heat and the effect of dust and liquids on the wearing properties of these products (Schafranoff).

Although the wearing of gloves, especially waterproof ones, is not always advisable, as in some cases it increases the injurious effect of the substance against which it is wished to protect the workman, it is nevertheless desirable to recommend the use of india-rubber gloves when the duration of work is not too long. Whilst india-rubber gloves are useful to protect the hands against the irritating
or poisonous effect of materials, in other cases it is preferable to use leather gloves. These, and also mittens made of coarse linen, have the advantage of costing less and of being easily washed. In some occupations suitable shoes should be supplied to the workers. This is the case with foundry workers, where the wearing of old boots or shoes explains the very high number of accidents caused by burns on the feet and toes. The indifference of workers in certain occupations has to be overcome and they have to be convinced of the necessity of wearing sufficiently thick leather boots which have suitable soles and heels.

Fig. 64. — Lockers in a Swiss factory (Sulzer Works).

With wet floors, such as are found in dyeworks, clogs are preferable. In some cases the use of non-inflammable asbestos stockings or socks is to be recommended. Men working in water are obliged to use boots of India-rubber or leather so impregnated as to be impermeable.

Wearing rubber gloves, clothing, or boots too long at a time must be avoided.

Legislation

The Governments of the following countries have made regulations which require the free issue of working clothes to workers, their maintenance and periodical washing: Germany (Order relating to factories where rubber articles are vulcanised); Prussia (Order relating to picric acid works); Austria, Belgium and France (the use of white lead in painting, factories for copper acet-oarsenite); Great Britain (combining and carding of wool and hair, spinning and weaving linen, the use of East Indian wool, accumulator factories, paint and colour works, smelting of substances containing lead, the manufacture of nitro and amino derivatives, and of alkaline chromates); Hungary (the preparing of animal hides); the Netherlands (work in mines). Impermeable aprons are required, for example, in Great Britain in the tinning of metal, the cutting of files by hand, and the pottery trade. Gloves must be supplied in Austria to workmen employed at certain operations in zinc and lead smelting; in Germany, in lead-smelting foundries, lead colour works, the polishing of metals, and the manufacture of nitro and amino derivatives; in France, in industries with a risk of lead poisoning; in factories for copper.

Working caps are chiefly required to be provided for operations giving off dust, in the spinning of horsehair, other animal hair and silk (Germany, Belgium, Great Britain and Hungary); in industries with a risk of lead poisoning; in works manufacturing white lead, colours, pottery, accumulators, in lithographic printing works, and enamelling works (Germany, Austria, Belgium, France and Great Britain); in works for alkaline chromates, works for nitro and amino derivatives, or where there is a risk from exposure to anthrax infection (Germany, France and Great Britain). Some Governments also make it compulsory for employers to undertake the drying of clothes moistened during humid textile operations and dyeing.

Special precautions should be taken for cleaning clothes and head coverings which have been worn during operations involving exposure to such dangers as poisoning by lead, benzene compounds, or aniline, or anthrax infection.

Cloakrooms

On entering the factory, as well as on leaving, the worker requires to take off his ordinary clothing and put on his working clothes, and vice versa, as quickly possible. For a long time only coat hooks, simple pegs, and quite often nails, were used for hanging the workers' outdoor clothes, which were thus exposed to dust, splashes from liquids and to steam.

Next it was thought to be enough to hide clothes so hung up behind a sufficiently long curtain. A board was provided for the boots which were thus kept away from the damp of the ground.
A so-called improvement consisted of a sliding door which replaced the curtain and transformed the cloakroom into a kind of general wardrobe. It was found at once that this system gave rise to danger of contamination; that it led to an offensive smell; that it required supervision by some responsible person since it cannot be kept shut.

Hence, only the separate clothes lockers, now so largely used, are to be recommended as the best solution of the problem.

They are made of wood protected with a coat of paint, or still better, of smooth sheet iron, with a door, fitted with a grating for inspection of the inside and for ventilation. The lockers are generally arranged in groups of four or five or more, and sometimes even in two stories.

The door must be closed with a padlock; otherwise the workers will distrust the lockers (figs. 63, 64, 65).

The locker should have one or several hooks inside, a shelf for putting boots on and another at the top for the worker to put his dinner on. A very simple arrangement allows of an umbrella being placed against the inside of the door.

In unhealthy trades, the workers should be provided with a locker having two compartments, one for outdoor clothes and the other for working clothes.

In new buildings, the cloakroom should be separate from the workshops, warmed in winter and situated in the same place as, or quite close to, the lavatories and douches (figs. 66 and 67).

Sometimes, principally in the mining industry, the clothes are hung on a bar and raised to the ceiling by pulleys during the working hours. This system has the advantage of avoiding thefts; but the workman prefers his cupboard with a key or padlock.

When the working clothes are dusty or covered with grease or poisonous substances, it is much better to hang them in the open air rather than shut them up, and to keep the lockers for the clean outdoor clothes.

Legislation.

As a general rule working clothes should remain at the factory. This rule is especially important in the case of unhealthy and poisonous trades.

Cupboards or cloakrooms, placed in a special part of the factory, separate lockers with one or two compartments, a lock and a ventilating opening, etc., are required by laws prescribing the provision or use of working clothes and head coverings.

In general it may be said that Governments, which have enacted measures for
the provision of lavatories or douche baths, and the supply of clothing for workers, require also the provision of lockers and cloakrooms, especially for industries with special risks or particularly dusty.

**Privies**

An installation, without useless luxury, but quite complete, is of the highest importance. Privies should be placed quite close to the workplaces, with which, however, they should not communicate directly, but should be separated by a corridor or vestibule. In large factories, privies are sometimes placed in small, separate buildings and are for the use of the different departments of the factory.

A privy includes a seat of special shape, a flushing pipe, a cesspit or a connection with the principal sewer. A privy should be so arranged that it (a) permits of the easy accomplishment of the function for which it is made; (b) is easily kept in a state of cleanliness; (c) is not liable to annoy the user by the escape of sewer or irrespirable gas; (d) does not allow these gases to spread into the working places.

Abba, of Turin, has studied the hygiene and structure of sanitary apparatus, hitherto constructed on empirical lines.

Simple analysis easily shows up defects of construction or working as well as the ill-effects which they may cause.

Persons who use privies can be grouped into a majority who sit over the pan, and a minority who squat; the latter, on this account, have to stand upon ordinary pans, thereby soiling them. Hence pans have been constructed with places for the feet on the sides, which enable these persons to squat without coming in contact with the pan.

It must be admitted that a large class of persons exists who do not appreciate that closets are, and should be, the cleanest parts of a house, factory or office.

The Romans studied the physiology of the act well and constructed seats which, as can still be seen at Pompeii,
are certainly rudimentary; requiring much water, but in keeping with the teaching of modern physiology, according to which water is the only disinfectant for closets.

The idea which predominated all through the Middle Ages is still embodied in the Turkish type of closet, represented by a slab of stone, or more rarely of wood, flush with the ground, with a central circular opening of about 20 cm. diameter, and either with or without a cover. But the circular form of opening does not ensure the evacuation of the excreta which spread over the slab and the ground. As a matter of fact, if the physiological act is observed, it is found that the directions of micturition and defaecation are divergent and that the opening consequently should not be round, but should take the shape of a long fissure narrowing from back to front (fig. 68).

If the squatting attitude, the abolition of the seat, places for the feet, and a flush of water are the indispensable principles for the construction of a practical hygienic closet, certain details of no less importance must still be taken into account.

The places for the feet should not be too low, nor too sloping, nor so slippery as to give the user a feeling of insecurity; the footplaces should be divergent and not parallel; the opening should be of the shape previously mentioned; the flush of water should not be automatic, for it might occur at an inopportune moment and wet the user.

When the pan system is adopted a type should be chosen which receives the excreta without any going on the floor of the closet. The type studied by Risso and constructed by Abba resembles a gondola in shape, 60 cm. long and 20 cm. wide, raised at the two extremities so as to facilitate the flow of excreta into an outlet opening of 10 cm. diameter (fig. 69).

In the case of a series of pans Abba does not advise a hydraulic flush for each pan, but a common flush for the whole series. Each pan discharges the excreta through a short pipe which dips into a collecting pipe filled with water.

The writer holds that as far as men are concerned the Turkish closet is preferable. In this case the seats are generally made of iron sheets, or slabs of cement or ceramic tiles. The water flush is then automatic, although this scheme is not very economical; but the type of flush depending on the user...
does not give satisfaction, as for various reasons it easily gets out of order.

In the case of outdoor privies a type of collective privy is represented by a series of closets made in cement, traversed by a channel, over which the users place themselves astride, putting their feet on the places marked for them. Every ten or fifteen minutes an automatic flush releases 20 litres of water in order to keep the channel cleaned out. The channel, of course, will be on a slope, to ensure good drainage, and must be cemented and impermeable (figs. 70 and 71).

The very common method of overcoming offensive smells by sprinkling the floor, the seats and pans with chloride of lime or other disinfectant, is, according to Abba, only one of many modern hygienic frauds.

Closets must be kept clean, even against the will of the users, and this method is only employed to excuse the carelessness of persons who ought to be clean, and of the staff entrusted with the supervision of the closets.

The offensive smell of excreta should not be replaced by a stronger one which only masks it, but the place should always be in a constant state of cleanliness; water, a broom and a little work are all that is needed to attain this end. But it must be constantly borne in mind that kitchens and privies are the parts of a building which should be kept cleanest.

Urinals are also of several types: slabs, troughs or basins with or without a water flush. Clearly in this last case they are open to criticism and should not be adopted.

Urine is a liquid which is responsible for most of the foul smells of closets. It rapidly ferments and gives off ammoniacal vapours which persist till the urine has completely evaporated.

The floor should not soil the walls or floor of closets or urinals. Unfortunately it happens too often that not only the floor in front of the slab is soiled with urine, but even further back, which increases the surface giving off foul smells.

In order to overcome this nuisance the person should be obliged to approach as close as possible to the urinal, so that the last drops of micturition fall into the receptacle. Hence the most appropriate type is that represented by a porcelain basin fixed on the wall at a suitable height, with the front part in the shape of a beak. This form, however, while it is suitable for private houses or offices, is not to be recommended for places used by persons who are less careful of cleanliness and do not take the necessary precautions not to soil the floor. In these places (factories and public urinals) a type with marble slabs or iron sheets may be used with advantage; these slabs should reach down to the ground, with a channel level with the floor, the front part of which should be in the shape of a beak, extending to the heel of the foot rest, which must be raised sufficiently above the floor. In this way the person is compelled to stand on the foot rest.
and the last drops of urine will not fall on the floor (fig. 72).

Cleansing of the surface of the urinal may be ensured by a simple channel with water running all along the upper border of the slab, over which it spills continuously.

This system ensures, better than any other, automatic flushing and the cleanliness of the urinal.

The most common type of slab urinals are usually made of marble, artificial stone, shale, or slate; those with a trough are made of glazed earthenware or iron coated with enamel, or, only too often, with zinc, which is very difficult to keep clean.

The care of privies, like that of lavatories, should be entrusted to a responsible and conscientious person. It should be borne in mind that the workman submits to regulations much more readily if clean, well-cared-for closets are provided for him; whilst, on the other hand, a model installation, if not properly cared for, loses its value.

Special mention should be made of movable receptacles or tubs which are used chiefly for underground workings in mines and tunnels (see articles "Ankylostomiasis" and "Mines: Hygiene in ").

It will be sufficient to say here that if movable tubs are well arranged they form quite a practical system; but they must, be quite watertight, removed regularly by a responsible person, and washed, or, if necessary, disinfected. The receptacles should be very strong, with well-fitting lids, shutting closely so as to avoid any spilling during transport, and should be made of metal in order to prevent impregnation by faeces and urine. Drain pipes for the outfall should be wide and smooth.

The tubs should be placed where they can be easily got at, or should be mounted on rails to facilitate their removal and emptying.

The lid fitted to the receptacle may be arranged so that each time it is closed it scatters over the faeces some such deodorising material as powdered peat, iron pyrites or lime. This system, however, requires much attention.

It is not necessary here to enter into details for the construction of fixed cesspools where no drainage system exists. Ordinary cesspools, septic or...
biological purification tanks belong to the public health department; and any arrangement of this kind should accord with the scheme adopted by the local public health regulations.

Legislation

Regulations generally require privies to be provided in numbers sufficient for the needs of the personnel. They must be separate for the two sexes, well looked after and disinfected, ventilated and lighted. Some regulations fix the number at one per twenty-five or thirty. Others at one per twenty or thirty. Some only require separation of closets for the two sexes when the number of persons working at the factory is more than five, ten, or even twenty. Working regulations for mines lay down very detailed rules for the arrangement and maintenance of movable tubs and cess pits, either on the surface or at the pit bottom.

Some regulations, concerned with work at hot and damp processes, such as in sugar refineries, paper works, and humid weaving sheds, lay down that the closets shall be arranged so that they protect the workers against too sudden changes of temperature and against inclement weather.

Spittoons

The habit of spitting on the ground is ingrained almost everywhere. In order to overcome this bad habit at the factory, as in the streets, people must first be educated. In various countries the authorities, as well as anti-tuberculosis associations, have published notices or rules forbidding spitting on the ground.

Spittoons at factories ought not to be necessary. But if it is necessary to suggest a practical type it must be admitted that none of those recommended is ideal. Spittoons have been made with covers and a water flush; as soon as the cover is raised the tap opens and water cleans the inside of the spittoon. Others are only open basins, hung on the wall at a suitable height, in which water circulates permanently over the interior surface. The use of spittoons of paraffined cardboard has also been recommended; they contain peat or sawdust impregnated with formol. The sputum is thus absorbed; and the cardboard boxes are periodically collected and burnt.

This system is certainly economical, but it requires strict supervision; moreover, the cardboard boxes are very fragile.

Types of spittoons placed on the ground should not be recommended, as drops strike the ground or against the wall. This in itself gives us some indication of the proper place for a spittoon. In addition the spittoon should be closed. If an enamelled metal or earthenware type is used, hung on the wall at 50 cm. or 1 m. from the ground, it is better to fill it with water, soda, or a solution of soap with cresol, rather than sawdust or sand, which dries up too quickly.

Another problem, which in practice is fairly difficult to solve, is the number and situation of spittoons required. It is not possible to arrange them conveniently for all persons who possess the bad habit of spitting, especially when the place is filled with machinery. As for some individuals spitting is a natural necessity, it would be better to arrange for them to use the privies;
but this requirement is somewhat exaggerated. The difficulty can only be overcome by teaching each individual how to behave.

The ideal would be to use pocket spittoons. It is certainly necessary to forbid spitting on the ground; and those who spit, whether sick or not, should be convinced that they ought to provide themselves with pocket spittoons and should look after them themselves.

Legislation

Several regulations have laid down that spittoons are to be provided in workshops and in dormitories attached to building yards. It will be sufficient to quote here the rules adopted by the Italian and Yugoslav Governments: "Spattoons in sufficient number containing a liquid must be placed in all workplaces. Spittoons must be washed out daily" (section 12, Yugoslav Regulations of 25 October 1921). "Employers must provide in workplaces, staircases and other passage ways, spittoons, which must be cleaned and disinfected in an adequate manner. In the workplaces and passage ways in question workmen must use the spittoons provided for them" (section 22 of the Italian Industrial Hygiene Regulations, 1927).

Seats

The standing position is tiring when prolonged; it weakens the attention, makes for painful flat feet, varicose veins, and, in women, affections of the pelvic organs. On the other hand the sitting posture is also fatiguing if prolonged. Roux (Lausanne) is quite right in stating that a child is an expert in changing: the same can be said of workers. Change of position gives rest; hence it should be arranged that persons who work standing are able to sit, and inversely that workmen and workwomen who work seated can from time to time stand up.

For workshops, as for trading shops, certain rules prescribe a number of seats equal to the number of persons employed. The wisdom of this rule is universally recognised; but its practical application leaves much to be desired. The number and duration of rest periods when workmen and workwomen obliged to work standing are able to sit vary a good deal.

For persons employed on machines in continuous motion an interruption of work has been proposed in the light of comparative experience. It has been found that the daily output increases from 6 to 10 per cent. when a rest of five minutes an hour is allowed with the possibility of sitting down. Here is an important point: the interruption of work increases the output, instead of diminishing it.

In the choice of seats several factors should be taken into consideration: operations in which the worker can do his work sitting; operations in which the worker can from time to time rest and sit; and the advisability of providing seats outside the workrooms during rest periods.

For work which can be done in the sitting posture the type of seat to be chosen depends naturally on the kind of work. The seat should be well designed and well placed, so that the workman is not forced into a bad attitude, which in the long run may cause disorders of the digestive organs, the abdominal organs, or even lead to deformities.

The shape of the seat, then, should be such that it will allow a normal and healthy position, quite freeing the legs from the weight of the body.

If the position of the piece to be machine cannot be suitably changed, a seat adjustable by the worker should be provided. The construction of these seats should be based on the principle that the elbow of the worker when seated at work should be at the same height as if he was performing the work standing.

In addition, the seats should be easily movable so as not to be in the way of a worker who wishes sometimes to sit at work and sometimes to stand; but they should be fixed to the floor if the machinery is dangerous.

Seats should be supplied with a back, which should be suitably sloped back and high enough to support the lower part of the back of the worker.

In some cases it is preferable to regulate the height of the table or of the working bench rather than that of the seats.

Seats should be provided with foot rests if they are very high and do not permit workers to place their feet on
the ground. If the floor of the workplace is subject to vibrations or to shocks, spring seats or seats with rubber pads on the feet should be used.

As regards operations of the second group, that is when the worker can rest from time to time, the machine only requiring such supervision as can be exercised while seated, the seats can be boxes, or better, chairs or forms placed along the walls. But if the place is full of machinery and workers, it will be useful to arrange folding chairs along the walls, by pillars, or even at the side of the machines.

It should not be necessary to insist on the fact that seats placed in the rooms should answer the purpose in view. Hence simple and practical patterns should be chosen, but especially those which enable workers to rest comfortably.

A good chair is not sufficient. There must be the right relation between the seat, the work table and the support for the feet. The Industrial Commission of the State of New York has formulated the following conditions as essential for a good chair, which should clearly suit the kind of work: the seat should be wide and not too high, so that it does not interfere with the lower part of the body, but not too deep, slightly saddle-backed with the front edge rounded; the feet should rest comfortably on the floor, or on a broad rest fixed to the floor, or to the table. The distance between the table and the seat should be sufficient to ensure freedom for the knees. No bar or other obstacle should interfere with a comfortable position for the feet. There ought to be a back to support the lower part of the body, but not too high, so that it does not interfere with movements of the arms.

Several firms in various countries now sell excellent types of working seats. A worker who works in an abnormal position tires much more rapidly and is more liable to accidents than a worker at ease. This increase of fatigue should be avoided as far as possible; and this can be done in many cases by replacing manual work by machinery. The miner who is obliged to handle his pick lying or crouching on the ground and the house painter engaged on whitewashing the ceiling, with his head held back, cannot keep at work long; more frequent rests should be allowed them and a reduction of the working spell.

Legislation

The Belgian Act of 25 June 1905 lays down that seats are to be provided for saleswomen employed in shops; and similarly the French Labour Code (section 76) lays down that "shops and stores or other places connected with them, in which merchandise and other articles are handled or offered to the public by a female personnel, must have in each room a number of seats equal to that of the women who are employed there."

The Italian Industrial Health Regulations lay down that workers in industrial and commercial undertakings, where the work is not continuous, shall be provided with a sufficient number of seats (section 23).

German legislation requires seats in the rest rooms for workers in building yards and yards for dressing stone. Seats are required to be provided: in Spain by the Act of 27 February 1912; in Finland and the Netherlands by the Acts of 1920; in Austria and Great Britain by the Acts of 1921; in Russia by the Act of 1922; in Argentina and Persia by the Acts of 1923.

Dining-Rooms

Laws rightly forbid persons employed in factories to take their food into the places of work. This prohibition applies particularly to works where poisonous substances are produced or manipulated, or where the operations carried on give rise to emanations which are unhealthy, disagreeable or poisonous, or generate dust, and, as a general rule, when the hygienic conditions are not satisfactory and where the health of workers may be affected.

As a logical result of this prohibition, especially if for special reasons the workers cannot take their meals at home or in a canteen, an obligation lies on employers to provide a dining-room for their workers, furnished with tables and seats in sufficient number.

Legislation

In all the laws examined above, measures are found dealing with the establishment and maintenance of a dining-room. It should be well ventilated, lighted, heated in cold weather, easily cleaned,
of a size in proportion to the number of workers and provided with the means necessary for heating up food.

Access to the dining-room should be arranged so as to compel the worker to pass through the place where the lavatories and cloakrooms are situated.

In some cases it is desirable that there should be several dining-rooms; for example, one for each floor or building, so that the workers do not have to go a long way. This disadvantage explains why in some cases the establishment of dining-rooms has not been appreciated by the workers as much as should have been the case.

The floor should be smooth, impermeable, easily washed down with water; the walls should be lined with ceramic tiles up to a height of 1.50 m.

Care should be taken to avoid giving the place any resemblance to a barrack mess-room or to a school; small tables should be provided with four to six places and seats rather than forms.

The tables may have marble tops or be covered with glazed tiles, which give a more aesthetic appearance; such tiles, moreover, are easily washed. It is also desirable to provide small separate pigeon holes wherein the workers can place the food they bring from home.

An adjoining place should contain apparatus for heating up food already prepared which the workers bring from home. For this there are now quite a number of cookers, employing either steam or gas heating; they should be sufficient in number.

As regards factory canteens, see article "Welfare".

In addition to alcohol, another poison which deserves special mention is tobacco. In the same way as alcohol, nicotine and the toxic substances absorbed with smoke are especially injurious to young persons, or the weak and delicate. Hence, in a number of works and in most of the industrial laws and regulations, especially for unhealthy industries, it is forbidden to smoke or to take snuff during working hours. This prohibition also covers the habit, unfortunately too common, of chewing tobacco, and it should be still more widely enforced, for the introduction of chewing tobacco into the mouth and even the act of putting a pipe or cigarette in the mouth with hands soiled by lead, mercury, or other poisons, facilitates the introduction of poison into the system.

**Petroleum and Lubricating Oils**

Crude petroleum or mineral oil is found in the ground at varying depths and is obtained by drilling. The pressure of gases accumulated above the oil is sometimes sufficient to cause it to spout up into the air, but it is often necessary to use pumps. The gases which escape from the bore-holes may cause serious conflagrations.

The most important fields are in the United States, Mexico, Russia, Persia, the Dutch East Indies and Rumania.

Crude mineral oils are found in the form of lands of variable fluidity, ranging in colour from a transparent yellow to blackish brown, with a green fluorescence and an allaceous odour. Their density is between 0.766 and 0.975. On burning they give off thick fumes without leaving any ash. They are not liable to spontaneous combustion.

Whilst readily soluble in alcohol, ether, benzene and carbon bisulphide and tetra-chloride, mineral oils are only slightly so in dilute alcohol and are insoluble in water.

From the chemical point of view, mineral oils are mixtures of hydrocarbons, and are divided into two main groups according to the predominance of paraffins (methane hydrocarbons, C\(_n\)H\(_{2n+2}\)) or naphthenes (cyclohexanes and methyl-cyclohexanes, C\(_{11}\)H\(_{22}\)). To the first group belong most of the mineral oils of the United States, while the Russian belong to the second. Some, e.g. those of Borneo, contain large quantities of benzene hydrocarbons.

A third group, containing the hydrocarbons of the two preceding series, is distinguished by certain experts; and in this are included the mineral oils of Rumania and Galicia.

All crude mineral oils contain a large number of impurities, notably naphthas, phenolic and sulphated compounds, organic acids, resinous substances, and pyridic bases. The presence of sulphur (up to 5 per cent.) gives a disagreeable odour and renders refining difficult.

The composition of mineral oil, however, varies widely from one region to another, and even from one bore-holes to an adjoining one.

**INDUSTRIAL OPERATIONS**

**Distillation of Crude Mineral Oil**

Crude mineral oil, which contains impurities from the soil, such as earth, sand and water, is stored in reservoirs, where a large part of them settle. Separation from water is sometimes effected by centrifugal apparatus Fur-
ther purification is carried out by distillation in vertical or horizontal stills, heated either from below or internally by means of pipes, or by introducing a current of superheated steam (Russia) which lowers the boiling point of the hydrocarbons and makes almost complete distillation possible; or again by a vacuum (the Steinschneider Porges process), used chiefly for the treatment of very viscous crude oils. The distillates thus produced in the stills travel to a cooled worm, either directly, or after having traversed a fractionating column, similar to those used for the rectification of alcohol. Each fraction is passed to a special worm, the heaviest fractions returning to the still.

In large plants, distillation goes on continuously in a series of stills arranged one above the other. The mineral oil flows from one still to another, and is subjected to higher and higher temperatures; the residue accumulates in the last still. The condensation apparatus is, in this case, simpler and consists of only a rectifier and a worm.

The dissolved gases set free during distillation are drawn off by pumps and liquefied, either by compression or by being redissolved. Part of these gases, non-condensed, can be used as fuel.

This first distillation of mineral oil gives the following fractions:

<table>
<thead>
<tr>
<th>Temperature of boiling at ordinary pressure</th>
<th>Density</th>
</tr>
</thead>
<tbody>
<tr>
<td>Petroleum ether</td>
<td>45-70°</td>
</tr>
<tr>
<td>Illuminating oils (kerosene)</td>
<td>150-300°</td>
</tr>
<tr>
<td>Light fractions Petroleum naphtha</td>
<td>70-100°</td>
</tr>
<tr>
<td>Mazout (heavy oils, residual tar)</td>
<td>300-100°</td>
</tr>
</tbody>
</table>

The light fractions may contain petroleum ether (see below: Fractioning of the Light Fractions).

The quantities of these fractions vary according to the source of the mineral oils.

Rectification

If the first distillation is insufficient, the products obtained are distilled afresh, in such a way as to split them into a certain number of definite products. The apparatus used is in principle identical with that used for distillation.

The distillation or rectification of light fractions or of benzenes, which are very inflammable, can only be done in stills heated by steam under pressure.

The refining of crude mineral oil, or more usually of certain fractions from the distillation, consists essentially in treatment with sulphuric acid, followed by neutralisation by means of soda lye. In some cases the mineral oil is lixiviated directly with caustic soda, or hypochlorite of soda, in order to decolorise and deodorise the products, to diminish the strength in sulphur, to render them more limpid and less sensitive to the effect of heat and light, and to give them greater illuminating power.

The operation is effected in large receptacles or "stirrers" made of iron, lined on the inside with lead, erected in the open air at a distance from the furnaces, but near the storage tanks and the consignment buildings.

A mixture of acid which has already been used and petrol is subjected to energetic stirring by means of a jet of compressed air. It is allowed to stand; the acid layer is then drawn off; and the operation is next repeated several times, using fresh acid at 60° B. The mineral oil, which is now reddish brown in colour and has a strong smell of sulphurous acid, is washed, and then treated with soda lye to remove the last traces of acid. Direct neutralisation is avoided after treatment by acid since the heat which results might cause combustion. In order to avoid accidents, the gases given off during these operations are continuously removed.

The illuminating oils are further passed through such filtering materials as Fuller's earth, clay or bauxite, which are piled up in large vertical cylinders. The heavy products arrested by the filtering material are recovered by heating in special apparatus.

**Fractioning of the Light Fractions**

Each of the fractions obtained at the first distillation is, in its turn, fractionated to obtain marketable commodities. The light fractions, when redistilled in apparatus heated by steam, give the following products, of which the density varies from 0.600 to 0.750:

<table>
<thead>
<tr>

<td>80-100°</td>
</tr>
<tr>
<td>Petroleum naphtha: B (ligroine) A</td>
<td>100-120°</td>
</tr>
</tbody>
</table>

There is a commercial product named "Rhigolene" (German, Rigolen) with a density between 0.60 and 0.62, some fractions of which boil below 55° and others above 55° C. It is used for local anaesthesia and as a solvent in freezing machines.
The petroleum ethers and gasoline, which constitute the light benzine of commerce, are colourless liquids with a strong and characteristic odour, insoluble in water, rather soluble in alcohol, and miscible in all proportions with ether and chloroform; they give off fumes three times heavier than air, and cannot form nitrated combinations. In commerce, petroleum ether and gasoline are often substituted for benzene (C₆H₆), from which fact comes the name of benzine which has been wrongly applied to them. Their capacity for dissolving fatty bodies leads to their use for scouring cloth, chemical or dry cleaning, the extraction of animal and vegetable fats (in the place of carbon bisulphide), and cleaning machinery and objects coated with oil; for polishing; and for preparing solutions of rubber (used on pneumatic tyres, mackintoshes and rubber shoes), or of such resinous substances as lacquers, varnishes and ink colours, instead of turpentine. But for the most part they are used as fuel for small motors.

Petroleum benzine and ligroine — known as middle benzines — serve equally for fuel and for dissolving fats, oils and resins. They are also used as cleansers for removal of stains in dry cleaning.

The last fraction, or heavy benzine, is used as a solvent in the preparation of lacquers and colours for printing, and as fuel for heavy engines.

Petroleum naphtha is the dearest of the derivatives of petroleum. For this reason efforts have been made to increase the proportion of light fractions in the crude oils by subjecting them to special processes. One of these, designated "cracking", is the dissociation of heavy oils by means of high temperatures and pressures, e.g., up to 500° C. at 15-20 atmospheres, in the presence of catalysts. The resulting products are the lighter fractions and a residue, which is a heavier oil or a coke. The processes of "cracking" are numerous, but only a dozen have come to be used industrially.

The utilisation of "cracking", improvements on ordinary methods of refining, and the extraction of light fractions from natural gases have led to a considerable increase in the production of petroleum naphtha. "Crack-
ing" has, moreover, made it possible to treat the heavy oils from certain districts, previously not distilled on account of their high sulphur content.

The other process, hydrogenation, is carried out generally at about 400 to 500° C., either at ordinary pressure in the presence of such a catalyst as iron or reduced nickel (Sabatier and Mailhe), or at pressures raised as high as possible (Bergius and Klung). It furnishes liquid hydrocarbons with quite low boiling points, the percentage of which may amount to 15 or 25 per cent.

It is worth mentioning in passing that the reproduction of mineral oil by synthetic means has been tried, either by direct hydrogenation of acetylene on nickel at 200° C., or with water-gas, or by the distillation of such fatty substances as whale oils.

In the refining process it is important to mention the operation for recovering agents from the spent solutions of sodic plumbite. The solution, which contains about 0.6 per cent. of PbO (in solution as sodic plumbite), 4 per cent. of PbS in the sludge, and 11 per cent. of caustic soda, is so treated as to obtain a clear solution containing 5 per cent. of lead oxide, to eliminate the sulphur and finally to yield sodic plumbite. Illuminating oils are subjected to rectification and refining in apparatus similar to those described above. Illuminating oil from Baku is known as "kerosene".

Rectified petroleum is a limpid and colourless liquid, without marked odour, having a density of 0.75 to 0.80. Its flashpoint, which should not be lower than a certain limit (varying in different countries; it is 21° in Germany, for instance), is determined by the Pensky or Abel apparatus. The addition to rectified mineral oil of ether or alcohol makes it explosive. Its fumes, when mixed in the proportion of 8 to 10 per cent, with air are also explosive.

1 Mineral oil is now not only a source of fuels and lubricants; it is, in addition, a chemical; for by using the aromatic mineral oils and some by-products, notably the gases from "cracking", extremely varied products are obtained.

Coke may be utilised as the carbon of an electrode: from methane, ethylene and other gases obtained by "cracking" may be obtained, by transformation, chemical products of higher value. The aromatic carbides of mineral oil make it possible for benzene to be separated, whence multiple derivatives can be obtained.

In the United States, the "cracking" industry is tending to undergo a change. It has produced anti-knock ethylene light fractions; and at present attention is concentrated on the utilisation of the fuels which it produces and on the manufacture of aromatic carbides. Among the processes, those of Holmes-Monley and Rittman enable a high percentage of benzene and toluene to be extracted.
Heavy Oils and Residues

The distillation of crude mineral oil, which is generally stopped at 300° C., leaves in the still a mixture of heavy oils, paraffins and tar, which constitutes crude vaseline. In Russia, this residue, called "mazout," is used directly as fuel for the boilers of locomotives and ships, for Diesel engines or for retorts for distilling mineral oil. Lubricating oils are extracted from the fraction of these crude products which, on distillation, passes over after the illuminating oils, crude products which, on distillation, constitutes crude vaseline. Lubricating oils are extracted from the fraction of these crude products which, on distillation, passes over after the illuminating oils, and is generally referred to as "residue".

The properties and proportions of these oils vary according to the nature of the hydrocarbons which enter into the composition of the crude mineral oil.

The residue distils at temperatures above 280-300° C. Its treatment comprises two principal phases: rectification-distillation, by which the oil is fractionated afresh into parts of different density and viscosity; and refining, by means of which the oil is freed from impurities and elements detrimental to lubrication.

Although the same order of operations is not always observed, the operations in the treatment of oils in most refineries includes: distillation; refining, which covers the removal of paraffin, chemical treatment, decanting, washing, treatment with absorbent earths, filtration and decoloration, washing and drying; the mixing and compounding of oils to comply with specifications laid down regarding viscosity, flash-point and freezing-point.

The manufacture of lubricating oils also yields some by-products, the greater number of which, depending on the nature of the crude mineral oils, are paraffin and petroleum asphalt, vaseline or oil of vaseline, petroleum jellies and coke.

The excess sulphuric acid, used for refining, is found in the vitriolic sediment. It is recovered or transformed into sulphate of iron or into superphosphate. If the asphalt is not extracted, these sediments are burnt under the stilts.

Treatment by acid has been given up, because the acid, which is difficult to eliminate, has such an injurious effect when the oils are used for lubricating machinery.

The residue of the distillation, diluted with ether and mineral oil and cooled, then leaves a deposit of vaseline, by means of a fresh distillation in vacuo, or by superheated steam, after the recovery of the solvent, heavy lubricating oils are obtained. The final residue is pitch.

These lubricating oils are liquids, varying in colour and viscosity. According to their physical properties, the oils produced are used for lubricating spindles, or gas engines, as light or heavy oils for machinery for cylinders, or for compressors. On mixing them with a soda or lime soap, greases of a firm consistency are obtained.

Gas-oil is a product of the distillation of tar obtained from mineral oil; it has a complex and variable chemical composition. Among the products which it contains are benzene, toluene, xylene and oils of creosote. Gas-oil occurs in the form of a light oil, with a density of 0.854; it gives off a peculiar smell, hardly to be defined, but persistent and disagreeable. It is used for the manufacture of grease and as a solvent, as an illuminant in lamps without glasses, or for making torches of a special type.

Residuary Waters

A great quantity of waste water escapes from a mineral oil refinery; it comes from (a) laboratories, store-rooms, and places for filling and despatching barrels; (b) the cooling of the condensers; (c) the tanks of crude mineral oil, from distillation by steam, from chemical treatments and from washing the barrels — all barrels after use are washed thoroughly before being used again.

The water from group (a) is simply run together and discharged into a river. That from group (b) contains only a small quantity of hydrocarbons; it is sufficient to pass it through a series of separators and then to filter it over coke.

The water from group (c), which is very impure, requires more careful treatment. Some of it being acid, and some alkaline, treatment is begun by mixing it in wooden barrels to cause partial neutralisation. The liquid so obtained has still an acid reaction; it is neutralised by milk of lime, and sulphate of lime is allowed to settle.

As a rule, all alkaline or acid water is strongly diluted with the other water coming from the factory, and the danger to the fauna in rivers is very small.

Toxic Effect

The toxicity of the products of mineral oil, and notably of benzene, is less marked than that of benzene (C₆H₆).
Heavy benzine is, in its turn, once and a half to twice as toxic as light benzine. These statements, however, have only a relative value, since the toxicity of the benzines, which are not well defined products, varies with their sources. But comparative studies on the toxicity of benzines from different sources have not yet been made.

The toxic effect of the volatile oils of petroleum acts chiefly on the nervous system. By means of experiments carried out on convicts at Bucarest, Felix found that, in most of the cases, 5 to 15 grm. inhaled for seven to twelve minutes caused dizziness, nausea, vomiting and sleepiness, as well as congestion of the conjunctivae and a sensation of burning in the chest. Anaesthesia and sleep were produced by inhaling 20 to 40 grm. for eight to twelve minutes, with individual variations from a marked susceptibility to a considerable resistance.

The inhalation of 45 mg. of light benzine vapour causes the death of such animals as dogs and cats at the end of two hours; but 60 mg. per litre of air — or exceptionally even 80 mg. — could, in some cases, be borne for twenty minutes without any inconvenience.

Haggard has experimented with gasoline fumes on dogs, and has found that the first disturbances occur with a concentration of 85 vol. per 10,000 vol. of air. When the concentration reaches 156, the animal is not able to stand; with 192 vol. per 10,000, muscular spasms are caused, and with 162, epileptiform convulsions occur. Another animal lost consciousness with a concentration of 238 vol. per 10,000 vol. of air, and death occurred after two minutes with 243 vol.

It has been possible to establish a definite gradation in the toxicity of the products of petroleum. Thus, petroleum ether is more toxic than benzine at 0.710 density, more toxic still at 0.740 density. It is not possible, however, to speak of an exact scale in the toxicity of these various substances, although it seems that the naphthene series are decidedly more toxic than the aliphatic series.

The toxicity of crude mineral oil is often due to the various impurities which it contains. This is particularly the case on the oil fields of Texas — the Panhandle Field, Big Lake Field, and McCamey Field — where among the harmful gases, sulphuretted hydrogen, which is present in the proportion of 0.20 to 10 per cent, in volume, plays a most important part. A mixture of one part of the gas from the McCamey Field with 50 parts of air is sufficient to cause loss of consciousness. In the mixtures of gas and air from the places where the men work, the concentration of sulphuretted hydrogen in the air varies between 0.01 and 0.07 per cent, and exceptionally, 0.10 per cent. Sulphuretted hydrogen accumulates especially in the confined spaces of the wells and tanks, which renders work in these places particularly dangerous. Its toxic effect is all the more formidable, and is exerted the more readily, owing to the fact that the olfactory sense of the workers is lost when they breathe this gas in high concentration. In many cases, the victim has not time to perceive his danger; and loss of consciousness occurs without premonitory symptoms. A fatal issue in such a case is quite frequent.

The refining of the residues of naphtha ("nigroses") after extraction from mineral oil, of gasoline and of the light oils, involves operations which are liable to produce toxic substances. Thus, the treatment of nitrate by sulphuric acid produces sulphur dioxide, the strength of which may vary from 0.54 to 1.29 mg. per litre of air, according to the operations. Experience shows that there is not, as a rule, acute poisoning, but that an injurious effect on the system is felt in the long run (Blinkoff).

It is important to note the report made by Lapkin and Jegorowa (1929), who found in Russian refineries of naphtha 0.20 to 16.80 mg. of fumes of light fractions per litre of air, large quantities of hydrocarbons amounting to 2 mg. and more per litre, as well as sulphuretted hydrogen. These quantities were naturally higher in very warm weather.

**Statistics**

Statistical data on the frequency and distribution of the various pathological conditions met with among oil workers are very limited. According to some Russian statistics of Berthelson dating as far back as 1895, it was found that among 8,485 workers there were 1,216 cases of dermatosis, 526 of burns, 1,475 of respiratory affections and 607 of physical exhaustion.

In another large Russian chemical works it was found, for 1896 and the following years, that per 100 workers there were 9.2 cases of diseases of the skin among the building workers and 11 cases among those who handled oils and colours.

An enquiry undertaken before the war in Germany by the Federal Bureau of Hygiene showed that out of 1,889 workers kept under medical observation for se-
In several years there were only 34 cases of acute cutaneous conditions and 9 of poisoning due to mineral oil. Chronic diseases or secondary complications were not observed. The cases of dermatitis occurred among persons employed on pumps and the distillation of mineral oil.

The reports of factory inspectors for the year 1919 show an increase for all European countries in cases of skin eruptions due to mineral oils. In Germany, 20 polishers out of 80 were affected by dermatitis; in Switzerland and the Netherlands, the affections have been ascribed to inferior oils used for drills, as well as substitutes for benzine and turpentine.

The incidence of dermatitis was especially great during the war years. The absence of cleanliness certainly contributed much to the development of these conditions. Thus, for example, Ullmann found that in a factory employing 1,000 workers the number of persons affected with acne fell from an average of 129 to 30 as soon as the taking of baths was made compulsory.

In Switzerland, the National Accident Insurance Fund notes under the heading of chronic poisonings by benzine from mineral oil: 1 case in 1922, 1 in 1923, 3 in 1924, 2 in 1925 (one of which was fatal), 1 in 1926, and 3 in 1927. The number of cases due to the skin due to the same injurious agent was 1 in 1922, 4 in 1923, 11 in 1924, 20 in 1925, 5 in 1926, and 12 in 1927.

In Ohio there occurred: from 1 July 1920 to 1 January 1927, 292 cases of dermatitis due to oil used on drills; 115 cases of poisoning by petroleum products made up of 68 cases due to light fractions, 29 from naphtha, and 16 from other derivatives of mineral oil; and 9 cases of sickness due to the effect of the volatile products of mineral oils.

In Azerbaijan, the number of cases of incapacity from sickness among mineral oil workers has been on an average equal to that observed among the remainder of the workers belonging to the Baku Insurance Bureau. Among the diseases, which, without, showing a particular frequency, seem to be characteristic of the occupation, are those due to frequent transport work, dermatoses due to chemical substances, diseases of the eyes and gastro-intestinal disorders. As regards the number of cases of sickness, there seems to have been a general increase compared with the situation before the war, whilst the gravity of the various cases seems to have diminished (Sevald).

In Argentina in 1931, studied the pathology of workers employed in the distillation of mineral oil. He groups the symptoms observed into two categories: those due to volatile hydrocarbons and those due to sulphur compounds. The ill-effects due to hydrocarbons are characterised by nervous disorders, irritation of the mucous membranes, nausea, vomiting, headaches, strokes; in the acute cases, by the form known under the name of petroleum intoxication; in the chronic forms, by anaemia, with eosinophilia and disorders of the digestion and of the liver.

**PATHOLOGY**

Occupational diseases in the mineral oil industry are due, on the one hand, to the inhalation of fumes from mineral oils and volatile oils, and, on the other hand, to the irritating effect exercised on the skin by petroleum, the light fractions or lubricating oils. Some general symptoms of poisoning have also been observed from the absorption through the skin of substances contained in the mineral oils.

**Mineral Oils**

The data relating to ill-effects caused by mineral oils are fairly numerous, but as a rule they are comparatively out of date. In Russia, while Burenin in 1888 denied the occurrence of ill-effects on the occasion of an enquiry he undertook, they had actually been noted since the beginning of the 19th century. Chiefly, Weinberger, in 1893, by Jesener and Bieleczky in 1896, by Korschewsky in 1887, by Lewin in 1888, who made a journey to the United States to supplement his Russian experience, by Sharp in 1888, by Istomin in 1896, and by Nikolajewsky in 1907.

In France, Chevallier in 1864 studied skin affections caused by mineral oil; Poincaré in 1883 reported some injurious effects among workmen breathing air charged with mineral oil vapour; in 1886 an inquiry was made by Broca and Remy to study the injurious effect of mineral oils on the skin. Dankworth in 1888 described cases of dermatitis under the name of petroleum intoxication; in France, Derville and Gueronprez in 1891 reported cases of papilloma among refiners with erythema, itching, eczemas and pustules. Sinatowsky observed similar cases in 1893. These observations have been confirmed in the different mineral oil centres where imported mineral oil is refined. In France, Derville and Gueronprez in 1891 reported cases of papilloma among refiners, which Brémond in 1895 considered as very rare if measures of personal cleanliness are adopted in the works; out of 300 refiners whom he was able to examine there was only one case of papilloma.

The ill-effects caused by inhaling the vapour of crude mineral oil, observed particularly in distilleries and refineries, varies according to the origin, e.g. American or Russian, and the purity of the oil. The sudden inhalation of mineral oil fumes, without sufficient
oxygen; leads to symptoms of very acute poisoning, with loss of consciousness and a fatal result if the victims are not at once carried into the open air. The most serious forms of poisoning have been observed among workmen employed in tanks or on tank wagons which have contained mineral oil, and have not been sufficiently ventilated. Then again repair operations (heating, soldering) may lead to the liberation of poisonous fumes from the residues of distillation sometimes found between the iron covering and the lead lining of the apparatus under repair. The flame of the blowpipe has, in some cases, caused an explosion in the apparatus.

The inhalation of an average quantity of vapour during a more or less prolonged period in an atmosphere insufficiently supplied with oxygen leads to varied conditions of acute poisoning: sometimes, a state of excitement resembling that of drunkenness, with confused ideas on the part of the workman who may refuse to leave the tank or place of danger he is in (Lewin); and sometimes a state of fatigue, somnolence, feeling of intracranial pressure, tinnitus and vertigo. In the most serious cases, lethargy lasting several days has been observed, with loss of consciousness, retrograde amnesia and excitement, which may go as far as to simulate an attack of real acute mania; and sometimes delirium and hallucinations.

In the body itself, tremors, tendon jerks and clonic convulsions have been described; neuritic disturbances, with paraesthesia and disorders of speech; of deglutition and respiration; sometimes a fall of temperature with diminution in the respiratory and associated cardiac frequency and cyanosis of the peripheral parts with a sensation of cold.

The inhalation of a small quantity of the gas causes states of slight inebriety or simply a sensation of vertigo and intracranial pressure, which disappears as soon as the victim is carried into the open air (Koelsch).

Chronic poisoning has also been described, characterised by anaemia, vertigo, rhinitis, mydriasis and general asthenia.

Mineral oil and its derivatives in addition cause respiratory affections: acute tracheobronchitis with violent cough and attacks of suffocation, notably in the case of persons who have inhaled fumes of crude mineral oil. This inhalation was followed in one case by an inflammation and a typical pneumonia; and in another case by cough accompanied by bloodstained sputum and a pleuritic effusion. Besides these acute forms, numerous cases have been observed, on the oil-fields of Baku, of chronic bronchitis, nervous disorders and anaemia attributed to the prolonged action of the products of mineral oil (Korschenewsky in 1887 and Petkevitch in 1898). Some fatal cases have been registered where the men worked in badly ventilated places. J. W. Hall reports cancer of the lungs among mineral oil refiners from inhalation.

As regards the digestive organs, anorexia, digestive disorders with regurgitation from the stomach and vomiting, intestinal disorders and diarrhoea have been observed.

Derivatives of indol (indican) have been found in the urine.

As regards the eyes, irritation of the conjunctiva, nystagmus, disorders of the pupils with mydriasis, and paralysis of the eye muscles have been observed (Ullmann). The conjunctival irritation seems to be due to the combined effect of emanations from mineral oil and sulphuretted hydrogen; it may reach serious forms with photophobia and temporary blindness. Often very painful lesions occur, which cause incapacity for work for several days. Many of the eye troubles are due to negligence or lack of knowledge concerning the danger, and to insufficient care taken about cleanliness.

Skin affections are quite common among workers in mineral oil, especially when the hygienic conditions are not all that could be desired; they are due, for the most part, to the injurious effect of the products of distillation. The chief impurities in question are those which sulphuric acid is capable of dissolving and eliminating. Purified mineral oil causes only slight dermatitis, with folliculitis and acne, accompanied by very great itching; whilst crude mineral oil causes chronic lesions with a tendency to hyperkeratosis, the production of warts and, often, epitheliomatous new growths.

Prosser White classifies as follows the injuries caused to the skin by mineral oil and its distillation products:

(a) Petroleum-benzine, petrol or gasoline naphtha (boiling point 150° C. and under): superficial dermatitis: dry, scaly skin, eczema with fine vesicles, pimples and pustules.

(b) Lamp or lighting oils (boiling point 150-300° C.): popular or pustulous eczema, miliaric folliculitis with or without perifolliculitis (acne) and abscess.
Petroleum and lubricating oils — 608 —

(c) residuum (boiling point above 300° C.) erythema, senile keratosis, punctiform folliculitis, warts, ulcers, carcinoma.

These cases of dermatitis may be complicated by the occurrence of secondary infections. A special form known as "refiner's itch" has been described.

Ullmann distinguishes clinically the following forms of skin affections:

1. Diffuse dermatoses, slight or severe, acute or chronic, situated usually on the upper limbs, more rarely on the face and lower limbs.

2. Eczema caused by crude mineral oil, with the formation of vesicles and pustules, generally situated on the hands, forearms and thighs.

3. Comedones and other follicular inflammations, situated chiefly on the face, on the dorsal region of the hands and the front of the thorax. The scalp and genital organs are more rarely affected. These affections cause intense itching, from which comes the name "refiner's itch".

4. Diffuse or circumscribed hyperkeratosis, with or without pigmentation and the formation of warts or other papillomatous excrescences, which are attributed to the action of certain elements in the heavy oils and crude vaseline.

5. Chronic ulcerations of the skin with malignant degeneration and a tendency to metastasis.

6. Pigmentation of the skin on places where there are eczematous changes or hyperkeratosis.

Gas-Oil

Gas-oil, when used for lighting, gives off smoke with a disagreeable odour, and gives such an insufficient and irregular light that it has been considered as liable to cause eye-strain. Workmen who use it complain of headache, vertigo, irritation of the respiratory passages with cough and expectoration, the nasal mucous membranes being charged with soot, loss of appetite, nausea, vomiting, gastralgia and constipation. After some time, wasting and fatigue make their appearance.

As a solvent or defatting agent gas-oil causes, in addition to symptoms of a general kind, local affections: itching, sharp sensation of burning of the skin, conjunctivitis, tinglings and sneezing.

On the skin, there may be found a persistent blackish coloration, with a tenacious incrustation — resistant to washing — about the follicles; small cracks and fissures appear, accompanied frequently by oedema, pruriginous erythema, acne, furunculosis and eczema, which may be dry or pustular. There have also been noted papules on the forearms, small and multiple warts; and also an extreme fragility of the nails (Langelez).

Some recent observations on cases of dermatitis from gas-oil among locomotive cleaners have shown that such cases are not caused by gas-oil when it is mixed with recuperated oil.

Petrol

Petroleum naphtha or petrol, which is increasingly used either as a fuel, or as a solvent, or for removing stains, causes not only more or less serious cases of acute poisoning, depending on the conditions in which the victim works, but also chronic affections. These latter are, according to experts, more common than is usually believed; for, unfortunately, the symptoms are not always sufficiently definite as being characteristic of this form of poisoning.

It is evident that the use of petrol as fuel is all the more dangerous when the place where the engine works is cramped and badly ventilated, e.g. in submarines and places for testing engines. Years ago Judell (1876), Lewin (1879) and Schroff (1881) showed that this substance acted on the blood by setting free the haemoglobin. Numerous authors have since then drawn attention to the danger from petrol (see article "Garages"). It is, perhaps, worth noting the importance of nerve disorders which have been described in some cases. Thus, Peters in 1900 observed a case of retrobulbar neuritis (non-occupational), and Soupault and François in 1901 reported some cases of polyneuritis in women who cleaned gloves with a mixture of benzene and ether from mineral oil. Gowers in 1908 reported a case of pseudomyas-thenia from the fumes of petrol in a person who tested engines running in a small and badly ventilated room. Hayhurst in 1913 reported 33 cases of injuries due to petrol among painters, enamellers, dry cleaners and varnishers in Ohio. Potts in 1914 described a case of paralysis with loss of consciousness in a workman who filled the tanks of motor-cars; and Dancer in 1915 observed a case of poisoning which was followed by a serious lesion of the spinal cord. Haden in 1919 reported a case of poisoning in a man who cleaned lithographic rollers daily.
using 9 litres of petrol; the patient suffered from vomiting, vertigo, a confused state, cyanosis and a slight leucopenia. Hamilton has studied several cases of poisoning among women who worked on rubber and among painters. In 1922, O. Spencer studied the effects of fumes of petrol or gasoline on a group of 42 workmen who showed slight chronic poisoning; among 22 of these workmen he found headache 13 times, of which 8 only occurred in the afternoon, somnolence 11 times, of which 5 only occurred in the afternoon, intoxication 9 times, orbital pains 8 times, irritation of the conjunctivae 12 times, excessive lachrymation 11 times, fatigue 8 times, and frequency of micturition 6 times.

In 1928, Merle described in France a case of serious poisoning during the repair of a petrol tank, with delirium, excitement, loss of consciousness and coma; and Escartefigue described 3 acute cases due to gaseous products from the combustion of petrol on a small boat on which a petrol motor was used to generate electricity. Duvoir has shown the general effect of mineral oil and petrol, with respiratory disorders, serous apoplexy, neuritis and conjunctivitis, as well as its local action on the skin, setting up superficial vesication.

Among women handling petrol as a solvent, authorities report frequent vomiting and attacks of euphoria or exuberance, which quickly disappears in the open air. In other cases vomiting is absent and those poisoned become stupified, and sometimes fall into a faint; these latter are women incapable of developing tolerance for the poison.

Cases of poisoning have been reported among workmen who have charge of small petrol motors in tunnels, by Johnson in 1913, and by Albaugh in 1916. It is, however, only in cases where carbon monoxide has not been detected, either in the air or in the blood, that poisoning can be attributed with certainty to petrol.

**Lubricating Oils**

These oils, which are very largely used in all industries, are generally classified in three groups: oils derived from mineral oils; oils obtained by distillation of certain shales; and tar oils from coal. In practice, it often happens that the mixtures of these different products, sometimes even with the addition of oils of a different nature (animal or vegetable oils).

Workmen who handle petroleum oils often have upon the hands and arms; pricks from shavings or from rough steel edges, invisible fraying, or burns caused by the projection of boiling oil in very fine spray, or indurations from the lubricant or from rags used for wiping the hands, arms or even the face may occur in consequence, thus resembling cases of dermatitis and oil acne, frequently met with in this class of workers.

As a matter of fact, mixed forms are more frequently met with, especially in the case of products distilling at the higher temperatures. Prosser White considers that the intensity of the dermatitis in these cases depends on still other factors, such as the strength of the iritant, and the kind of resistance and reaction offered by the skin.

Blaschko in 1911 described skin affections due to oil among printers who clean or lubricate large machines; this same author, as well as Alfred and Fisch in 1920, described lesions which he observed under four groups: indolent folliculitis, which is often prurigenous; follicular keratoses, melanodermia of the exposed parts of the skin; and warts. Davis in 1920 described lesions which he found in workmen employed on presses where paraffin oil is obtained. W. J. McConnell in 1922 published the investigations he had begun in 1919 on the action of oils for drills. Among 2,000 workmen examined, he found a characteristic dermatitis 557 times (27 per cent.). Collis has reported 14 cases of dermatitis caused by a mixture of turpentine and an alkaline emulsion of petroleum; he has also observed some cutaneous affections caused by shale oil among mechanics. In a sewing-machine factory at Potsdam, 120 out of 1,000 workmen were affected by dermatitis caused by lubricating oils containing hydrocarbons. The workmen of a spring factory at Frankfurt-on-the-Oder suffered from affections caused by an oil which contained creosote; and the workmen of a string factory suffered from skin affections due to a mixture of mazout and tallow (6 per cent.) with which the manufactured article was smeared. Oil from lignite was regarded as the cause of dermatitis found among the workmen in a pottery factory by Saxe in 1920; and lubricating oil to which phenol had been added caused affections among 20 per cent. of workmen in a factory. Among workmen handling tar oils (Schmieröle) a special skin condition has been reported, which was particularly noticeable during the war. It consisted of a moist dermatitis
rarely serious, characterised by comedones, pustules and sometimes by eczema, situated on the hands, forearms, the neck, and, as a result of contagion by dirty hands, on other parts of the body. A case of rhagade on the lips has even been observed. Examination of the oil revealed the presence of naphthalene in a proportion of 1 to $\frac{1}{3}$ per cent. (Eisner, 1924).

An oil used for lubricating the valves of motors caused several cases of dermatitis. It was purplish-blue, with a smell of oil of gaultheria, and is known as penetrating oil; it is used for cleaning and as an anti-corrosive. It usually contains mineral oil, benzene, petrol and oil of paraffin, alone or in different combinations. It has also become common to contain heavy oils, phenols, cresols, colouring matters and even deodorisers. When this oil is used on a motor which is running, aldehydes and acrolein are given off.

The action of various ingredients and impurities which lubricating oils contain, such as hydrocarbons, sulphuric acid and alkaline sulphophenolates, has led Blum to think that the skin lesions ought to be attributed to foreign bodies which contaminate the oils, and not to the oils themselves.

Oil Acne

For almost twenty years skin affections, known under the names of "furunculosis" or "oil acne", have been recognised as due to infectious agents.

Oil acne, which was first described by Purdon, of Belfast, in 1887, appears most commonly on the parts exposed during work: hands, forearms and face. Sometimes it occurs upon the abdomen, the thighs and the legs, in consequence of the clothes of the workman being soaked with oil. Oil acne may be accompanied by a sensation of heat and itching; the patient scratches himself; the lesion extends; and the dermatitis may become generalised on the hands and the forearms, generally bilaterally. When the lesion becomes infected secondarily it is accompanied by the complications which are common to all occupational dermatoses. In that case it lasts several months.

In 1911 an epidemic of furunculosis was observed in a factory at Cleveland (Ohio) among half the workmen employed on lathes requiring lubrication with lard oil, the use of which is rather exceptional for the lubrication of machines. The consumption of oil was about 4,500 litres per month. By centrifuging, in order to separate off the solid particles, and sterilisation of the product, the infectious agents were eliminated. In 1917 Shie reported an outbreak of furunculosis in another factory which employed about 2,000 persons, where 35 per cent. of the turners were affected.

Purification of the oil, infected by pyrogenic organisms, was carried out by chemical disinfection, using cresols 0.5 per cent. In 1918, Albag and Hayhurst found that. in a factory at Columbus where metal articles were made, the oil used for the drills carried Staphylococcus aureus. These authors consider that chemical disinfection may increase the irritating effect of the oil, and they have advised sterilisation by heat. On the other hand, Page and Bushnell have reported that some bacteria retain their vitality in oil for long periods, such as eight months.

In some cases the particular use determines the injurious action of lubricants. Thus, an oil which is not irritating even if rancid, e.g. lard oil, becomes so as soon as it has been used on machinery.

The quantity of lubricating oils employed every day in industries is considerable; in the United States some automobile works use about 6,000 litres a day. It is obvious, that, in these conditions, it is essential to study the best method for recovering a part, at least, of this quantity. With this object in view, recourse is had to the centrifuge and to heat; to sterilisation followed by a fresh centrifuging; to sedimentation; or, again, to these methods combined. In this way the metallic particles are removed and the infectious germs which the used oils may carry are destroyed. Neutralisation of lubricating oils by washing with alkaline solutions and then filtering is recommended, as far as this is possible. On the other hand, mixing oils and hydrocarbons must be avoided, and the number of days the oils are used must be reduced to a minimum.

Chemical analysis has shown that the degree of alkalinity of some products was not excessive; on the other hand, acidity varying between 0.08 and 0.34 per cent. has been found. Thus it may often be that an exaggerated acidity, over a long period, may cause direct affections, or at any rate impair the resistance of the epidermis to bacterial infections. The presence of such light or volatile hydrocarbons as oil of illuminating, may cause an irritant action similar to that produced by acidity; the proportions are, however, very small, and can only
play a part of secondary importance. Bacteriological analysis has shown that, in addition to some oils which are sterile, there are others which contain microbes (almost exclusively staphylococci). The presumption is thus also be taken for granted in the so-called "clean" rags used. Now, all these factors are capable of causing oil acne, as well as other forms of dermatitis.

In 1916, in French turning shops, Etienne Martin reported numerous cases of oil acne. The same year, Borne and Kohn-Abrest laid before the Society of State Medicine their researches on this subject. Whilst under normal conditions of work this affection was formerly very rare or even unknown, the use during the war of some machine tools which required considerable quantities of oil, from 50 to 100 times more than usual, brought some machines into permanent contact with veritable showers of oil. This thread, laid before the war, was utilised, up to the point of extinction of any lubricating power, soapy water, petroleum containing vegetable oils derived from peanuts and colza, ammonia, acids, and an oil of American origin called "compound". The use for a whole week of the same lubricant pumped round and round according to the requirements of the tasks, kept the microbes in the atmosphere, some of them containing vegetable oils, but not vegetable or animal oils, this author has found suppurative folliculitis; in the midst of the hair follicles and of the blocked sebaceous glands pointed projections appear which are at first red, but undergo suppuration later. The charge from the suppuration of the gland forms a crust on drying. This is of the opinion that the condition is encouraged by the abrasions due to fine particles of iron contained in the used oils; the base of the hairs and the ducts of the sebaceous glands are in these patients filled by small, solid, black masses, formed of fine particles of iron. According to Thierry, oil acne occurs as a round pustule, 2 to 6 or 8 mm. in diameter, usually slightly raised, with tough walls containing thick pus. This pus is composed by a layer of a narrow, red, slightly infiltrated, inflammatory zone, which tends to open spontaneously. Once open, the orifice remains in that state for one or two weeks and the inflammatory zone surrounding the pustule slowly disappears. In addition to this type of pustule, there are other types without infiltration at the base, which develop more rapidly and form a large quantity of pus. These pustules multiply by auto-inoculation and show several characteristics of streptococcal erythema. In some persons, numerous comedones and acne spots develop, usually around a hair.

Blum, when studying oil acne, notes that at the beginning this lesion is accompanied by a slight itching. Little by little, a number of black points develop, which are not removed by washing; then, by blocking of the follicles with dust mixed with oil, violet red or brown, or sometimes pink pustules are formed, generally flat, more rarely conical; their size varies from that of the head of a pin to that of a small pea. Some pustules have a raised centre containing a drop of yellowish pus, with a black spot in the middle; that is the papule-pustule. In other cases the pustule has a vesicular aspect, constituting a vesicular pustule. The lesions, however, vary with the kind and quality of the oil, the duration of exposure, the microbial infection, the dirt, dust, and metal in suspension in the oil.

It has been found among ships' firemen that the increasing use of mazout has led to a greater development of oil acne. In 1921 Noell, of Montpellier, investigated occupational dermatitis caused by mazout. Huguenin in 1926 described a cancer of the skin which developed on a burn from mazout. Further, the investigations undertaken under the auspices of the Manchester Cancer Committee into the part played by lubricating oils in the production of cancer have led to the admission of the existence of a carcinogenic substance in some oils. This substance, used in a solution of 5 per cent., has been found more active than bituminous oil (shale oil), which is considered as the most dangerous. (See articles "Shale Oil Industry" and "Tumours of Occupational Origin (Occupational Cancer)."

**HYGIENE**

Mineral oil workers should be supplied with means to enable them to practise good personal hygiene. All contact with injurious substances must be avoided by providing the workers with impregnated head coverings with broad brims and coverings for the neck, overalls, mackintosh aprons, gloves and high boots. The condition of the skin of the workers must be
regularly examined in order to detect slight irritations which may end in more serious skin conditions. Cleaning the hands with benzine, which is quite common in the refineries and distilleries of mineral oil, should be prohibited, for, though the skin is thus thoroughly cleansed, in the long run this method causes an injurious effect by removing the grease from the epidermis, and rendering it rough. On the contrary, thorough washing of the skin with soft soap must be insisted on, followed by greasing with lanoline or carbolised glycerine.

Men working in wells, tanks or other closed spaces where the amount of toxic gases may be dangerous, should be provided with respiratory apparatus and life lines, and with special goggles against the irritating effect of the gases. One or more first-aid stations should be provided, equipped with necessary appliances and drugs, and especially with oxygen apparatus.

Tanks and workplaces must be thoroughly ventilated, and they must be warmed with steam before they are opened, and before the entrance of workmen, either for cleaning or for repairs. All gases from the plant should be mechanically absorbed and rendered inoffensive. Protection must be provided against the high temperatures of the distilling apparatus.

Gases may come off from wells, even at 5° C.; hence danger from explosion and fire is always present. Careful supervision must be exercised over the liberation of these gases, and particular attention must be given to the pipes carrying the liquids to the tanks and retorts. Explosive mixtures with air must be avoided; for this purpose every receptacle must be connected to a system of carbon dioxide under slight pressure (about half an atmosphere) in such a way that the oxygen of the air cannot come in contact with the inflammable liquid.

There must be a special system of artificial lighting, and safety lamps should be used. Smoking should not be allowed in the department used for extraction, distillation or refining mineral oil. There should be a system of hydrants with hose and also a fire brigade.

Before discharging the waste products, they should be collected in cement tanks sunk into the ground, regard being had to the grave danger from explosion, and the ease with which combustion of a mixture of waste with benzine hot liquid tar takes place. The discharge of waste water containing hydrocarbons into sewers must be prohibited, as experience has shown that men working in the sewers and using naked lights may be injured by explosions. The unhealthiness of work in gasoline factories is due to the nature of the raw materials used, the process of extraction from natural gas, and the kind of product obtained.

The factory should be isolated as much as possible so as to minimise danger from fire or explosion. The various sections of the works should be spaced out. The height of the tanks should be reduced. The construction of the retorts should be supervised. There must be automatic regulation of pressure; adequate ventilation; and meticulous control of the strength of all the parts of the apparatus. The workshops where the most dangerous operations are carried on should be isolated as far as possible. Any possibility of ignition, say from static electricity, must be guarded against; smoking must be absolutely forbidden; use of naked lights must be forbidden. and electric lamps should have a double cover. Volatilisation of gasoline in the tanks must be prevented as far as possible; with this object a low pressure should be used.

Experience shows that 18 per cent. of industrial accidents are due to bad lighting, which, in addition, has the effect of reducing the workers' output. It must be remembered that chlorine gas, when mixed with certain hydrocarbon emanating from gasoline, liberates hydrogen, forming an explosive mixture, which explodes with all the more violence since sunlight may set the reaction going.

Stationary extinguishers should be numerous; provision for these should be made even during the construction of the factory. Inspection of temperatures and, pressures should be periodical and careful.

As regards work with petrol it is recommended that nervous women and alcoholics who do not acquire tolerance should be excluded. Further, workers who have had intermittent fevers, or those who are insufficiently nourished, bear the effect of these fumes badly. As a general rule these fumes are not so easily tolerated on Mondays, or in thundery weather, or during sudden changes of temperature.

The prophylactic measures to be observed for workers handling lubricating oils were summarised by A. C. Hall in 1923 as follows: non-irritating oils, if possible free from germs, should be used; there should be periodic bacteriological examination of oils; the oils should be filtered and sterilised. Workers should be selected; personal cleanliness should be insisted upon; spitting
into the oil should be prohibited; the use of common towels must be forbidden; separate towels should be provided for each worker; soft soap should be used; washing the hands with alkaline water must be forbidden; workers who have infectious diseases of the skin must be dismissed; even the simplest lesions of the skin must be treated without delay. Propaganda is needed for the instruction of workers (leaflets, and advice during medical examinations).

LEGISLATION

Women are as a rule excluded from the refining and distillation of mineral oil and of hydrocarbons. Young persons under sixteen years are excluded in Belgium and in France both from warehouses and factories where work on a large scale is carried on in mineral oils, shale oils and petroleums; children under fifteen years and women under twenty-one years are excluded in Italy.

In Germany the measures laid down for the protection of workers employed in the extraction and refining of mineral oil (25 January 1905) have been reproduced in the Ordinances of the States (Prussia, 3 February 1905, etc.).

Other special regulations have been laid down in Canada (Alberta: Regulation of 15 May 1928 on the boring of wells); in Mexico (Regulation of 17 October 1927 on mineral oil work: sections 335-336: Health and Safety); in Rumania (Regulation No. 716 of 6 April 1926 on the inspection of operations with mineral oil and its gases); in the U.S.S.R. (Order No. 312-412 of 3 December 1955 on the work of men employed in cleaning boats used for carrying naphtha).

Injuries caused by mineral oil and its derivatives, during refining and during its industrial treatment are subject to compulsory notification in the Netherlands; those caused by benzene from mineral oil in Bavaria and in the U.S.S.R.; those caused by mineral oils, used for lubricating, etc., in France and the Netherlands. The same injuries are compensated in Finland, if due to benzene from mineral oil, in Great Britain, if due to mineral oil. In Western Australia, in Queensland, in Minnesota, and in the State of New York, cancer so caused is subject to notification in the State of Ohio, cancer and superficial ulceration of the cornea; injuries caused by hydrocarbons are subject to notification in Argentina, Brazil, Bolivia, Minnesota, New York, and Ohio; in Pennsylvania and Switzerland those due to the volatile products of mineral oil.

BIBLIOGRAPHY

Pharmaceutical Chemists, Druggists and Herb Vendors

Even the ancient writers — Dioscorides, Forestus, Leonardo da Capua, Antoine de Haen, Ramazzini, etc. — were already aware that the occupation of pharmaceutical chemist and druggist involved numerous risks to health in consequence of manipulation of diverse toxic substances of mineral or vegetable origin (lead, preparation of plasters, syrups, etc.).

Amongst modern authors Koelsch has devoted a study to injuries to which pharmaceutical chemists and druggists are exposed in grinding, crushing, kneading, pulverising, distillation, evaporation, etc., i.e. the preparation or simple manipulation of numerous organic and inorganic chemical products which it would take too long to enumerate. Koelsch has noted, as symptoms of poisoning by mercury, nervous irritability with excessive perspiration and anaemia, especially amongst women workers, and marked dental deterioration. In the case of thirteen workers he noted irritation around the lips and nostrils, small cutaneous ulcerations on the fingers and alteration of the nails (friable nails and inflammation) which he ascribed to the corrosive action of the sublimate.

Alkaloids cause an irritation of the skin and the mucous membranes or, idiosyncratic, reactions which are often very serious amongst persons with special predisposition. Manipulation of alkaloids (strychnine, brucine, atropine, apopatrine: Héxheimer, 1912; morphine: Lewin, 1908; codeine, cocaine, quinine, opium, etc.) may give rise to characteristic troubles, which have also been noted with hydrastine, vombine, quinine and various products of ergot of rye (see the articles “Cocaine”, “Opium”, “Quinine”, etc.).

Sorting, mixing and grinding of various vegetable substances involve liberation of dusts, the harmful action of which varies in accordance with the product in question. Dust from birch leaves causes sneezing, that from gallnuts dryness of the mucous membrane and giddiness, that from hops somnolence; ipecac. and quillaja powder may give rise to facial oedema accompanied by conjunctivitis, opacity of the cornea, cold, sialorrhoea, spasm of the oesophagus, bronchitis and attacks of an
asthmatic type (Varekamp), nausea, vomiting, shivering, etc. Amongst the most recent cases noteworthy are some mentioned by Widal, Abrami and Joltrain, a pharmaceutical chemist who suffered from asthma after inhaling the odour of ipecac, and a laboratory assistant who suffered from eczematous dermatitis of the face after handling emetine powder. The prolonged action of mustard fumes causes an injury of the cornea analogous to that caused by nitro-naphthaline fumes. According to Pick (1901) the workers affected suffered from slight but total opacity of the cornea more perceptible at the centre where it appeared as a very broad horizontal band. The opacity was due to small superficial transparent vesicles very close to each other on the open side of the cornea corresponding to the palpebral opening, with consequent diminution of sight, sensibility of the cornea and myosis. The vesicles do not open. Healing commences at the periphery, progresses towards the centre and is complete in the course of some weeks. The case of Neustatter (1901) was that of a pharmaceutical chemist attacked by fumes from mustard oil, which caused marked conjunctival hyperaemia, lachrymation, photophobia, with corneal opacity from the first few days onwards; it had not cleared up. The injury is due to the essential oil of mustard which is formed during grinding as soon as the mustard comes in contact with hot water. Eating grains of mustard has caused painless necrosis of the teeth.

Irritations of conjunctival irritation have been recorded in consequence of the handling of euphorbium, vanilla and podophyllum powder (see article "Podophelline").

Pulsatille powder has caused attacks of colic, vomiting and ocular troubles (conjunctivitis, anaesthesia of the cornea and hyperaemia of the retina, etc.). Sabadilla powder causes violent sneezing, rhinorrhagia, headaches, pharyngal catarrh (action of veratrine, an alkaloid of sabadilla). Croton tiglium, handled without precautions, causes, besides irritation of the mucous membranes, oppression of the chest, gastralgia and vertigo accompanied at times by collapse, dyspnoea and mydriasis. In the course of drying cakes made of dust of the castor-oil plant (1/250,000) a chemist is reported to have suffered from irritation of the eyes with lachrymation, corzya and asthma (Breton, 1923). The powder of Veratrum album causes sneezing; epistaxis, laryngo-pharyngal catarrh and headache. Workers engaged on a preparation of colocynth have suffered from symptoms of poisoning (see article "Colocynthia"). Intestinal troubles may be caused by phenolphthalein and alizarine red, the latter causing also red coloration of the urine and excreta. Pyrethrum powder may induce chronic rhinitis, asthma, conjunctivitis and certain forms of dermatitis on the face and hands.

A case of itch in a druggist due to an acarus has been described by Ciarrocchi (1930).

Prosser White (1920) has assembled under the designation "drysalters' itch" all the forms of dermatitis noted as occurring amongst this category of workers. Cutaneous troubles have been reported as following from the manipulation of borax (Hazen, 1914), various preparations of sugar, hydrochlorate of phenylhydrazine (localised or radiating erythemas on the face, scrotum or thighs, etc.; Hall, 1899; Galloway, quoted by Alibutt and Roleston, 1911), formic aldehyde (dermatitis and lesions of the nails: 5 cases noted by Galewsky, 1905, amongst chemists and laboratory workers, six to nine months after employment in handling the product; one case of generalised urticaria: Glover, 1901). Forms of dermatitis have been caused by the preparation of plasters or tinctures of cantharides (Oppenheim, 1914), by the manipulation of peroxide of hydrogen and iodine (Sabouraud, 1915). Apart from these cases, due to products which they handle, pharmaceutical chemists and druggists are further exposed to the risk connected with tools and apparatus utilised by them; inhalation of combustion gases (gas jets, etc.), cuts and wounds from glass, explosions (solvents: alcohols, ethers, etc.), burns, etc. (See also article "Medical and Allied Professions (Occupational Pathology of").

Reference has also been made to forms of cramp and paresis amongst workers engaged in preparing by hand pills and tablets, etc. The constant spread of mechanical apparatus is eliminating this risk.

Two cases of anthrax have been reported among druggists engaged in cutting up leaves of Dalatura stramonium from Hungary.

**Hygiene**

Hygienic measures comprise protection of workers engaged in operations liable to give off harmful gases, fumes and dusts; fitting of effective ventilation devices on apparatus without hoods; execution of operations as far as possible in closed vessels; provision
of masks or respiratory apparatus for workers and of oxygen in case of necessity; personal hygiene: washing accomodation, douche baths, working clothes, etc. Instruction of workers in the risks attending their work.

**LEGISLATION**

Women and young persons under eighteen years of age in France, and of boys under sixteen and women under twenty-one in Spain are excluded from mustard plater manufacture with hydrocarbons (workshops in which solvents are handled).

**BIBLIOGRAPHY**

**Phenols**

The phenols are those of the substitutive derivatives in the benzene series that have OH groups in the place of one or more atoms of H of the benzene nucleus. Some phenols are partly soluble in water; all are soluble in alcohol and ether; they distil unaltered. When distilled with zinc powder, the phenols give the corresponding aromatic hydrocarbons. Speaking generally, they have a reducing action. They react with the nitro compounds and other substances to give dye-stuffs. With formic aldehyde they yield characteristic resinous products of condensation, e.g. bakelite (see that article).

Phenols are extracted from tar obtained by the dry distillation of coal or wood. They have a characteristic odour (phenol, thymol).

Anisol (C₆H₅O.C.H₃) is obtained by heating the alkaline phenates with alkyllic iodides.

Among the halogen phenols may be mentioned tetra- and penta-chloroanisol (C₆Cl₅O.C.H₃). (For cresols, see that article.)

Anethol is another homologue of the phenols; it is solid and colourless, with a very agreeable odour of aniseed.

The diphenols, or bivalent phenols, contain two hydroxyls joined to the C of the benzene nucleus. They are prepared by processes similar to those used for the monovalents, to which they are closely analogous. There should also be mentioned pyrocatechin, resorcin and hydroquinone. (See also the articles "Dinitrophenol", "Aminophenols" and "Pieric Acid").

Pyrogallol, or pyrogallic acid, is one of the trivalent phenols. Among the polyvalent phenols it will suffice to mention hexoxybenzene.

The quinones remain to be mentioned; they may be considered as derivatives of the phenols by the elimination of hydroxyl, with consequent displacement, and partial elimination of the double links in the benzene nucleus. They are generally yellow in colour, with a piquant odour. They are oxidisers; and can be carried by steam, undergoing partial decomposi- tion during this volatilisation.

**TECHNICAL DATA**

Phenol or carbolic acid is extracted from tar oils treated repeatedly by small portions of caustic soda solution, while a current of air keeps it agitated. First, phenol is extracted, then the cresols, and finally, with a more concentrated solution of caustic soda, a large part of the neutral tar oils can be dissolved. The alkaline solution of phenol, after being decanted, may be purified by means of a current of steam which eliminates the naphtha-line; the phenol is then separated by means of carbon dioxide or sulfuric acid. After several washings with water, crude phenol, or "grey phenic acid", is obtained; it is of variable composition, and appears as a reddish or brown liquid, with a strong and repellent odour, containing 50 to 95 per cent. of phenol, homologues (cresols) and variable quantities of hydrocarbons.

The crude phenol is purified by several fractional distillations between 175° and 185° C., or until it crystallises and does not become red on exposure to the air. By suitable operations a chemically pure phenol can be obtained.

Synthetic phenol was obtained during the war, starting from very pure benzol. The necessary quantity of
concentrated sulphuric acid is first poured into an iron vat, heated indirectly by steam; it is stirred without heating; the temperature is then raised to 115° C. in order to obtain benzene-monosulphuric acid; the acid mass is then poured into a hot, almost saturated, solution of sulphate of soda to remove the excess of sulphuric acid, and to separate, by cooling, a crystalline mass of benzene sulphonate of soda. The crystals are centrifuged and poured into melted caustic soda, which is then heated. The melted mass of phenate of soda and sulphite of soda is poured into a little water; the sulphite is thus separated from the solution of phenate of soda; it is filtered; by means of dilute sulphuric acid, the phenolic acid is liberated as it floats on the solution of bisulphate of soda; it is decanted and the crude phenic acid is distilled in a vacuum to give very pure phenol.

The Bergius and Meyer process enables phenol to be obtained by heating chlorobenzene with alkaline water under pressure at 300° C.

Pure phenol occurs in the form of white crystals with a characteristic odour, melting at 41° C. and distilling unaltered at 182° C. Humidity lowers their melting point and they may then liquefy. Phenol is slightly soluble in cold water, but more so in warm water; alcohol, ether, chloroform, and petrol; it is insoluble in acetic acid and the fatty oils.

**USES**

Phenol is used in the chemical industry for the preparation of numerous compounds and products, such, for example, as phenyllic ether or phenyl oxide, used in perfumery as the essence of geranium; hexaline or cyclohexanol, used for the preparation of emulsions with the mineral and fatty oils; salicylic acid, and numerous disinfectants and antiseptics known under the most varied names; it is also used in the rubber industry as "faturan".

Since 1911 very comprehensive researches have been directed towards obtaining new synthetic tannins, organic products more or less defined, which possess the property of combining with proteinaceous matter, such as gelatine and hides, and giving rise to imputrescible substances which possess some resistance to the action of water.

These new synthetic tannins may be classified in two categories, according as they are related to (a) condensation products of sulphonated aromatic carbons or of sulphone phenols with themselves; or (b) condensation products of sulphonated aromatic carbons or of sulphonated phenols with formol or another aldehyde. The products at present existing on the market under the most varied names belong almost entirely to the second category. They correspond principally to various types of condensation of formol with the sulphonated phenols and, in particular, with crude sulphonated cresol.

"Acrolite" is an artificial resin based on phenol and glycerine, with 4-12 per cent. of formaldehyde. It is used for impregnating fabrics or sheets of paper and asbestos, and for making moulded objects which are unattacked by chemical agents and resist high temperatures.

For industrial hygiene and pathology relative to the substitution products of halogenated phenol, reference should be made to the corresponding articles. It is sufficient here to say that many of these products are used in the chemical industry for the preparation of synthetic organic dyes, synthetic medicaments and organic developers used in photography.

Anisol, or methylphenic ether, is used as a solvent in the manufacture of certain chemical products and certain perfumes.

Trinitroanisol, or methyl ether of picric acid \((C_6H_4OH\cdot(CNO)\)) is used in the chemical industry and especially in the manufacture of explosives.

**SOURCES OF DANGERS**

**During preparation.** — The risk arises chiefly from the operation of sulphonation (synthetic phenol). (For dangers during the distillation of coal tar, see article "Coal Tar".)

**During use.** — Years ago the use of carbolic acid for disinfection during surgery (Lister's method, introduced in 1867) in the form of carbolic spray, was the cause of serious cases of poisoning among the medical personnel, both doctors and nurses. The use of its solutions for disinfection or preserving has been abandoned, and still is, the cause of cutaneous lesions.

Risks also arise during certain operations in the preparation, as well as in the use, of phenol compounds and chemical products with a phenol base: in factories for antiseptic dressings; in certain operations, such as the renovation of old rubber with phenol; in the manufacture of "faturan" and bakelite; and in the impregnation of wood by "carbineum".
Mention should also be made of injuries caused by the phenol released during certain operations: distillation of coal tar, if the phenol is not recovered; cleaning of the matter from purifiers for illuminating gas; treatment of ammoniacal liquor from illuminating gas. The ammoniacal liquor from the coke ovens of the Ruhr mines contains phenol, and endeavour is made to recover this by the use of benzol. It has been possible to push the recovery to such a point that there does not remain more than 0.7 to 0.8 grm. of phenol in the treated liquor. About 25 per cent. of benzol must be used to the quantity of liquor treated. There is left in the liquor 1.2 to 1.4 grm. of benzol, of which it is possible to recover about 75 per cent. Lastly there are risks of fire and explosion from trinitroanisol, which is an inflammable product.

**TOXIC ACTION**

The toxicity of the phenols due to the hydroxyl radicle increases with the number of these radicles. Hence pyrogallol, which is a trihydroxybenzene, is more toxic than phenol, which is a monohydroxybenzene (see also article “Benzene Derivatives”).

Phenol exercises both a local and a general effect. Locally it attacks the skin, for it precipitates and coagulates albumen. This caustic effect is naturally more marked on the mucous membranes, on which it causes burns and necrosis.

The toxic dose seems to vary greatly according to individuals. A large number of fatal cases are known from doses of 2 to 3 grm. But it is an accepted fact that 15 to 20 or even 30 grm. may be necessary to cause death. In industry as a general rule there only arises the question of poisoning by inhalation of phenol vapours. Reabsorption takes place, affecting chiefly the central nervous system; it is manifested by paralysis, preceded, in the case of animals, by intense excitement. Phenol, and especially the phenates, have a marked haemolyzing effect (Loewy) on the blood. According to the experiments of Paul Bert, the blood of the right side of the heart in cases of rapid poisoning is black; that of the left side is red. If phenol has been injected into the veins, the blood is black all over the body; it does not coagulate, but on exposure to the air it becomes red and coagulates. The red blood cells are changed. Sometimes fatty degeneration of the liver and kidneys is found. The urine develops a deep brown colour soon after taking the poison; elimination of phenol by the urine is therefore rapid. Hence Salkowski estimates that chronic poisoning by phenol is scarcely possible. On the other hand, there exists a definite tolerance in some subjects, so that many doctors using the carbolic spray never feel any ill-effects.

Part of the poison may be eliminated by the respiratory passages, and cause inflammation there. Phenol is found in the urine partly as such and partly as conjugated or sulphonyconjugated acid, or conjugated glycuronic acid. Falkson, after using for two and a half hours a 2 per cent. carbolic spray, eliminated in twenty-four hours 2.06 grm. of phenol, or fourteen times the maximum dose used at that time in the pharmacopoeia.

The chlorinated and nitrated compounds of phenol have a caustic effect analogous to that of phenol and perhaps even more pronounced. In animals the mononitrophenols transform haemoglobin into methaemoglobin.

No case of industrial poisoning is known from chlorophenol (ortho or para) which has a certain practical interest, since it is used in the manufacture of antiseptic products, and of aniline dyes.

From experiments (Karpow, 1893, and Binet, 1896) they appear to cause muscular spasms, trembling, collapse and then death. There is no difference in the action of the two isomers. The kidneys are the most affected (haematuria and casts). Chlorophenol and trichlorophenol have a greater caustic effect than phenol; their fumes irritate the conjunctiva and cause severe lachrymation (Erben).

Dambloff (1908) caused the death of a rabbit by applying on the skin ortho-nitroanisol in the dose of 0.5 grm. per kilogram of animal. Death was due to pulmonary haemorrhage. According to the French Committee on Munitions, dinitroanisol was one of the two most poisonous compounds with which it had experimented upon animals.

The aminophenols and the diphenols exercise a similar action. Trinitroanisol is distinctly less toxic than nitrophenol; but it has, nevertheless, a local caustic action and a general action, as became evident during the war in the manufacture of explosives and during the filling of grenades.
PHENOLS

STATISTICS

Cases of poisoning of occupational origin are very rare. Hamilton in 1880 reported three rapidly fatal cases which occurred in the United States: a chemist who had stepped into a small pool of phenol and splashed his leg, and two workmen whose clothes were splashed accidentally.

In Great Britain, Collis, in 1910, drew attention to some cases of eczema among workmen in the engineering industry who used mineral oils containing creosote and phenol. Bridge, in 1918, reported several cases of dermatitis with acute erythema and swelling of the face from phenol vapours. In 1923, there were reported two cases of multiple warts among young workmen employed in the extraction of creosote from wood.

This source of injury was also reported in Germany during the war. In 1913, in Passau, some cases of eczema were observed in a rubber factory where "faturan" was manufactured: three cases in 1912 and six in 1913.

In Upper Silesia, in 1922, several cases were reported of vomiting and malaise caused by a lacquer called "Phonol", containing tar distillation products and having a very distinct odour of phenol. This product had a strong irritating action on the skin. At the beginning of the same year numerous cases of eczema were reported in the Luneburg district in a rubber factory, and particularly in the marbling workshop, where umbrella handles were made by running a liquid mass of "faturan" into troughs and moulds. Six women workers out of twelve fell sick at the end of a few days. Whilst in 1913 the cases were due to phenol, in the instance in question the "faturan" contained neither phenol nor formaldehyde; but it is possible that the disease was due to a substance which was formed during condensation. Measures of protection were adopted, which included the application of lanoline on the forearms; these gave good results.

Numerous cases of dermatitis from condensation products with a basis of phenol or cresol and of formaldehyde were noted in Bavaria during 1923-1924, and also in Austria. In one factory the workmen who were the most exposed were those who washed the moulds containing the residue of a condensation product with a hot and concentrated soda lye.

In Switzerland, 3 cases of poisoning by phenol were reported in 1911 and 1 case in 1912; 5 cases of eczema or of burns in 1917-1918; 1 case of poisoning in 1926; 21 cases of eczema and burns from 1919 to 1925; 2 cases in 1926 and 1 in 1927 due to phenol and formaldehyde; 1 case in 1927 from nitroso-phenol.

Egli-Rust noted a fatal case, that of a railway worker who had dipped a finger into a solution of phenol, used for the impregnation of wood, and also cases of malaise (headache, vertigo) in work on artificial leather containing derivatives of phenol, liberated by heat and acid sweat.

In the U.S.S.R., Naumov noted in 1929 a large outbreak of poisoning among persons employed on impregnating wood with "carbolineum" (dermatitis, haemorrhage from the gums, nausea, vomiting and cough). On analysis, acridine and anthracene were found to be present in the "carbolineum".

PATHOLOGY

The local effect of dilute solutions of phenol on the skin is shown by dermatitis, with exanthematous, macular and papular erythema, by paraesthesias which may extend as far as loss of sensation, by tingling, pigmentary changes, and loss of the normal softness of the skin, which takes on the appearance of parchment, and becomes yellow and yellowish-brown. The more concentrated solutions cause burns, with the formation of white dry scars, which later turn yellowish-brown. Very high concentrations cause more or less deep erosions, which pass on to gangrene. Healing may be obtained by eliminating the necrotic parts, with cicatrical contraction; but cases which have ended fatally are known.

Among medical staffs a true eczema, which spreads rapidly and is increased by an individual susceptibility, has been observed (Blaschko).

A special sequela is phenic chromosis, a melanotic coloration of the cartilaginous or similar parts of the body, as well as of other parts, including the face, external ear and hands; it is the result of chemical reactions with transformation of the colouring material of resorcin and hydroquinone by a ferment, tyrosinase.

Occupational poisoning by phenols is not very common. The acute or subacute form may appear in the case of extensive and strong splashing with the product; it then occurs in the form of an accident (breaking of a carboy or some other apparatus). The symptoms described are: loss of consciousness, death from respiratory paralysis, preceded by muscular spasms and convulsions. In the less serious cases burning and noises in the ear are noticed, headache, vertigo, fainting, mental confusion, excitement, delirium, pallor of the face, dyspnoea, irregular respiration, with small pulse, phenomena of excitement, enlargement of the pupils, and then paralysis and death.

These symptoms have been caused also by the inhalation of phenol vapours, which irritate the mucous membranes and may engender catarrh and erosions of the respiratory passages, with laryngitis, tracheitis, bronchitis...
and broncho-pneumonia, and affect the eyes, setting up conjunctivitis, keratitis and leucoma, especially among workmen employed in mixing tar, and the oils of tar, with phenol for impregnating wood. The damage is particularly serious when splashes of phenol enter the eye. Cases of oitis caused by phenols have also been reported.

Many authorities at the present time fail to admit that there exists a chronic form of poisoning. However, a chronic general form, known as "phenic marasmus" was described by Czerny for the first time in 1882 among doctors and their assistants who used the carabolic spray regularly. Von Jaksch has also described it among workmen employed at factories where carabolic dressings are made. This marasmus is characterized by digestive symptoms, including serious disorders of nutrition, with vomiting, difficulty of swallowing, ptomaine, diarrhoea and anorexia, by nervous disorders, with headache and mental disturbances, and by sexual symptoms — vertigo, fainting and skin eruptions of every kind. In serious cases degeneration of the kidneys, causing chronic nephritis, and of the liver has been described. When these symptoms appear, the development is usually fatal. The authorities previously mentioned consider that more doctors than is generally recognized have died in this manner in consequence of the regular use of the carabolic spray.

As regards the local and general action of nitrated phenols, the reader is referred to the article "Dinitrophenol".

Of the aminophenols, amido exercises a local caustic action on the skin, and originates paraesthesia, as well as signs of irritation of the mucous membranes. Metol causes eczema, chiefly in blond people (for full details, see article "Aminophenols").

Hydroquinone and resorcine exercise a similar action. During their manufacture, scrotal hyperkeratosis and an effect from reabsorption, similar to that of phenol, have been noted.

Guiacol causes diminution in the sensibility of the skin, and sometimes eczemas, vesicles and superficial necroses. In stronger doses, the effect of absorption is to cause attacks of sweating with a fall of temperature, polyuria and pyrexia.

Creosote causes very irritable lesions of the skin, with eczema and erythema, especially when hot. Legge has seen some cases of this in needle factories, caused by oils of tar containing creosote. Exposure to creosote fumes leads to a brown coloration of the cornea, and, after long exposure, to desquamation of the corneal epithelium.

Local effects on the mucous membranes of the conjunctiva, nose and pharynx, have also been described. Cookson reported, in 1924, the case of a workman who was exposed for many years to the action of creosote; he had an epithelioma on the right hand complicated by warty excrescences on the left arm. The course was rapidly fatal.

Among the trivalent phenols, may be mentioned pyrogallol or pyrogallic acid, the local effect of which is shown by erythema, dermatitis and burning, while the general effect is shown by headache, shiverings, vertigo, vomiting, diarrhoea, pallor, anuria, diathesis, diarrhoea, pallor, thirst, feeling of malaise and lassitude, headache, vertigo, anorexia, thoracic constriction, restlessness, rise of temperature, and, in serious cases, inflammation of the lungs and haemorrhagic nephritis. Cessation of work and suitable treatment arrests the malaise in two to three weeks. No special sequelae have been observed. It is, however, to be noted that a special sensitiveness of the skin remains, not only to trinitroanisol, but also to various other chemical substances which are of themselves only slightly irritating (Koelsch).

In the case of poisoning by phenols, the urine is pale yellow or bloody or reddish brown, turning, on exposure to the air, greenish-black. Urine treated by barium chloride does not give a precipitate of barium sulphate, for all the displaceable sulphate is used to
form phenol-ethersulphuric acid. The urine also often contains albumen and casts. As regards the chlorinated compounds, see above.

DETECTION

In addition to their special and very characteristic odour, the phenols have various reactions which make their recognition easy. The most convenient process of estimation consists in transforming phenol into tribromophenol, and measuring the quantity of bromine water required for this transformation. (See text-books of chemical toxicology.)

HYGIENE

Scrupulous personal cleanliness is required, and also adequate organisation of first aid; some firms provide a supply of alcohol for immediate removal of splashes caused by phenol.

All the measures proposed for the manufacture of chemical products, and, in particular, of nitro and amino derivatives, should be applied in the preparation and manipulation of phenol.

Nowadays, such up-to-date apparatus is used that any escape of the product is almost completely precluded. Recourse should, however, be had to localised exhausts for the fumes whenever that is possible. Work in glass cages with openings for the passage of the arms has, in some cases, been effectively employed.

Dephenolisation of waste water is of the first importance from the point of view of hygiene and of industrial economy. Phenols are found in large quantities in water used for scrubbing and condensing illuminating gas, and at cokeries, but mainly — it may even be said almost entirely — in water from the condensation of refrigerants. Hence the need for collecting this water separately, so as to treat smaller, but richer, quantities of liquid, use less solvent, and obtain a higher output. It is estimated that as much as 99 per cent. of the phenols — that is, of phenol and cresols — can be recovered.

The methods of dephenolising can be classified in two groups: first those where the destruction and elimination of the phenols does not permit their recovery, the use of water for quenching coke, sending water into a tower in order to bring it into contact with fumes or combustion gases, or treatment by a biological process with Emscher's filters, and secondly those which permit recovery. After clarification and exhaustion with benzol, with the addition of sulphuric acid, the benzene solution is treated by a caustic alkali (method of Weiss). The phenol is found in the water, either as such or in the form of calcium phenate, when the water has had lime added to it in order to liberate the combined ammonia.

Replacement of toxic products by others not having the same disadvantages should be resorted to wherever possible. Other measures recommended are the use of means of protection for the workmen (application of lanoline or other fatty substances), the selection of workmen after medical examination, with elimination of sensitive subjects and periodical medical supervision.

LEGISLATION

Legislation is the same as that laid down for chemical products in general and for nitro-amido derivatives of benzene and their homologues (see those articles).

The Argentine Government excludes women from any work which brings them into contact with phenols and cresol; likewise in Japan, young persons are excluded from operations which involve contact with phenols. In the Netherlands the law protects adolescents and women (Decree of 1920), working in places where they are in contact with these products. Cases of poisoning by phenols are compulsorily notifiable in U.S.S.R., and there is compulsory compensation in Finland and Switzerland.

It must, however, be noted that skin lesions and poisoning by phenols are compensated under laws which compensate dermatitis due to chemical products, as well as poisoning by the nitro-amido derivatives of benzene and their homologues, and laws which compensate occupational diseases by "definition".

Phenylhydrazine

Hydrazines are obtained by reduction of salts of diazonium with a hydrochloric solution of stannous chloride. By replacing this stannous chloride by sulphite of soda, there is obtained the diazoureasulphinate, which, by the addition of zinc and acetic acid powder, followed by boiling with hydrochloric acid, separates out the chlorhydrate of phenylhydrazine.

Phenylhydrazine \((\text{C}_6\text{H}_5\text{N.H.NH})\) is obtained from chlorhydrate treated with an excess of caustic soda at 30 per cent., after cooling it is extracted with benzol from which it is separated by distillation of the solvent in a vacuum.

It is an oily, colourless liquid which turns brown on exposure to air. When it is very pure phenylhydrazine takes the form of a colourless crystalline mass which melts at 19° C. and boils at 243°. With powerful reducing agents it furnishes aniline and ammonia. With nitrous acid it gives nitrosophenylhydrazine, which is highly toxic.

Amongst the other compounds of this group mention need be made only of \(\beta\)-phenylhydroxylamine, which is obtained by oxidation of aniline or by a reduction of nitrobenzene with zinc powder and water.

Phosgene

(Carboxyl Chloride, Carbon Oxychloride)

PROPERTIES

Phosgene is the name commonly given to carboxyl chloride or carbon oxychloride \((\text{COCl}_2)\). It was discovered in 1812 by J. Davy, who prepared it simply by exposing to the sun a mixture of one volume of carbon monoxide and one volume of \(\text{Cl}_2\), obtaining thereby one volume of \(\text{COCl}_2\). Hence its name of phosgene, which means “product of light”, derived from the two Greek words \(\phi\omega\sigma\nu\gamma\epsilon\mu\gamma\alpha\) and \(\gamma\epsilon\omega\zeta\alpha\omicron\nu\).

Phosgene is a colourless, pricking, suffocating gas with a disagreeable smell; it is three and a half times as heavy as air. At 7° C. it changes into a colourless liquid, very unstable, which has a specific weight of 1.433 at 10° C. and boils at 8.2° C. At -120° C. It solidifies in a snowy white crystalline mass.

Phosgene is a compound of slight stability: when heated it decomposes into carbon monoxide and chlorine. Hot water, and still better steam, decompose it quickly, giving carbon dioxide and hydrochloric acid \((\text{COCl}_2 + \text{H}_2\text{O} = 2 \text{HCl} + \text{CO}_2)\).

Metals (potassium, zinc, tin, etc.) at a high temperature fix chlorine from phosgene. Treated with cadmium sulphide at 270° C., phosgene forms sulpho-carbonic acid. According to Langenbech and Schumberg, phosgene is as readily formed as a product of decomposition of chloroform administered to patients in a room lit by petrol or gas. Certain surgeons have even attributed various disease symptoms to this gas, and cases of death after chloroform have been noted amongst patients and even amongst medical men and their assistants. Bréaudat, however,
never found that burning pure chloroform gave phosgene, but merely hydrochloric acid and a bitter and acid oil, containing perchlorated benzene, perchlorated ethylene chloride and chlorine. Another statement by Schumburg, to the effect that phosgene once absorbed into the system decomposes and gives off carbon monoxide, likewise remains without proof.

According to Glaser and Frisch, phosgene is also formed during the decomposition of carbon tetrachloride used as a fire-extinguisher. Similarly, phosgene is obtained when ultramarine is treated with carbon tetrachloride (CCl₄) and phosphorus.

Phosgene is readily soluble in the following products: glacial acetic acid, benzine, benzene, xylene, toluene, nitrobenzine, chlorobenzine, acetylene tetrachloride and numerous other hydrocarbons. Inversely it is one of the best solvents of certain substances, amongst which may be mentioned chlorine, chloropicrine, yperite (bichlorated ethyl sulphide) and hydrochlorate of diphenyiarsole.

Phosgene is sold in cylinders or in iron bottles after liquefaction by cooling to −35° C.; or dissolved in a 20 per cent solution of toluene. Thus dissolved it can be kept in glass tubes or flasks.

**PREPARATION**

The methods of preparing phosgene are numerous. From the time of Davy, who obtained it by the action of the solar rays, it has been prepared successively by making carbon tetrachloride at a high temperature act on carbon monoxide (Schutemberg, 1868), by means of phosphorus pentoxide (Gustarson, 1872), and by causing a mixture of carbon dioxide and chlorine to pass over incandescent powdered animal or vegetable charcoal and using an excess of carbon monoxide (Paternò, 1870). The reaction is more rapid and complete if red-hot platinum foam be used, but the process is more costly. Helbig in 1816 perfected the Paternò method and applied it in the manufacture of colouring substances, using as a catalyster small briquettes of very activated animal charcoal and pure carbon monoxide obtained by a special process. He later obtained (1917) phosgene at the Rumianca (Novare) factory by means of the following reaction: CO+SbCl₅=COCl₂+SbCl₃. But already in 1906 Michalske had manufactured it by heating in an electric furnace a mixture of quicklime, calcium chloride and powdered coke. With this reaction carbide remained in the calcium furnace and phosgene was given off. During the war phosgene was manufactured in several countries by a method that was simpler and quicker but more expensive and less efficient as regards output than the methods enumerated above. Fuming sulphuric acid at 100° C. (with 60-80 per cent. of free SO₃) was heated in iron boilers fitted with cooling apparatus, causing carbon tetrachloride to pass through the cooling pipes. The reaction was as follows: CCl₄+2SO₃=COCl₂+S₂O₅Cl₂ (chloride of pyrosulphuryl).

**USES**

During the war phosgene was one of the asphyxiating gases most commonly used by all the belligerents, either by itself or with other volatile substances, soluble in it (chlorine, yperite), with a view to increasing its deleterious properties.

On account of its capacity for disassociation it is largely used in the chemical industry for transforming into chlorides certain mineral oxides such as oxide of zirconium, thorium, uranium, cerium, ittrium, lanthanum, or to obtain anhydrous oxides of certain acids or hydrated oxides such as acids or oxides of vanadium, tungsten (wolframite), titanium and tantalum. It is also used for preparing numerous other products such as arsenic trichloride, acetychloride and acetic di-oxide; to effect synthesis of benzoic acid and benzo-phenone; in the treatment of phosphates and platinum ores; for the preparation of a great number of medicinal substances (dyphenylurea, duotal, creosotal, salol, urethane, etc.). The greatest quantity of phosgene is used, however, in the manufacture of aniline dyes derived from di- and triphenylnethane (diamethylaniline, Victoria blue, crystal violet, ethyl violet) and numerous azo dyes (true benzoic orange 8, wool yellow G, etc.).

**TOXIC ACTION**

The toxic action of phosgene on the system is similar to that of chlorine; the former is much more dangerous though the latter is more irritant.

It is estimated that the ratio of danger is about 15:1 and also that the risk from phosgene may depend on its tendency to cause pulmonary oedema.

The pathology of phosgene was first studied by Bréaudat (1892), then by Trümmler (1896) and Schumburg (1898).

According to experiments engaged in by Müller (1910) on rats and a cat with a view to determining the minimum fatal dose, the quantity of phosgene capable of killing rats in twenty-four hours was 0.02 per cent. in volume.
The numerous observations recorded during the war in cases of serious poisoning of large bodies of troops by asphyxiating gas did not always disclose the true nature of the gas. This explains why but little light has been thrown on the special pathology of phosgene. Experimental research by Lo Monaco and his pupils (Bilancioni and Sammartino) on white mice and rabbits has proved that the minimum fatal dose for white mice weighing 80 grm. is between 5-10 cub. cm., and for rabbits weighing 1 kg. between 15 and 20 cub. cm. With the maximum doses death occurred always within twenty-four hours.

As regards human beings, no certain data exist because, on the one hand, different individuals vary as regards their resistance to phosgene and, on the other, the degree of concentration of the gas in the atmosphere must be taken into account.

Koëbert states that human life is endangered by ten minutes spent in an atmosphere containing 450 mg. of phosgene per cub. metre of air.

According to the experiments of the American Bureau of Mines (1921), the physiological response to various concentrations of phosgene in the air are as follows: minimum quantity of phosgene detectable by its odour, 5-6 parts to a million of air; minimum quantity causing immediate irritation of the eyes, 4.0; of the throat, 3.1; causing coughing, 4.8; maximum concentration tolerable during prolonged exposure to phosgene, 1.0; dangerous quantity even for short exposure, 25; rapidly fatal, over 25 parts.

A unique opportunity for studying the pathology and morbid anatomy of phosgene occurred in May 1918, when an explosion took place in the neighbourhood of Hamburg in a depot containing about 11 tons of phosgene, during which ten people perished and thirty required hospital treatment (Heegler, Wohllwill, Mayer).

The experimental research effected by Winternitz, Wislocki and Finney on phosgene poisoning have shown that in dogs the consequences vary in accordance with the length of time the animal survives exposure to the gas. There is first of all pulmonary oedema with extreme congestion, which reaches a maximum towards the end of the first twenty-four hours and gradually disappears in the case of animals who live for ten days. There is besides fibrous exudation especially around the finer bronchial tubes, with resultant lobar or pseudo-lobar pneumonia, often complicated with necrosis of the walls of the bronchial tubes and formation of abscesses. Where recovery takes place there are sometimes zones of obliterating bronchiolitis and organised pneumonia, which may constitute focal of chronic infection.

Research of the same type effected by Achard, Leblanc and Binet on dogs and rabbits revealed, during the stage of acute pneumonia a marked increase of red corpuscles, of the haemoglobin and of the respiratory capacity of the blood representing a reaction of the system against asphyxia. At the same time polynuclear leucocytosis was noted on the day following exposure to the gas. In the week following the experiment there was often found increased coagulability of the blood and a slight diminution of the albumins in the serum; after disappearance of acute symptoms, progressive diminution of red corpuscles, of the haemoglobin and of the respiratory capacity of the blood, followed by a progressive anaemia which would appear to be of a toxic nature. The more intense the exposure to the gas, the slower the recovery.

STATISTICS

After the cases of Braudat, Trümmer and Schumburg there appeared in medical literature several cases of occupational poisoning by phosgene studied in 1906 by Klocke, in 1907 by Sury-Bienz, in 1910 by Müller (3 cases), in 1911 by Bender (3 fatal cases), in 1912 by Gremitske (3 cases), in 1914 by Roos (5 cases, 2 of which were fatal), in 1917 by Floret (1 case).

Legge in the reports of the British Factory Inspectorate, reported 27 cases of poisoning in 1917 and 69 in 1918 in munition and asphyxiating gas factories.

Three cases affecting chemists were studied in 1920 by Irene Gerbert and two fatal cases by Sheridan Delépine.

In the case, described by Osvaldo in 1928, of a worker who inadvertently caused a grenade to explode, there were chemical burns and serious ocular lesions (opacity and ulceration of the cornea, hypopyon, symblepharon), due perhaps to the presence of chlorine and bromine mixed with the phosgene.

SYMPTOMS

According to clinical observations made at the time of the explosion of the depot at Hamburg, and also during similar earlier occurrences, it appears that the odour of phosgene is discernible in the breath and clothes of the victims. However that may be, it is true that the skin and mucous membrane of the eyes and of the upper respiratory passages (nose and pha-
rynx) under the action of phosgene are subject to irritation only a little slighter than that provoked by chlorine. A short time after breathing phosgene, those affected suffer from a bad taste in the mouth and a smarting sensation in the throat, rapidly followed by more serious phenomena, particularly a dry cough and dyspnoea with a sensation of constriction of the larynx, respiratory exhaustion, suffocation, vertigo, nausea, violent pain in the epigastrium and often vomiting. In very acute cases oppression increases more and more, followed by cyanosis, especially of the lips and ears, profuse sweating and in four to six hours collapse and death by asphyxia. The immediate cause of death always seems to be intense swelling of the mucous membranes with bronchial spasm and consequent pulmonary oedema which interferes with the circulation of the blood and of the air in the lungs.

In acute cases which are not fatal phenomena of asphyxia mostly cease, within thirty-six hours, though the patient remains for a few days subject to respiratory oppression which obliges him to remain stationary in order to avoid dyspnoea and causes him to take very deep breaths from time to time. The cough returns in violent fits, similar to those in whooping cough; the expectoration is fluid with a sort of scum often mixed with blood. The temperature is mostly sub-normal. The pulse slow and strong.

Fairly frequently there is a daily rise in temperature up to about 38° C., followed by a drop. Albumin and casts are sometimes noted in the urine; the blood shows at first pronounced leucocytoses (Roos), then becomes viscous and thick.

Consciousness is always retained; there is never manifestation of nervous symptoms. Where no secondary infection occurs causing purulent bronchitis or pneumonia or broncho-pneumonia foci, complications which may cause a fatal issue of all these symptoms die down gradually in two to eight days, but complete cure is always tardy.

It has been considered possible to distinguish three typical clinical forms due to asphyxiating gas: super acute, acute and subacute effects of asphyxiations.

Poisoning by phosgene may obviously give rise to these same clinical forms.

For Meek and Oyster the physiopathology of phosgene poisoning has two chief aspects: (1) lesions of the deeper respiratory passages with inhibition and reflex vasoconstriction, alteration of the red corpuscles, capillary embolism, increased resistance of the small circulation and dilatation of the right heart; (2) transudation of the plasma into the sub-parenchymatous spaces and the alveoli, death due to fall in blood pressure and anoxaemia of the tissues.

Amongst numerous individuals inhalation of phosgene causes slight symptoms: (1) lesions of the mucous membrane, coughing, vomiting), followed by a period of well-being lasting some hours. Then suddenly very serious symptoms set in: dyspnoea, cyanosis, pulmonary oedema, which in serious cases lead to death (Ferraloro). This is explained rather by the greater resistance of certain individuals to inflammation of the respiratory mucous membrane with a consequent delay in the appearance of pulmonary oedema, than by delayed decomposition of the phosgene absorbed into the system and hence formation of carbon monoxide (as believed by Schumberg). This hypothesis is confirmed by the fact that the symptomatology takes a more serious turn in the case of fair and red-haired individuals (Heger). It has likewise been remarked that black cats resist poisoning better than white cats. Fairly strong doses of phosgene cause spectroscopic changes of the blood (presence of the rays of acid hematine and after reduction by ammonium hydrosulphide, of hematine reduced to alkaline solution or haemochromagen).

At the same time there is a disturbance of the liquid which the appearance under the influence of a slight excess of hydrosulphate (Kohn-Abrest).

Mayer (1928) attributes the formation of hematine to the action of hydrochloric acid resulting from the decomposition of phosgene in a damp medium: \( COCl₂ + H₂O = CO₂ + 2HCl \). Kohn-Abrest considers, however, that even in a case of death occurring in an atmosphere very rich in phosgene the chemical study of the blood will not, unless in exceptional circumstances, provide any useful data, the effects above referred to being only capable of detection in blood of which one-third at least is saturated by phosgene.

Autopsy of fatal cases discloses marked congestion of the larynx, the trachea and the bronchial tubes (Corcio, Wohwill), oedema of the glottis, sub-mucous and sub-pleural haemorrhages. The lungs are voluminous, the alveoli filled with a frothy liquid, and there are often small pneumonia or broncho-pneumonia foci and thromboses in the pulmonary arteries (Roos). As regards the other organs there is dilatation of the ventricular cavities of the heart (Müller) and fatty degeneration of the liver and kidneys, and slight
thromboses in the brain, intestines and limbs (Roos). Anatomical lesions in animal experiment (Müller, Lo Monaco) have confirmed the frequency of necrobiosis of the mucous membranes of the bronchial tubes and haemorrhages throughout the whole pulmonary field and have shown besides marked corrosion and haemorrhage of the gastric mucous membrane (Bilancioni, Sammartino).

Groll, on the basis of 150 autopsies on persons who succumbed to phosgene poisoning, distinguishes three forms of fatal issue: (1) death by asphyxia, characterised by chemical burns, congestive hyperaemia, oedema and pulmonary emphysema, which is equally sensitive to hydrochloric acid. Yet if litmus paper and another paper impregnated with Suchier's reagent be placed side by side in the same gaseous current, it is the litmus paper which will turn first if hydrochloric acid is present, and the dimethylinomobenzaldehyde if phosgene, which enables the two gases to be distinguished.

HYGENE

In industrial establishments where phosgene is prepared or handled, protection of the workers must not be restricted to the use of masks, since they can only be worn by workers employed for short periods and are therefore only to be used in exceptional conditions. It is essential therefore to adopt measures of hygiene calculated to ameliorate the surroundings: provision of adequate ventilation, of means for preventing escape of phosgene from closed apparatus and from piping, of exhaust plant for withdrawal of the fumes at their point of production, and of means for neutralising and decomposing them immediately by means of effective reagents (with a resorcin or phenol basis, with carbonate of soda, soda sulphophenate, mixture of carbon, soda and lime, etc.). Frequent change of working clothes is indispensable, especially since phosgene possesses the property of becoming fixed in materials. Frequent washing of the skin (douches and baths) is very effective, as is likewise the use of alkaline solutions for rinsing the mouth in order to prevent traces of phosgene dissolved in the saliva from causing irritation of the stomach.

Artificial respiration should never be applied to victims of phosgene poisoning (Ferraloro).

DETECTION

According to Kohn-Abrest, in detecting phosgene in the atmosphere an indication is provided by the symptoms produced by traces of this gas on the system. Traces of hydrochloric gas should then be sought for, coming from partial decomposition of phosgene fumes. If necessary, traces of hydrochloric gas can be got rid of by the aid of a piece of soda sulphate melted in its water of crystallisation; thereafter a solution of potassium is stirred with air to absorb the phosgene by decomposing it and forming chloride and carbonate. The presence of chloride in the alkaline solution is confirmed, and if possible that of the carbonate. This last fact is merely of value when the air studied does not contain unduly strong traces of carbonic gas.

Another method consists in desiccating the air by melted calcium chloride, passing it through absolute alcohol which retains the phosgene, and calculating the amount of chlorocarbonic ether formed in the alcoholic solution. A third method consists in shaking air in a tube with diluted potassium and then measuring first the chloride formed and as a control the amount of carbonate.

Kling and Schmutz have measured the phosgene content by combining it with aniline and finding out the weight of the diphenylurea precipitate. Suchier (1929) indicates the presence in a gaseous mixture (air) of traces of phosgene by using highly sensitised reaction paper impregnated with a mixture of dimethylaminobenzaldehyde and diphenylamine, which becomes yellow under the action of carbon oxychloride. The reagent is easily modified by the action of air and light and may turn yellow by spontaneous oxidation; for this reason it is essential that it should be prepared and stored under conditions which exclude atmospheric oxygen.

With a content of 1 c.c. per litre, it turns yellow almost instantly and in presence of phosgene; it requires twelve to fifteen minutes with an amount of 4 mg. per cub. metre. The reagent is equally sensitive to hydrochloric acid. Yet if litmus paper and another paper impregnated with Suchier's reagent be placed side by side in the same gaseous current, it is the litmus paper which will turn first if hydrochloric acid is present, and the dimethylinomobenzaldehyde if phosgene, which enables the two gases to be distinguished.

LEGISLATION

Legal measures for protection of workers against poisonous and asphyxiating gas are obviously generally applicable to phosgene.

In several countries storing and transport of phosgene are subject to special regulations dealing with poisonous gases (in Italy, for instance, under the Decree of 9 January 1957).
Those who come in contact with phosgene should be subjected to medical examination on engagement and to monthly examination thereafter to determine their state of health (such examinations have been made compulsory under Italian legislation: Ministerial Decree of 20 March 1929).

Cases of poisoning by phosgene are subject to compulsory notification in France and the Netherlands: they entitle the victim to compensation in Switzerland and in those countries in which compensation is afforded for poisoning by gas and fumes. Further, such cases may be considered as accidents and compensated as such.

BIBLIOGRAPHY

Phosphoretted Hydrogen (Phosphine)

French: Hydrogène phosphoré (Phosphamine).
German: Phosphorwasserstoff.
Italian: Idrogeno fosforato.
Spanish: Hidrogeno fosforado.

Properties

Phosphoretted hydrogen (formula PH₃) is a colourless, irritating gas, with a peculiar smell like rotten fish, heavier than air (1 litre weighs 1.52 grm. at 0°C. and 760 mm.). At ordinary pressure it liquefies at —85°C. and solidifies at —135°C.

It is only slightly soluble in water (0.1 volume in 1 volume of water — Zangger), rather more so in alcohol; it burns giving rise to phosphoric acid and, when complete combustion takes place, to phosphorus and water. The temperature of ignition is below 100°C with the pure product, but with impurities present (e.g. liquid phosphoretted hydrogen) it takes fire spontaneously at ordinary temperatures.

Mixtures of air and phosphoretted hydrogen are very unstable (with risk of spontaneous explosion), and this instability is greatly increased when the mixture comes into contact with different reagents (potash, potassium pyrogallate) or when the pressure of the mixture is reduced.

Chlorine, iodine and bromine destroy it readily; mixed with chlorine it detonates violently with formation of hydrochloric acid and trichloride of phosphorus.

It is absorbed by numerous solvents, copper sulphate, silver nitrate, sublimate, by the different kinds of charcoal (wood, coconut), bone black, etc. Nitric acid absorbs it in decomposing it, whence the use of this substance in the quantitative estimation of phosphoretted hydrogen. Similarly, it is absorbed and destroyed by the hypochlorites (used with a view to its technical purification). The best absorbent, however, is a solution of cuprous chloride in hydrochloric acid (1 volume of the solution absorbs 130 volumes of phosphoretted hydrogen without decomposing it). On heating or addition of potash this reagent gives off the phosphoretted hydrogen it has dissolved.

Phosphoretted hydrogen is a powerful reducing agent: use is made of this property to separate it from other gases containing it.

Sources of Poisoning

Poisoning occurs in the course of reactions in which phosphoretted hydrogen is given off as a by-product; and in the manipulation or the manufacture of chemicals containing phosphorus, because the latter combines as readily with hydrogen as it does with oxygen.

Such reactions may take place in the preparation in the laboratory of phosphoretted hydrogen and of phosphorus, the conversion of white into red phosphorus, the preparation of sesquisulphide of phosphorus, the action of acids on metallic sulphides, the reduction of silicate of iron containing phosphorus under the action of humidity, the use of cyanamide of calcium containing phosphate of lime or carbide of calcium, and the manufacture of acetylene with impure carbides of calcium containing calcium phosphates as the starting point. The amount of phosphoretted hydrogen in acetylene may be 0.02 per cent. (acetylene obtained from Swiss carbides — Wolff), 0.04 per cent. (acetylene obtained from American carbides — Wolff), or 0.06 per cent. (Lunge). Dittrich is even said to have found amounts varying between 0.8 and 1.7 per cent. Most countries have, however, placed a limit on the
phosphorus content of calcium carbide (this is done, however, more as a precaution against fire than on account of toxicity). A further source of poisoning is the preparation, storage or use of impure ferrosilicon made in electric furnaces (Holtzmann) (see the article “Ferrosilicon”).

“Simonal” is a mixture of silicon, aluminium, iron and ammonium treated in an electric furnace. Under the influence of damp air it gives off small quantities of phosphoretted hydrogen (in 1927 this gas caused three cases of poisoning, including one fatal, among the crew of a Rhine barge).

In 1929 sprinkling of a rat poison based on zinc phosphide on the floor of a Genoa factory where fish were pickled in acid brine led to several cases of poisoning, including one fatal. According to Zangger, the toxicity index is of the same order as that of hydrocyanic acid, perhaps slightly less for acute, and slightly more for chronic intoxication.

**TOXIC ACTION**

Phosphoretted hydrogen enters the system by way of the respiratory organs and is carried into the tissues by the blood, which is not modified although it readily absorbs the gas (about 0.27 volume of the gas in 1 volume of blood — Zangger).

The poison is also eliminated through the respiratory organs (in exhaled breath). According to Zangger, the toxicity index is of the same order as that of hydrocyanic acid, perhaps slightly less for acute, and slightly more for chronic intoxication.

The toxic action has been studied by numerous writers (Eulenberg, Hender- sen, Dybkowsky), but particularly by Lehmann and Yokote. According to the last two, relatively high doses can be borne for a short time without much damage by test animals. A strength of 0.09 mg. produced malaise for three days in animals after an exposure of 30 minutes. Death occurred in 30 minutes after exposure for 30 minutes to a strength of 0.06 mg. With 0.02 mg. it takes two and a half hours to kill the subject. Animals also die, if they absorb doses of 0.004 mg. several times a day and for several consecutive days.

Anatomical lesions are absent in acute, but are found in chronic, poisoning; they consist of haemorrhages in the respiratory organs, pulmonary oedema and fatty degeneration of the organs. A dose of 0.01 per thousand can be regarded as the most the human subject can tolerate. According to Thiele, a strength of 0.25 per thousand is fatal; 1 per 4,000 is injurious (Kohn- Abrest). Before death metabolism is notably reduced. Unlike arseniuretted hydrogen gas, phosphoretted hydrogen gas causes no alteration in the blood, although some writers maintain that it is a blood poison (Dybkowsky) with a haemolytic action (Koschlakoff and Popoff). Most authorities consider that the action of the gas is to paralyse the central nervous system after a period of excitation. Besides its toxic action in the doses indicated, phosphoretted hydrogen gas can give rise to explosions.

**STATISTICS**

Statistics are few. Glaister has reported two cases of poisoning among chemists handling the pure substance and Eulenberg one fatal case. Dietz and Huhne- feld have each reported a slight case. A fatal case has been reported in the Netherlands: a workman employed in welding a boiler with an oxy-acetylene flame. Most of the cases of poisoning result from ferrosilicon (see that article).

**SYMPTOMS**

The clinical picture resembles that of arseniuretted hydrogen. In severe cases the onset is sudden and occurs immediately after inhalation of the poison. The patient complains of tiredness, lassitude, anxiety, oppressive- ness, preternial and diaphragmatic pain, soon turning to a burning sensa- tion and taking on a lancinating char- acter, disturbed respiration, buzzing in the ears, rigors, vertigo, etc. Some- times pulmonary lesions are found (inflammation or oedema), also symp- toms pointing to involvement of the central nervous system, such as nausea, vomiting, staggering gait, tremor of the extremities, dilatation of the pupil, cold clammy sweat, clonic and tonic convulsions. When the intoxication is fatal, weakness increases. There is loss of consciousness, collapse, failure of the pulse and respiration, unconsciousness and delirium, coma and death.

In slight cases there is bronchitis, and the illness usually passes off without complications.

Accurate diagnosis cannot be made without knowledge of the possibility of inhaling the poison as no trace of it is found in the body.
PHOSPHORUS

DEMONSTRATION

(a) In the air: this is carried out (according to Kohn-Abrest) as for arseniuretted hydrogen (see that article).

Another reaction consists in passing the air to be analysed into a solution of silver nitrate, which absorbs the phosphoretted hydrogen and decomposes it. Two-thirds of the phosphorus is precipitated as silver phosphate; the rest remains in solution in the phosphoric acid and phosphorus can be detected by the ordinary reagents.

According to Lehmann it is necessary to bubble the air containing phosphoretted hydrogen into bromine water, remove the bromine, precipitate by a mixture of magnesia the phosphoric acid formed, which is thus identified.

(b) In the body: Gleister states that phosphorus has been identified by means of the Marsh apparatus (animal tests).

PHOSPHORYICATION

As regards first aid and prevention, see article "Ferrosilicon".

In exceptional circumstances, however, gas masks can be used as means of prevention. Exhaust ventilation should be downwards as the gas is heavier than air.

LEGISLATION

Poisoning by phosphoretted hydrogen is compulsorily notifiable in the Netherlands. Compensation is granted in countries where poisoning by toxic gases is compensable, and by those in which phosphoretted hydrogen is specifically mentioned in the list (Finland, Switzerland).

Prof. H. Zangger
(Zurich).

Phosphorus

Phosphorus (symbol P) is a metalloid which is not met with in the free state, but only in very numerous geological formations in the form of phosphates (especially tricalcic phosphate or phosphorite) or of other mineral phosphates, such as apatite, vivianite, wavellite, etc. It is also present, but in small quantities, in rocks, fertile soil, the sea, in all vegetables whence it passes into the animal frame, localising itself especially in the bones of vertebrate animals as tricalcium phosphate. Traces are found also in the air.

CHEMISTRY

Solid at the ordinary temperature, phosphorus freshly prepared is colourless. Sunlight turns it yellow; and it then becomes covered with a pinkish white opaque film. Its atomic weight is 31.0; its specific gravity 1.83 at 10° C. Soft like wax, phosphorus becomes hard and brittle when cold; has a garlic-like odour; melts at 44.46° C. and boils at about 290° C. At 34-40° C., on contact with the air, it ignites spontaneously and burns with a luminous flame; it gives off white fumes, phosphorescent in the dark, which are formed by the oxidation of the phosphorus vapour, and consist of phosphoric and phosphorous acids and phosphorous vapour. If the air is moist, ozone, peroxide of hydrogen, and nitrate of ammonia are produced at the same time. It is insoluble in water, very slightly in alcohol (0.3 per cent.) and ether (1.13 per cent.); it dissolves better in turpentine (4 per cent.), in oils (2 per cent.) and fatty substances, and very readily in carbon bisulphide, chloroform and chloride of sulphur.

MANUFACTURE

Discovered in 1669 by the alchemist Brandt (of Hamburg), who obtained it by heating urine with sand, it was for the first time extracted from bones by Scheele by the method used to-day.

Industrially, phosphorus is produced from the natural phosphates (or from bones that have had the grease removed and been calcined in furnaces), by treatment with sulphuric acid which converts carbonate of lime into insoluble sulphate and the neutral phosphate of lime into the acid phosphate. The solution is filtered and the concentrated filtrate is mixed with coke or sawdust and treated in muffle furnaces. A red heat is applied in earthenware retorts and the distilled product is condensed in iron pipes. The phosphorus, still contaminated by coal particles, is purified by distillation with steam in an atmosphere of carbon dioxide or by filtration through a porous plate of clay, covered with a layer of animal black, or finally through chamois leather. The liquid product is finally run into cylindrical form or into blocks, under warm water, by the use of moulds of the required shape.

Nowadays the method of Wöhler is preferred, which employs bone meal and allows of the extraction of 80 or even 92 per cent. of the phosphorus therein contained. This method is applied also to natural phosphates. The process consists in heating in an electrical furnace at 1300°-1450° C. a mixture of the bone meal, quartz sand, and coke. The furnace is hermetically closed and communicates with a conden-
ser; the silica attacks the phosphate of lime, converting it into a silicate and setting free phosphorous pentoxide which, attacked by the carbon, forms carbon monoxide and phosphorus according to the following reaction:

$$2\text{Ca}\left(\text{PO}_3\right)_2 + 6\text{SiO}_2 + 10\text{C} = 6\text{CaSiO}_3 + 10\text{CO} + 4\text{P}.$$  

The phosphorus, in the form of vapour mixed with carbon monoxide, arrives at the condenser where it is immediately condensed and run under water, whilst the silicate of lime remains as a residue in the furnace.

Phosphorus must always be kept away from air. For this reason it is always marketed in water (with small quantities of alcohol or glycerine to prevent freezing) and packed in well-closed metallic receptacles, which again are placed in very solid wooden boxes or small barrels painted outside with tar and wrapped round with straw and canvas.

Phosphorus is marketed in two forms as white or yellow phosphorus and red phosphorus.

The first is ordinary phosphorus such as is obtained by the methods described.

**Sources of Poisoning**

Crushing of bones gives off much dust if adequate precautions are not taken.

During the treatment of the bones, nauseous fumes are given off during the reaction, due especially to phosphoretted hydrogen and carbon monoxide. Treatment of the mixture by sulphuric acid also gives off sulphuric hydrogen, carbon dioxide, hydrocyanic, hydrochloric and hydrofluoric acids. The phosphorous fumes can vitiate the air of the workroom if suitable preventive measures are not taken. This risk is similarly present in all the industries which manufacture or use phosphorus and its compounds. Another danger exists in the use of solvents, especially carbon bisulphide, which, mixed with the phosphorus, is a very common cause of fire.

The workrooms and especially the evaporating and drying rooms are very humid, and in others the temperature is relatively low.

**Uses**

For most purposes white phosphorus is now replaced by the red, and in the factories which manufacture it, it is almost entirely converted into red phosphorus. It is, however, still used in the preparation of certain compounds of phosphorus, of certain synthetic colours, bronzes and phosphides (see articles "Phosphorus (Compounds)"); in metallurgy; in the manufacture of liquid and incendiary projectiles, smoke screens, etc.; in the manufacture of manure, of powders against pests such as rats and mice, of artificial fires, of paraffined strips of phosphorus paste for relighting miners' lamps, alloys, etc.

Phosphorus in the form of fumes or of its compounds may be present in other industries or processes. Thus, for example, it can be given off, under certain conditions, from ferro-silicon in the form of phosphoretted hydrogen (see that article), and may be contained as an impurity in acetylene (see that article).

The number of persons, however, coming into contact with phosphorus at the present time is very limited; further, as the processes are almost all mechanical, the risk of poisoning by phosphorus is very much reduced.

**Toxicity**

The toxicity of chemically pure phosphorus, minimal so far as the element alone is concerned, is very remarkable when it is a question of the oxides. Phosphorus fumes are the product of the slow combustion of phosphorus exposed to moist air. The toxic agent, however, has not yet been identified, as the determination of the products which are formed by the oxidation of phosphorus has not yet been effected. Certain authorities attribute the toxic action to phosphorus, while others incriminate phosphoric acid and still others phosphoric acid (at a dose, however, three times that which suffices to produce death with phosphorus). The fatal toxic dose is given by certain authorities (Kobert) at 5 centigrams, by others at 20 centigrams, whilst Kobert considers that a dose of 1.5 centigrams is sufficient to cause serious illness. Ogier is of opinion that 5 centigrams of phosphorus may exceptionally cause damage, but that in an adult poisoning is not caused except by a dose of 20 to 50 centigrams. Children are affected by smaller doses (from about 10 to 15 mg.).

No difference has been noted in the two sexes in susceptibility to phosphorus; the general state of nutrition is of little importance; age is of slight importance, although persons under eighteen years are said to be particularly sensitive. Poisoning, however, is more frequent among persons aged 30 to 40 years, perhaps because it is then they are most exposed to the risk in their profession.
An hereditary predisposition has not been proved. The frequency of morbid signs in the same family can be explained by living together and intimate contact, especially through the work-clothes brought home, and a certain family weakness in certain organs or tissues is recognised. The influence of individual susceptibility, which in some persons can reach a high degree, is evident.

Phosphorus reaches the system, especially in the form of vapour, mainly through the respiratory tract, and through the digestive tract when foodstuffs or fingers carried to the mouth are soiled by particles or even phosphorus fume. The skin can only very rarely be a channel of absorption.

The presence of fatty substances in the stomach favours the absorption of phosphorus which is dissolved in the intestinal juices, thanks to the bile. Part of the absorbed phosphorus undergoes change and part is dissolved in the tissues and is found in the blood whence it is eliminated in the form of phosphate. The principal channels of elimination are the kidneys, the lungs and the skin. Phosphorescent phosphorus from bones; in France, since 1880, 9 cases have been reported in the chemical industry; in 1897 Haup traced a

Phosphorus poisoning may be either general (phosphorus cachexia) or local (necrosis of the maxillary bones). The origin of the latter form can be explained by three theories: (1) as a selective action of phosphorus on bone; (2) as a gingival or periosteal infection, or (3) as a sequela of dental caries. Generally it is difficult to decide whether the toxæmia always precedes the local manifestations or whether the phosphorus acts directly on the gingival mucous membrane and bones with or without the association of a local predisposition or pre-existing inflammation.

If the reproduction experimentally of phosphorus necrosis has failed, Vallardi has nevertheless shown that, in the absence of necrosis, changes in the blood, organs and nutrition, characteristic of phosphorus poisoning, are found, while the majority of authorities are agreed that the harmfulness of phosphorus is attributable to the fumes (oxide of phosphorus) on carious teeth or on lesions, small though they may be, of the gums and periosteum. Perussia has proved that the changes in the maxillary bones can be observed even without dental caries and periostitis. When an individual, as a consequence of nasal defects, is compelled to breathe through the mouth the phosphorous vapour comes in contact more easily with the carious teeth and exerts its pernicious action on them the more readily.

Phosphorus, in passing over the soft tissues, might bring about changes in the nutritive processes of the external membrane of the bones. The bones of workers in match factories suffering from necrosis and not completely recovered are said to be more fragile as a consequence of a general morbid state, of which the picture is not that of a simple local infection. The bones of these workers are said to contain an excess of phosphoric acid. The adversaries of the dental caries theory think that a gingivitis takes on a septic condition which degenerates into an osteitis. Actually the general conclusion is that the phosphorus itself does not set up necrosis of the bones, but that it is the predisposing cause of primary lesions which later on develop, especially as the result of inevitable infective complications. Removal of the patient from contact with phosphorus serves to arrest a periostitis which is in the stage of evolution, even if it has already gone on to an ossifying periostitis. Phosphorus fumes would then have a simple secondary action.

Persons engaged in the manufacture of phosphorus are also exposed to the risk of poisoning from acid fumes, from carbon bisulphide and phosphoretted hydrogen (during distillation), and eventually from arsenurettet hydrogen.

**Statistics**

Occupational phosphorous poisoning was not coincident with the discovery of the element, but developed 150 years later with the discovery of matches (1833) (see article "Matches [Lucifer]").

Cases of phosphorous poisoning, however, have been reported among workers manufacturing phosphorus, and in industries and trades using it. Pieraccini cites cases among workmen in factories making phosphorus from bones; in France, since 1880, 9 cases have been reported in the chemical industry; in 1897 Haup traced a
case to the manufacture of phosphor bronze (0.76 parts of phosphorus to 100 parts of alloy). In Germany, in 1913, of two cases among 70 workers in a factory for making lights for miners' lamps, one recovered after 50 days sickness, while the other was permanently disabled. A third case which occurred in Saxony was that of a worker employed as a spinner in whom the disease developed three months after cessation of work; illness lasted 114 days. A fourth case was reported in Bavaria in 1919, but no cases have been notified recently in Germany from the manufacture of phosphorus, although the output has been very great.

Koelch stated that 12 cases occurred in Germany during the war.

Three cases of necrosis were recorded from 1920 to 1926; 12 cases of phosphorous poisoning were reported from 1926 to 1929 (only one compensated).

The cases in Austria were due to phosphor bronze.

From 1927 to 1929 one case “probably” due to phosphorous was reported.

In the United States (New Jersey) cases of necrosis have been traced recently to a factory for fireworks.

Five cases of necrosis were reported in France (1927) among workers in a white phosphorus factory (Borard and Durnel); one case in a woman was caused by making phosphorescent lighter for miners’ lamps.

In Great Britain cases of phosphorous poisoning have been more frequent than on the Continent (see the Report by Thorp, Oliver, and Cunningham of 1898). They state that in the course of 50 years 17 cases were reported in a phosphorus factory using apatite as the raw material. From 1915 to 1919 the total cases of phosphorous necrosis coming to the knowledge of the Factory Department were 21 (with 4 deaths), of which 12 (with 1 death) occurred in the manufacture of phosphorus. It is interesting to note that after 1915 cases occurred among workers employed at the condensers and that two were reported among those engaged in making amorphous phosphorus. Since 1919 no case has been reported.

In the U.S.S.R., necrosis was found in two men who had worked fifty-two and sixty-three years respectively in match-making (1926, Asbel). The illness had begun forty years earlier and was exceedingly chronic. Several of these men’s workmates had died in the meanwhile from phosphorous necrosis.

In 1929, Schritter reported necrosis in a workman who had been employed for four years in the department of a chemical works manufacturing red and white phosphorus and phosphoric anhydride.

**Symptoms**

Locally, phosphorus sets up burns and painful caustic lesions, which heal very slowly; cases of dermatitis (on the hands, fingers, and feet) are described as well as conjunctivitis; itching, burning sensation in the tongue and throat, loss of appetite, air hunger, nasal irritation, cough, etc., have been stated to occur in workpeople preparing rat paste or powder.

In acute or chronic poisoning after ingestion of phosphorus the morbid symptoms come on very rapidly—in the acute form mostly after a few hours—and are noted throughout the whole duration of work on the unhealthy process. In chronic poisoning (manifested in the form of necrosis), on the other hand, the symptoms do not appear until after several weeks (7 weeks on an average), and even generally not until after several years (on an average 4 to 6 years) of exposure to risk. Not infrequently cases are reported with duration of employment of 18, 25, and 30 years, and even in workpeople who have left the work for several months or years (frequently 4 and sometimes after 8 years). These late cases are usually severe.

Two anatomoclinical forms of phosphorous poisoning, therefore, can be distinguished: the acute form, fairly frequent as an accident, and the chronic, which is peculiarly industrial.

The onset and course of the acute form can sometimes be rather slow with subjective symptoms—bad taste in the mouth, allaceous or garlic-like taste more or less marked, developing some hours after ingestion of the poison and (as an objective symptom phosphorescence of the breath in the dark) followed by a feeling of numbness, constriction and pain at the back of the throat, along the oesophagus and in the epigastric region. Subjective symptoms supervene then: nausea, biliary vomiting, haemorrhages occasionally, pains, colic, hiccup. The vomit is black with garlic-like characteristic smell, phosphorescent in the dark; the blood in it is often abundant but rarely red in colour. Sweating is more or less abundant, thirst intense and diarrhoea rare, giving place to constipation or more often the one alternating with the other. The faeces are also phosphorescent and often bloodstained.

An almost complete period of remission follows in general and the patient appears cured. But after two or three days, in about half the cases, a second period develops, of which the most important symptom is an intense jaundice—sometimes limited at first to the conjunctiva and extending thence to the whole of the body. Biliary pigment is formed in the urine; the faeces are pale and clay-like. The liver and spleen become enlarged. The urine becomes scanty (or there is even suppression),
with choluria, albuminuria, often haematuria and even the presence of leucin and tyrosin and rapid diminution of the urea. The temperature falls, the pulse becomes feeble and slow, and collapse and lipothyemia are frequent and sometimes precede the fatal issue. Respiration becomes rapid, with dyspnoea, which is perhaps due to the change in the blood. At this stage subcutaneous haemorrhages occur, digestive disturbance (nausea, vomiting and diarrhoea), photophobia (with myosis). Rise in temperature may occur but is unimportant. Severe lightning pains in the head, along the vertebral column, in the epigastrium, etc., are described, as well as painful cramps and contractions in the limbs. The sufferers are hypersensitive and over-excited (hallucinations, delirium, and insomnia).

There follows a state of depression very marked and characteristic. Further, there is loss of sensation in the skin, dilatation of the pupils, abolition of the reflexes and localised paralysis. The fatal issue is ushered in by collapse or syncope (paralysis of the vagus or internal haemorrhages in the brain or lungs) and is sometimes rapidly induced by severe haemoptysis.

The course of acute phosphorous poisoning does not usually last more than a week, rarely two or several weeks, with a subacute form characterised by alternating exacerbations and remissions. Where there is recovery the kidneys, liver or the myocardium may be the seat of permanent degenerative lesions.

If the haemorrhagic and nervous phenomena take the principal place in the clinical picture the poisoning is either of haemorrhagic type (with vasodilatation of the skin and digestive tract, purpura, ecchymoses, epistaxis, melaena, gangrene) or of nervous type with fatal issue in a few hours, preceded by muscular paralysis, peripheral neuritis, painful cramps, somnolence, delirium, convulsions and very intense jaundice. In the nervous type mortality is very high (one-quarter of those affected).

A special form with symptoms belonging both to the acute and chronic conditions is characterised by loss of appetite, gastric pain, colic, headache, cough, muscular pains, etc. It is met with especially among workpeople coming for the first time into contact with free phosphorus, and disappears, generally after a little acclimatisation, but there remains a tendency to catarrh, bronchitis, gastric pain, and colic. Persistence of these symptoms is there fore in the majority of cases a sign of chronic poisoning.

This chronic poisoning occurs in two forms:

(a) A general chronic condition, the onset of which is characterised by digestive troubles, blood changes (increase in the number of white blood cells and leucocytes, especially of sudanophiles (Biondi), more pronounced and widespread degenerative changes in the leucocytes, which have polymorpho-nucleares and which appear loaded with fat) and by qualitative changes in the urine (presence of free phosphorus, of urea in excess, but rarely of sugar). The excreta and breath have a garlic-like smell. The sufferers complain of loss of appetite, dyspnoea, vomiting, diarrhoea. Swallowing is difficult as a result of complications affecting the nose, tongue and pharynx. A chronic condition of the back of the throat and pharynx is common as well as bronchitis and broncho-pneumonia. The liver and kidneys present the same lesions as those which have been described under the acute form. Fragility of the bones, anaemia with pallor of the mucous membranes and a jaundiced tint of the skin, tired eyes, fever, hesitation in speech, mental dulness, general weakness and insomnia complete the morbid picture. Phosphorus seems to absorb all the faculties and to cause a loss of energy and courage for work.

(b) A localised form, of which the typical symptom is necrosis (phossy-jaw) generally a late symptom. This form was described for the first time in 1845 by Lorinser of Vienna, and then by Heyfelder (Vienna), Erlangen and Strohi of Strasbourg, it was made the subject of a classical monograph by Bibra and Geist published in 1847. The necrosis is ushered in by pain like that of toothache, followed rapidly, however, by swelling of the gums, which become red and bleeding: this is alveo-dental periostitis. In most cases the tooth, often carious, is extracted and pus wells up out of the alveolar cavity. The lesion affects also the gum and the sound teeth. In spite of the extraction the pain does not stop but on the contrary gets worse and extends to other teeth which in their turn have to be extracted. Pain and suppuration continue. The teeth loosen, the gums and surrounding tissues become inflamed, ulcerated and a prey to supplicative processes — a sign of the destruction of the jaw-bone — which make their way through the cheek by fistulous tracts. The sufferer experi-
ences difficulty in opening the mouth, in speaking and eating. Sometimes particles of bone are extruded. If the second orifice is emptied in newly formed bone the tempo-maxillary articulation becomes rigid and ankylosed. But if the sufferer survives for months and years without surgical interference, fragments of necrosed bone can be found in the mouth recalling pieces of coral.

Workers with gingivo-dental lesions are attacked three times as frequently as those with an intact denture (Koelsch). The lesion is also more serious in this case.

Either the inferior or superior maxillary bone, or both, can be affected on one side or on both sides. The course and complications following the necrosis depend on its situation. The lower jaw is attacked more frequently than the upper (60 times as against 40) and the infection is more widespread.

The value of statistics on this point is rather fallacious because they take no account of local and general complications attending the maxillary necrosis. If account were taken only of the data from France and Italy the upper jaw would be found to be attacked in 62.4 per cent. of the cases, the lower in 69.4 per cent., and both together in only 6.3 per cent. in a total of 48 cases.

There are no data as to primary lesions of the bones of the face and nose. When it is a question of the upper jaw the infection spreads sometimes to the orbital plate and even to the base of the brain setting up there a meningitis or encephalitis with neuralgia so violent as sometimes to drive the patient to suicide. The mucous membrane of the palatine vault may hang down so low as to come out of the mouth like a second tongue. If, as sometimes happens, the bone becomes detached, healing takes place, leaving, however, a permanent opening between the mouth and the nasal fossa. At this period the disease is accompanied always by general symptoms — dyspepsia, wasting, sometimes fever, oedema, albuminuria and cachexia. The disease terminates fatally in half of the cases which have run on for an average of two years. Spontaneous cure without surgical intervention takes place in 51 per cent. of the cases of necrosis of the upper jaw and in 57 per cent. of the lower. Other writers give the following figures: 79.5 per cent. of spontaneous cure with total loss of the lower jaw, 10.5 cases of spontaneous cure with partial loss of the lower jaw; in the case of the upper jaw 22.3 per cent. with total loss of bone and 67.7 with partial. Spontaneous cure can take place equally by elimination of the necrosed parts of bones with partial or total regeneration of the bone. Even after healing, however, the necrotic process can break out again in another place if the workman does not withdraw altogether from exposure to absorption. Surgical treatment is said to effect a cure in about 85 per cent. of the cases and certain writers assert that no cure without such surgical treatment can take place. Without it a fatal issue would be the rule in 45 per cent. The first statistics gave lower values (6.4 to 21 per cent.) for the cases resulting in death after operation; the more recent give an average of 17 per cent. for all cases with a slight difference (0.3) in favour of the cases operated upon.

Arnaud in 1897 described conjunctivitis affecting women coming into contact with phosphorous paste in the manufacture of matches. A yellowish tint of the conjunctiva among such workers is often present, but it is unattended by complications. Troubles of sight, which are rare, vary with the susceptibility of the subject. There may be retinal haemorrhage, congestion of the vessels (Niederhausen, 1875), and very small maculae recalling albinuric retinitis. Although there are no precise data optic neuritis cannot be excluded, but such a lesion must be, at any rate, very rare. A case of trigeminal neuritis has been described (Henschen, 1900).

**DIAGNOSIS**

For an early diagnosis of phosphorous poisoning the idea ought not to be persisted in that a substance is not, or only relatively, toxic because other persons exposed to the danger in question show none or very slight signs. In the case of phosphorous poisoning a wrong diagnosis means exposure of the sufferers to a frightful mutilation of the face. Every case of toothache in workpeople handling phosphorus or its products should be watched and the medical man ought to insist on the suspension (temporarily or, if necessary, permanently) of the workman.

The diagnosis is not difficult, especially if the occupation of the sufferer is borne in mind. Examination of the blood is useful in helping to an early diagnosis: any workman suffering from leucopenia, noting especially the poly-morpho-nuclears which do not always stain well; the leucocytes contain droplets of fat sometimes quite large, or a more or less considerable number...
of coloured spots of dark blue when stained with brilliant cresyl blue (Biondi, 1807). With jaundice present a differential diagnosis must be made between the jaundice set up by phosphorus and that due to acute jaundice or to disease of the liver. The digestive disturbances are among the earliest and gravest symptoms. Jaundice and albuminuria, on the other hand, are not so remarkable; multiple haemorrhages occur late and are less grave.

**TREATMENT**

This comes within the province of the medical man; but it is well to remember that of the three methods practised surgically — expectant, resection, and early subperiostial resection — the last named is to be preferred. Discussion, however, is always open. Those who oppose surgical intervention, impressed by the bad results obtained and especially by those of plastic operation, prefer to limit themselves to extirpation of the sequestrum when the necrotic process has completely finished.

**DEMONSTRATION**

*In the air.* — Phosphorescence in the dark is insufficient to decide with certainty that free phosphorus is present, because many other substances yield the same phenomenon. Free phosphorus in the presence of air becomes converted first into phosphoric acid and then into phosphoric acid; but proof of these acids does not suffice to conclude that free phosphorus was present originally in the air in question.

*In man.* — Phosphorus remains a long time in the organs, where it can be detected many months after death. Use is made of the characteristic property of phosphorescence in the dark after having slightly acidified the substance to be analysed. Pedrazzini has proposed the following reaction: Treat the substance to be analysed with sulphuric acid and pure zinc; cause the gas which comes off to bubble through a very weak solution of silver nitrate. Treat the filtrate with ammonium molybdate. In presence of phosphorus a yellow precipitate is obtained soluble in presence of ammonia. If chloride of ammonium is added and a salt of magnesium hastening the formation of the precipitate by rubbing the interior walls of the test tube), a white precipitate of ammonio-magnesium phosphate is obtained.

**PREVENTION**

It should be emphatically stated that, if the dangers of the manufacture and preparation of phosphorus can be limited, they can only with great difficulty be abolished.

So far as white phosphorus is concerned it must be replaced by other substances in the preparation of pastes and powders intended for use as rat, etc., poisons, in the preparation of strips for lighting miners’ lamps, and other articles of commerce.

In addition to measures of prevention common to all dangerous trades, certain special measures should be adopted in certain branches of the industry.

The factory should be remote from houses and built of fire proof materials. Bones should be pulverised in closed apparatus placed in special rooms. The mixture intended to be calcined should be kept in sheds with impermeable floors.

Calcination should not be done, except with bones that have been boiled and dried in closed apparatus of which the joints have been well luted. These operations are generally done in other premises. Further, the apparatus should be placed under a large hood connected to a very high chimney stack and the fumes should be condensed on an intensive plan. The injurious gases would be rendered harmless by ignition. If necessary the duration of the calcination of the bones should be limited to certain hours.

Precautionary measures should be taken at the moment of opening the furnaces. Cylinders, retorts, and condensers must be luted with the greatest care. The gases given off in the course of distillation as well as the condensation and residual water, no matter of what kind, should be collected.

The bone meal should be treated by sulphuric acid and the phosphoric solution obtained concentrated in suitable apparatus. Injurious emanations should be controlled by good locally applied exhaust ventilation. The downward ventilation should be sufficiently powerful and the condensation of the sulphurous gas very intensive.

Washing the product with carbon bisulphide should be done in well-closed apparatus installed in a special room. Distillation should be done in special apparatus having the necessary provision against fire, explosion, and escape of phosphorous fumes. The condensation of these vapours should be as perfect as possible and vigorous inspection of the refrigerating pipes should be organised to avoid obstruction.

Purification should be done in a bain-marie under water pressure; moulding the phosphorus by suction with the mouth should be prohibited.
The phosphorus should be kept under water in a reservoir of cement quite watertight and in boxes submerged in the water.

The acid residuary waters should be completely neutralised before discharge into a drain.

Large open receptacles filled with turpentine should be placed in rooms where phosphorius fumes are given off.

Consumption of food and drink in the workroom should be prohibited; careful washing and dental toilet before leaving work should be enjoined, together with change of clothes, etc.

Medical examination before commencing employment, and periodically afterwards, should be carried out on all persons coming into contact with phosphorus or its compounds or preparations containing it. Workers with dental caries should be suspended and the condition of teeth rectified before again working with phosphorus. The dental inspection, according to Koelsch, ought to be carried out every four weeks.

Statutory regulations have been passed for factories manufacturing phosphorus, especially with a view to the prevention of fire and explosion. To this end fire drill should be strictly organised; dynamos should be isolated (so as to prevent sparks igniting the volatile vapours which can be dispersed in the premises): the current quantity of material should be limited to that actually required; manufactured goods should be removed so as to avoid overcrowding of the workrooms; good daylight illumination or, failing that, incandescent electric lamps should be provided. The electrical installation should be carefully safeguarded and periodically inspected; lamps should be placed outside the windows or enclosed in double and triple envelopes; switches, commutators, etc., should be placed outside the workrooms: the steam heating apparatus should be separated by an adequate distance from the workroom; all hearths should be outside the workrooms and chimneys should be provided with baffle plates or other suitable arrangements to keep back cinders and sparks; smoking and the introduction of boxes of matches or naked lights, etc., in the workrooms should be prohibited; workers should not be allowed to enter them with nail shod boots, etc.

Legislation

The work of manufacturing phosphorus should be closely regulated. Women and young persons should be excluded altogether. While in certain countries the exclusion of women is only limited to the manufacture of white phosphorus, in others it is extended to the use of all phosphorus (Netherlands) and even, as in Japan, everywhere where there is production of dust, vapour and gas, given off from phosphorus or its compounds.

Admission of young persons in these factories is fixed at 15 years in Italy and Japan, at 16 in Belgium, Spain and Greece, at 18 in the Netherlands, and in the States of Maryland, Massachusetts, Ohio and Pennsylvania (unless it can be shown there is no risk), etc.

The periodic medical examination should be made monthly, and special attention should be given to the state of the teeth.

Notification of cases of phosphorius necrosis is obligatory in Austria, Baden, Bavaria, Great Britain, Hungary, the Netherlands (in the chemical industry and in laboratories), Poland, Prussia, Saxony, Switzerland, in the British Dominions (Alberta, South Australia, British Columbia, Manitoba, New Brunswick, Nova Scotia, New South Wales, Ontario, Queensland), in the United States (California, Connecticut, Illinois, Maine, Maryland, Massachusetts, Michigan, Minnesota, Missouri, New Jersey, New York, Ohio, Wisconsin), Yugoslavia, and in Argentina.

Compensation is provided for in the legislation of the following territories: Alberta, Australia: Northern, Western and South; Austria (including agricultural workers), Bolivia, Brazil, British Columbia, Finland, France (manufacture of miners' lamps, toys), Germany, Great Britain, India, Irish Free State, Italy (including fireworks), Japan, Manitoba, Minnesota, New Brunswick, New Hampshire, New Jersey, New York, New Zealand, Norway, Nova Scotia, Ohio, Ontario, Porto Rico, Quebec, Queensland, Rhode Island, Sweden (including manufacture of phosphor bronze and similar substances), Switzerland (including phosphorus chlorides), U.S.S.R., Venezuela, Victoria, Yugoslavia.

Phosphorus (Amorphous or Red)

Chemistry

Red or amorphous phosphorus, discovered in 1844 by Kopp, and suggested in 1847 by Schroetter of Vienna as a substitute for white phosphorus (in the preparation...
PHOSPHORUS (AMORPHOUS OR RED) — 636 —

of the paste for matches), is an allotropic modification of ordinary phosphorus.

Industrially it is obtained by heating white phosphorus to 250° or 300° C., in the absence of air, in closed iron vessels. This transformation can be also obtained below 200° C. if the reaction is carried out in the presence of a little iodine.

Purification is effected after cooling with carbon bisulphide or with a solution of caustic soda to remove any unchanged white phosphorus.

Red phosphorus presents the appearance of an amorphous powder of a reddish brown, red or crimson colour, which oxidises slowly in the air; it is inodorous, insoluble in bisulphide of carbon; its specific gravity is between 2.12 and 2.34.

Heated in the air, it gives off vapour at 100° C.; but does not ignite until 260° C. It is not phosphorescent.

Heated above 260° C. in the absence of air, or in presence of carbon dioxide, it changes again into white phosphorus; heated with lead in sealed tubes, it dissolves in the lead and separates out on cooling in the metallic state (Black phosphorus or Hittford's).

Red phosphorus is considered to be, probably, a solid dissolution of white phosphorus in metallic phosphorus.

USES

It is used especially in the manufacture of matches; in the preparation of the triehloride and iodide of phosphorus and other iodides used in the preparation of organic compounds or of synthetic colours; in the manufacture of incendiary projectiles, etc.

TOXICITY

Already in 1855-1856 Chevalier declared that red phosphorus was non-toxic, and to-day Pouchet considers it to be inert. Jaksch also maintains the same view as in the case of matches made with the sesquiphosphate. Erben considers that any toxicity it may have is due to traces of white phosphorus contained in it, and Robert that it is at any rate infinitely less toxic than white phosphorus. Texevara also in his monograph on matches (1901) concludes that red phosphorus is quite harmless.

If tradition supports the opinion that red phosphorus is harmless, it is not shared by the small number of experts who have studied the substance. Nasse (1885) on injecting 20 centigrams of red phosphorus into the jugular vein of rabbits found they lost their appetite in three days and died in from six to eight days. Post-mortem fatty degeneration of the kidneys, and especially of the liver, was always found.

Filippi (quoted by Giglioli) is said also to have shown some years ago that red phosphorus is not quite innocuous to animals, but that it is at any rate less injurious than white phosphorus. Biondi and Ferrannini (1917) share this opinion. The latter concludes his systematic study of the question by saying that red phosphorus is an enemy less violent and less aggressive to the body than white phosphorus, as it is insoluble and less likely to be absorbed, but that it is not less toxic in itself.

Red phosphorus lessens sensibly the power of resistance of the organism (natural haemolysin, natural haemolytic amboceptor, haemolytic complement, anti-complement, opsonines) even if apparently it does not modify in any striking way the general health. In the blood it acts particularly on the white blood cells, of which it alters the number (first leucocytosis and then leucopenia) and their shape, as well as the red blood cells of which it reduces the number. Further, it reduces the haemoglobin and the coagulability of the blood, increases the cellular resistance and the electrical conductivity of the serum of the blood, stimulates the activity of the myeloid tissue and still more that of the lymphoid tissue (active hyperplasia of the spleen with fatty infiltration and remarkable hyperaemia).

In the liver it sets up degeneration of the cells of the acini, diminishes the quantity of nitrogen and causes the disappearence of the glycogen, but does not modify the amount stored up. In the kidney it brings about the histological changes of acute nephritis and in chronic cases either lesions of acute parenchymatous nephritis or those of interstitial nephritis. It diminishes the adrenal content of the suprarenal capsules, provokes hyperplasia of, and increase of function in, the genital glands of both sexes, causes degenerative changes in the nervous tissue, myocarditis, irritative effects and sometimes ecchymoses and haemorrhagic lesions in the digestive tract and lesions in the bones. Occasionally it induces alopecia and an abundant desquamation of the skin, modifies the respiratory exchange, disturbs the nitrogen exchange, etc.

STATISTICS

Villaret describes the data collected by Ris (1892) according to which troubles terminating in cachexia were said to have been observed in persons handling only red phosphorus in a certain factory. They were, however, due to the chlorates which were ingested through dirty hands rather than to phosphorus.
During the manufacture the workpeople can also be exposed to the inhalation of vapour of phosphoretted hydrogen, and bisulphide of carbon.

Recently it has been stated that in China a certain number of suicides were traced to matches made of red phosphorus and antimony trisulphide, as the probable agent (1923).

**Prophylaxis**

Although laboratory experience proves that red phosphorus is poisonous to animals, this does not mean that it is necessarily toxic to man; and in practice this is the conclusion arrived at. When red phosphorus was first used employers were advised, as a matter of prudence, to adopt in the course of its manufacture the same precautionary measures as in the case of the white variety. The Swiss Regulations of 1882 requiring periodical medical examination in phosphorus match-making were repealed in 1898, except for matches made with sesquisulphide. During later years, no case of poisoning having been notified either to the inspectors of factories or to the Accident Insurance Office, the examination was abolished in all the factories.

It can be concluded, therefore, that red phosphorus does not require the same control as white, and that it can be manipulated with little danger even when precautionary measures are not strictly applied. (See also the articles "Phosphorus", "Phosphorus (Compounds)", and "Matches (Lucifer)".)

**Phosphorus (Compounds of)**

Among the hydrogen compounds, phosphoretted hydrogen is of the greatest interest here (see that article).

Of the halogen compounds, the most important are the chlorides, which irritate intensely the respiratory tract and the eyes, because, in contact with the moist mucous membrane, they decompose into hydrochloric acid and an oxyacid of phosphorus.

On bringing dry chlorine slightly heated into contact with slightly heated white phosphorus in a retort, the trichloride (PCl₃) is obtained (French: *Trichlorure de phosphore*; German: *Phosphor-Trichlorid*; Italian: *Tricloruro di fosforo*; Spanish: *Tricloruro de fosforo*), which is found mixed with pentachlorides. If a little white phosphorus is introduced, the pentachloride is converted into the trichloride. The trichloride is a colourless liquid with a penetrating smell, fuming in moist air and at ordinary temperatures; it boils at 76° C. In contact with water it splits up readily into phosphoric and hydrochloric acids. In causing chlorine to act on the trichloride, the pentachloride PCl₅ is obtained (French: *Pentachlorure de phosphore*; German: *Phosphor-Chlorid*; Italian: *Pentachloruro di fosforo*; Spanish: *Pentachloruro de fosforo*), which is a solid in the form of small yellowish white crystals. It is the most disagreeable of the three compounds, all of which serve in industry for the introduction of chlorine into organic compounds.

On treating the pentachloride with water or in oxidising the trichloride of phosphorus with chlorate of sodium, the oxychloride POCl₃ is obtained — a colourless liquid, fuming strongly in the air and decomposed by water into phosphoric and hydrochloric acids. In order to lessen the reaction it can be prepared by treating the chlorate by phosphorus oxychloride and then by the trichloride, or again by heating the pentachloride with phosphorus oxychloride of lastly by the distillation of dry oxalic acid.

One case of poisoning by phosphorus oxychloride was reported in France in 1929.

In the preparation of the chlorides of phosphorus apart from the action of the chlorine gas and of the hydrochloric acid, account must be taken of the injurious action of phosphorus and its
PHOSPHORUS (COMPOUNDS)

compounds and to some extent, too, of bisulphide of carbon (solvent of phosphorus) and of carbon monoxide (in the preparation of the oxychloride and of arseniuretted hydrogen).

Butjagin, in Lehmann's Institute, has found that the trichloride has an action on animals analogous to that of hydrochloric acid, but five to ten times as intense as the hydrochloric acid which it forms. It acts mainly by withdrawing from the tissues the water which it requires for its decomposition.

Cases of intoxication have been reported in persons working in chemical laboratories, especially in workmen, where the necessary precautions are not taken.

In literature, we find the cases recorded by Egli (1902); Vaubel (1903), Leymann (1896), Vinassa (in a student), due to the trichloride, and the three cases by Rumpf caused by escape of oxychloride from a broken tube (1906). These three cases were very severe and characterised by acute bronchitis, pneumonia with bloodstained expectoration, cough, air hunger, etc. Another case of tracheal bronchitis was reported at Baden (1913), two cases of conjunctivitis in Switzerland (1917-1918), and lesions of the skin and conjunctiva in Bavaria (1919) in a workman who had unintentionally brought about the decomposition of the compound into phosphoric and hydrochloric acids.

The manufacture of the halogen compounds of phosphorus is carried on in hermetically closed apparatus, which prevents escape of toxic fumes. Application of this system has given the best results in certain German factories.

Transport of halogen compounds of phosphorus should be effected in receptacles of iron, lead, or copper with the lid soldered on, or in glass carboys with ground glass stoppers (paraffined) and covered over by a capsule of parchment paper. The bottles should be packed in boxes stuffed with fossil meal.

Among the oxygen compounds, only phosphoric anhydride is of interest. It is produced by the combustion of phosphorus in a current of air or dry oxygen. It acts as the most energetic dehydrating agent known. It occurs in two modifications: the crystalline (P₂O₅) and the hydrate or orthophosphoric acid (H₃PO₄), which may contain impurities of arsenic, nitric, sulphuric, and hydrochloric acids. It is used as a mordant for the preparation of organic acids, chemical analysis, etc.

The combinations of phosphorus with sulphur are numerous, but it is sufficient here to recall the sesquisulphide or trisulphide (P₃S₃). It melts at 142° C. and is very soluble in bisulphide of carbon. Prepared from red phosphorus as the starting point (because the action of white phosphorus on the sulphur would be too violent) it is used in the manufacture of matches (without phosphorus), of deflagrators, etc. It is regarded as non-toxic. The researches of Bachem (1904, Bonn thesis) and those (unpublished) of Lehmann confirm this view.

Savène and Cahen have administered it by way of the stomach up to 3.5 grm. daily, corresponding to about 6,000 matches, without finding ill effects. A case of necrosis was described, however, in 1919 in an English phosphorus factory, the occupation having been the drying and finishing of the sesquisulphide.

In 1929 Nicolas, Gate and Roussel noted two cases of occupational dermatitis in workers handling phosphorus sesquisulphide in match making. The illness began with lesions on the exposed parts (hands, forearms, conjunctivae) which became general in from twenty-four to forty-eight hours. There was intense erythema of all the integuments with oedema of the face, malleoli, and penis; and then vesicles which soon changed into pustules; and in some places a veritable superficial epidermic necrosis. The patients complained of intense burning sensation and thirst, and shuddering. The lesion then develops; desquamation begins and there is a veritable generalised exfoliating erythrodermia. For several days the patients smell strongly of phosphorus, especially when they are greased. Phosphorus is present in the urine (0.201 grm. per litre in one case). The course of the disease is benign, and there are no symptoms of general intoxication. Conjunctivitis may accompany these lesions or appear separately. The lesions have been induced experimentally in both men and animals. The workers most frequently attacked are those employed in packing the substance.

Cases have also been reported (Swarz, 1929) of dermatitis due to the phosphorus sesquisulphide on the friction strips of match boxes.

The prophylactic measures consist in the elimination of dusts.

Among the phosphides those of lime, of barium, and of strontium should be mentioned. They are used for signals of distress at sea, for safety lamps, etc. Phosphide of calcium is used mainly for the production of phosphoretted hydrogen (see that article); phosphide of zinc in solution (1-5 per cent.) is used for the destruction of rats in
country districts. Being very toxic, it requires every kind of precaution to be taken in both its manufacture and use.

Compounds containing phosphorus and nitrogen are interesting, especially in relation to the manufacture of asphyxiating gases (see this article).

**Legislation**

See the article "Phosphorus".

***

**Photo-Engraving**

The invention of photography has led to stupendous progress in the technique of photo-mechanical reproduction. The various methods of engraving formerly followed have all their counterpart in the modern photo-mechanical processes: photo-lithography, collotype, photo-typography or relief engraving usually known as photo-engraving or photo-zincography, process-engraving and hollow heliography.

The German authorities classify the various processes under three heads according as the portion of the plate intended to impart its impress is located above (Hochdruck), on a level with (Flachdruck) or below (Tieffdruck) that part of the surface of the plate which does not receive the ink. The first group comprises, for instance, typographic printing, the second flat printing on stone, zinc, the offset process, photo-lithography, etc., and the third known as "Tieffdruckerfahren" hollow incision, or intaglio printing, also known as heliography and photo-engraving.

The progress realised is due to the discovery that certain substances become soluble after exposure to the action of light. Further, other substances — resins — are found to resist the etching action exerted on metals by mineral acids. These resinous substances have therefore been used to coat designs traced on or applied to stone or zinc or copper plates so that the acid may etch the non-protected parts of the surface and give the required relief.

For perfect technical reproduction, an original must possess certain qualities. It is because of this that the resources of photography (orthochromatisation, special lighting, time of exposure, etc.) and especially retouching are called in to correct the defects of the original and prepare it for reproduction by photo-engraving.

Retouching is at present effected by an aerograph spray worked by compressed air which projects the coloured solution in powdered form on to the photograph to be retouched.

Photographic reproduction of the original also demands special technique involving the most up-to-date photographic apparatus and methods (lenses, lighting, plates, etc.).

The plate used in photo-engraving must necessarily be freshly finished, that is to say, prepared as required for the work in question. The sensitised surface consists of collodion or special emulsion. As a rule, albumen is used or a bichromate collodion.

Photo-lithography is little used. Photo-typography is now widely used for the printing of illustrated postcards.

Below are some particulars of photo-engraving, which is the most commonly employed process.

In this process and in that used for the reproduction of pictures in half-tones, the model is represented by combinations of points and lines more or less thick and more or less spaced. The success of this principle has been demonstrated by typographic photo-engraving or American process-engraving with the use of lined screens of glass. The presence of the screen in front of the sensitised plate results in the transformation of the continuous lines and variable opacity of the image into broken lines formed exclusively of dots of similar opacity but of unequal dimensions, the more or less spaced arrangement of which provides a sensation of shading reproducing exactly the values of the original image.

The screen used varies according to the object in view (commercial work, artistic work, etc.), the paper to be used in printing, etc. The plate, after preparation and utilisation for reproduction, is developed, fixed, reinforced and dried.

Then follows preparation of the film bearing the reproduction. Layers of para rubber and collodion are spread over it to give it resistance in the course of later manipulation, and it is detached from its glass support. It is then placed on the metallic block (zinc or copper), which has first been rendered sensitive to light.

As in all processes of graphic reproduction, this layer is rendered sensitive to light by means of double
salts of chromium (bichromates) in the presence of an organic substance (albumen, gelatine, fish glue, gum, etc.). The colloid thus formed and dried is subjected to the action of natural or, more frequently, artificial light. The transparent parts of the negative allow the light to arrive on the sensitised layer and in the parts thus illuminated the colloid undergoes reduction of the bichromate, which is converted into a black compound of chromic oxide. The latter loses the property peculiar to the bichromate of being soluble in water. Hence, in accordance with varying intensity of the negative, the bichromated colloid will become more or less soluble to the extent to which the various parts of it have or have not been affected by light.

For line-etching, a layer of ink is spread with a roller, which is passed over the surface and the parts of the emulsion corresponding to blanks in the picture made soluble by light are removed. For reticulated or coloured etching, the design is inked with methyl violet, and the film is heated to turn the glue into a substance which will withstand the etching bath (enamel). In a plate containing line etching, however, inking does not suffice to protect the incision sufficiently against the action of the acid bath. For this reason the surface is dusted with resinous substances (bitumen, pitch, colophan or "dragon's blood"), which melt under heat and intimately mix with the ink.

A coating of varnish is thereafter applied to the back and sides of the plate, which is passed through an etching bath or sometimes under a spray of acid solution.

Parts which do not require any further exposure in the bath are retouched with fatty inks, and such retouching and exposure are repeated as often as necessary until the results desired are obtained. The action of the acid is sometimes replaced by the use of a milling tool, whilst small defects of mechanical and chemical incision are corrected with a burin.

When copper replaces zinc, the etching bath consists of chloride of iron rather than nitric acid.

The plate is finally mounted on a block of wood or lead.

For the etching bath, nitric acid in a 10-12 to 25 per cent. solution at 15-40° B. is used, varying according to the country and the type of engraving. For deeper engraving, sulphuric acid at 15-20 per cent. is used. To this is added sometimes hydrochloric acid, nitrate of ammonium, ammonium chloride or acetic acid. A solution of ferric chloride or nitrate of potassium, hydrochloric acid and alum with an average strength of 16° B. is also used.

The vats may be made of tarred wood, earthenware or stone. In the workshop they are generally provided with a wooden cover. Three types of etching baths are in use for engraving in Great Britain: (1) the "Levy" bath, in which compressed air driven through fine nozzles into an acid bath causes fumes to rise which impinge on the zinc plate placed on a shelf above the bath; this operation is carried out in a closed apparatus provided with a device for drawing off the acid fumes; (2) the "Mark Smith" bath, which is a closed receptacle in which the nitric acid passes through holes in the bucket of a rotary paddle which sprays it on to the plate to be engraved (splash type of etching machine); this receptacle is covered with an aluminium lid which, when not fitted tightly, may allow some of the acid fumes to escape; in large establishments a double bath is used; the amount of the fumes escaping into the workroom cannot be very great; they tend rather to keep down in the bath; (3) "rocking tubs", usually automatic, are now used mainly as finishing baths, and the percentage of acid in these is lower than in the other two; elimination of fumes is effected by general ventilation, improved in certain cases by mechanical devices. Where the intaglio process is used, engraving is done on large copper cylinders and the etching material has a ferric-chloride basis so that no dangerous fumes arise. There are now highly improved engraving machines provided with ventilating devices for exhaust and elimination of acid fumes, and these new systems render the use of strong acids unnecessary.

Corrosion in the etching baths depends on the layers of ink and resin previously applied to the plate, and on the depth of the cavities and the clearness of the impression which it is desired to obtain. For reticulated incision the enamel suffices for protecting the black parts and the plate is passed into the etching bath without requiring inking or the application of layers of resin.

After the acid bath the plate is washed, dried and printed with printing ink as a means of controlling the incision.

In a new process called in Germany Tieferdruckverfahren (intaglio, roto-engraving, heliography) the etching is not in relief, but in intaglio.
Copies are printed by filling the hollow parts of the etching with ink and then applying the paper by means of a press. This process is very much used at present especially for the printing of illustrated periodicals, and the plate may then be adapted to rotary cylinders.

A negative plate of the subject is first printed and then a positive plate, which is photographed by artificial light on a paper with a gelatine pigment which shortly before its use is sensitised by being passed through a bath of bi-chromate of 3-5 per cent. During the printing operation a very fine network effect, which is acid proof, is imparted by the use of a screen. The paper applied to the prepared copper plate is developed in hot water, which dissolves the bi-chromated gelatine in those parts which have not been acted on by light, and causes a more or less extensive loss of colloid in the other parts in proportion to the amount of light to which they have been subjected. There follows washing in cold water, drying, and a final bath of hot water for elimination of the paper. In the etching bath which has a basis of perchloride of iron in a concentrated state or in an accurately calculated solution, the parts of the plate are acted on by the acid in proportion to the thickness of the gelatine layer. The hollows of the plate are thus more or less deep and form intaglios which serve to retain the ink. The operations of inking and wiping are effected by mechanical devices. A roller which rubs over the surface removes any excess of ink.

The bi-chromated coating is applied by hand — the liquid mass is poured on to the plate and spread uniformly by means of a pad or by machinery which not only spreads the mass but also dries the plate.

According to circumstances, the developing bath may be alcohol, glycerine, acetic acid, citric acid, glycol or calcium (a concentrated solution of chlorate of lime), etc.

In helio-typography, or photo-typography, use is made of the property of gelatine of holding ink on the dry parts but not on the wet; and of not holding water on parts made insoluble by light and vice versa. A bi-chromated gelatine in this process is applied to a large crystal plate and the copies are printed directly on to the gelatine coating.

In reproduction by three-colour printing the direct process is now used which does away with screens and positive plates, the whole process being reduced to one single operation, which provides at the same time the colour selection and the corresponding negative already stopped out.

The collodion emulsion containing bromide of silver specially coloured for each reproduction enables the plate to be sensitised only for certain rays. There are naturally simpler and easier colour reproduction processes which need not be dwelt upon here.

Galvanotyping and stereotyping involve only reproduction or duplication of existing plates.

Galvanotyping is effected by taking a hollow wax imprint or a negative of the original plate and passing it through an electrolytic copper bath, having previously rendered the imprint a good conductor by the application of graphite. The electrolytic process deposits the metal in a layer on the matrix and it thus gives a positive reproduction of all details recorded on the wax imprint. On removal from the bath the positive reproduction is retouched and the layer of copper is rendered more resistant by mounting it on an underlying layer of lead. It is there after usually mounted on a block.

In stereotyping the imprint is obtained by means of a powder or a special kind of cardboard (utilised as matrix for direct fusion of the positive reproduction) and a mixture of lead and antimony (see article "Printing Trades").

In the "pantone" process invented in Great Britain silvered plates are used for printing and these are cleaned by means of a powder with a mercury base. Similarly, a paste with this base for the printing off of copies. Experiments by Koelsch show that the surrounding temperature suffices to cause the very fine layers of mercury remaining on the plates to liberate fumes in sufficient quantity to represent a danger to the workers' health.

The technical advantages of this process assure it of a great future but it is essential that from now onwards efforts should be made to ensure the provision of good localised ventilation over the machines and the adoption of adequate general precautions (periodical examination, personal hygiene, in particular of the mouth, effective methods for detecting mercury in the air of the workrooms, etc.).

Hardly any type of artificial light other than electric arc lighting is now used, the carbons utilised being specially prepared. Mercury vapour lamps have completely disappeared.
PHOTO-ENGRAVING

SOURCES OF RISK

As regards causes of injury, account must be taken of the chemical products employed by photo-engravers: mineral and organic acids, methyl alcohol, ammonium-hydroxide and -chloride, aniline, benzene, benzine, chrome acid and bi-chromate, bromides of copper, of cadmium, alkalis (ammonia, carbonate of soda and of potassium, and caustic soda), phenic acid, chloroform, chloride of silver, chrome alum, cyanide of potassium, sulphuric ether, formaldehyde, potassium iodide, mercury bi-chloride, mercury, ammonium sulphide, collodion coated with verdigris, etc. (E. J. Volz). The principal danger to which photo-engravers are exposed arises from the liberation of small quantities of acid fumes (nitrous or sulphuric) when photogravure is effected in open or inadequately covered vats. An analysis made in Italy in order to determine the quantity of nitrous fumes liberated at a surrounding temperature of 16° C. by nitric acid (using the method of absorption by calcium) has provided the following figures:

Hence a weak solution of nitric acid only liberates a small quantity of nitric oxide, which is immediately transformed into nitric di-oxide when in contact with air. This liberation increases in direct proportion to the increase in the acid content.

According to the interesting and detailed report of Engelhardt and Mayer (1931) on cases of eczema due to chromates in the printing industry (photomechanical reproduction), workers are exposed to injuries to the skin in consequence of contact with these products in the course of preparation of the mother liquors and dilutions of bi-chromates; in the course of rubbing by hand with a pad, of transport of the sensitised layers, of sensitisation of the paper-pigment, of development and various washing operations of the bi-chromated surface (the bi-chromate being present in the water) of the etching bath, and during printing.

Photo-engravers are further exposed to the harmful action of luminous rays emitted by unprotected lamps, notably those rich in ultra-violet and infra-red radiations, as well as to that of dust from the products employed (graphite, pitch, tar, "dragon's blood") chiefly during grinding; also to the harmful effects of benzol, xyloc, toluol, and toxic gases from the drying stoves, etc. They are likewise exposed to excessive heat produced by the rheostats, to fragments and turnings projected by filing machines and lathes, etc.

STATISTICS

Statistical data concerning this group of workers are relatively scarce. According to information furnished by the German Union of Lithographers and Allied Workers, whose membership comprises 98 per cent. of the German photo-engravers, the number of deaths for the period 1919-1921 was 63, with an average age of 39°/2 years, and an average duration of sickness of about twenty-five weeks. Amongst the causes of death, respiratory diseases appeared 22 times, cardiac diseases 12, gastro-intestinal troubles and kidney trouble 10, and suicide and accidents 9 times.

According to information furnished by the Berlin Sickness Fund for Lithographers, 76 photo-engravers were incapacitated for their work during the year 1922 by influenza, colds (28 cases), respiratory diseases (12), rheumatic affections (6), internal diseases (8), nervous diseases (6), eye trouble (5), affections of the external organs or accidents (19).

For the period 1906-1921, the total number of deaths amongst German photo-engravers was 245, the average age at death was 34 years and 9 months in 1906-1910, 37 years in 1911-1915, 39 years in 1916-1920 and 39°/2 years in 1921. The causes of death were as follows: tuberculosis (92), respiratory diseases (9), heart diseases (32), diseases of the peripheral nervous system (4), of the central nervous system (25), of the stomach, intestines and kidneys (30), miscellaneous diseases (23), suicide and accidents (30).

An enquiry effected by Engelhardt and Mayer covered 114 workers engaged in photomechanical reproduction; 19 suffered from eczema due to chromates, 11 had previously suffered from it, 84 showed no eczema — thus there was eczema due to chromates in 26 per cent. of the workers examined. Of the 114 workers affected, 24 (80 per cent.) showed positive reaction to the test (bi-chromates).

In the United States an enquiry undertaken in 1926 amongst photo-engravers in
New York revealed the fact that 64 per cent. suffered from throat trouble. A comparison of the mortality rate due to various causes in this industry, and of the incidence of pulmonary diseases, revealed a high incidence of such diseases.

In Great Britain it was reported that generally speaking, members of the Amalgamated Society of Lithographic Artists, Designers and Engravers are particularly liable to complaints of the respiratory system, and that probably line-etchers would be more susceptible than workers in other branches. In 1929 Overton visited thirty-one workshops and examined about 150 workers engaged in photo-lithography. She found that 7 per cent. of the workers suffered from dermatitis, more particularly those engaged in transfer work, in photo-lithography and in the printing of proofs. She attributes the causes of these lesions to chronic acid, salts of chromium and turpentine.

In Italy Sinapi undertook an investigation in 1924 among 15 workers belonging to three different zincographic establishments, and noted 17 cases of diseases of the digestive system (113.8 per cent.) distributed as follows: stomatitis (4), Burton line (2), decayed teeth (8), constipation (2), intestinal colic (1). Sinapi considers that these cases represented chronic poisoning by zinc. As regards the respiratory system, 13.3 per cent. of the cases were bronchial catarrh. Finally, he reports an occasional stigma consisting of a callus situated on the radial side of the third phalanx of the right index finger. This stigma would appear to be due to manipulation of the burin, since the two workers had been previously engaged in wood sculpture.

Biancalani in 1931 met with several cases of eczema, due to chromates, amongst photo-engravers in Florence.

**Pathology**

The work of photo-engraving does not of necessity set up a specific disease in all cases, but it has been noted that in the long run the general system becomes affected. In the Manchester district workers who had carried on this trade for about fourteen years were usually pallid, though it was not possible to detect symptoms of poisoning. Certain of these workers complained of a constriction of the chest, or irritation of the throat accompanied by fits of coughing, especially when they were engaged on etching a plate of large dimensions. It would appear that these symptoms occurred during the use of open rocking baths and were not present when "Levy" and "Mark Smith" baths were used. The introduction of these types of baths in England appears to have considerably improved working conditions amongst photo-engravers.

It has been observed that acute or fatal diseases might occur in consequence of the inhalation of the products liberated from etching baths, which would seem to indicate the possibility of poisoning by arseniuretted hydrogen (toxic jaundice). In this connection several samples of zinc were analysed for arsenic and lead in the chemical laboratory of the Labour Inspection Department of the Netherlands, but the results were negative. The possibility of the acid fumes liberated during etching exercising a harmful action, and even giving the clinical picture of acute poisoning due to nitrous fumes, cannot, however, be excluded. A case of this kind was encountered in the Netherlands in a photo-engraving shop where the manager had an attack of pneumonia, following on the inhalation of these fumes. In the case in question, the liberation of these fumes was, however, the fault of the worker who had thrown sawdust on concentrated nitric acid which had escaped from a broken flask.

The harmful effect of acid fumes on the teeth has been confirmed on various occasions.

Stoke reports a case of acute poisoning by xylo1 and toluol in intaglio printing, and Koelsch reports cases of mercury poisoning caused by the "Pantone" process.

It is not necessary to deal in detail with the skin lesions which may be encountered amongst photo-engravers, and to which reference has already been made. Pankhurst in 1925 noted cutaneous lesions amongst workers engaged on the cyanographic process. Casazza in 1928 noted a case of acute eczema affecting the hands of a phototypist, accompanied by rhagades and progressive alteration of the nails. Tests for skin reaction to the numerous products handled point to bichromate as the sensitising substance. Fellow-workers of the patient also suffered from cutaneous injuries, due to bichromates.

**Hygiene**

Special importance must be accorded to the ventilation of the workrooms. It is hardly necessary to insist on the importance of cleanliness and good lighting.

Photo-engraving, and in particular etching — especially in the presence of strong acid solutions — should be carried out in an adequately ventilated workroom. The baths should be provided with exhaust hoods for removal of irritant fumes outside the premises.
It is very desirable that mechanical manipulation should increasingly replace work done by hand. All adequate protection should be afforded to avoid the projection of acid droplets and splashings. It is advisable that the operation of applying resinous substances should be effected in a special workroom set apart for this purpose. This provision of exhaust withdrawal of metallic dust is essential during milling, where such operation is necessary and during the polishing of the cylinders used in roto-engraving.

Carboys containing concentrated nitric acid, should be encased in straw and kept outside, or in a cellar. Similar measures should be taken for the storage of all dangerous materials used especially liquids.

Artificial light should be installed in such a manner that dangerous radiations are filtered and adequate protection of the eyes is afforded when necessary against injury from powerful sources of light.

Adequate personal hygiene should be enforced for all workers engaged.

Protection of the hands and the exposed skin in general from the irritant or caustic action of substances manipulated is essential; in certain cases a periodical medical examination is to be recommended.

Finally, the attention of workers should be drawn to the risks which they incur, and more especially, as occasion arises, to the dangers connected with nitrous fumes, chromates, toluol, xylol, mercury, etc.

**LEGISLATION**

No special provision exists relative to this category of worker. Skin diseases, as well as certain forms of poisoning are frequently covered by the general formulae adopted in laws on compensation. Optic neuritis and retinitis, as well as ulceration of the cornea, and conjunctivae occurring amongst photo-engravers, are subject to compulsory notification in the Netherlands.

**BIBLIOGRAPHY**

***

**Photographic Industry**

**TECHNICAL DATA**

**Photographic Plates and Papers**

The photographic industry receives from glassworks glass of a quality corresponding exactly to the purpose for which it is intended, in the form of plates of a size which is generally a multiple of that of the product which is to be manufactured. The glass plates are carefully examined as regards thickness and the absence of defects, cleaned in an aqueous solution of boiling soda and covered while still in the wet state with a very thin layer of a dilute solution of potassium or sodium silicate or of chrome alum, the purpose of which is to facilitate adhesion of the layer of gelatine. This solution is poured from a receptacle through a layer of material (apron) stretched over the plate which passes underneath. The plates then pass to a drying trough and are ready to be covered with a photo-sensitive gelatine. Meanwhile, they are sorted out in order of size and placed on shelves which must be dust free.

Preparation of the sensitised emulsion involves very careful manipulation and demands long experience. The very pure quality of gelatine used is subjected to sorting, careful washing in water and thereafter in an alkaline solution. An aqueous 6-7 per cent. solution of gelatine is treated in a water bath with a slight excess of potassium bromide and a nitrate of silver. The chemical reaction which takes place in the solution differs to a great extent from the similar reaction in an aqueous solution since the presence of a compound albuminoid substance of varying composition exerts a chemical action on the grains of bromide of silver both at the moment of reaction and later during what is called "maturation". The length of time required for digestion, subsequent thermic treatment or maturation depends on the increase of the photo-
sensitivity as well as on the point of sensitivity, the gradation and other physical constants. The reaction terminated, the emulsion is poured into nickel capsules and caused to cool gradually from the temperature of the solution down to about $-2^\circ$ C. The gelatine congeals and is then passed through a filter press and then washed in filtered and distilled water at $10^\circ$ C. and thereafter in alcohol in order to eliminate the nitrate of silver.

The emulsion is then treated with a view to freeing of silver. The film obtained is cut out into cubes which are then washed in filtered and distilled water at $10^\circ$ C. and thereafter in alcohol in order to eliminate the nitrate of silver. The emulsion is then treated with a view to freeing it from any chemical impurity. It is filtered under pressure through parchment and then through a cloth filter and through cellulose. An antiseptic mixture is added in order to ensure conservation and the product is kept in freezing chambers at about $-2^\circ$ C. Before use the emulsion has to be carefully examined in the laboratory.

In all workshops which have to serve as dark rooms lighting is only provided by a few red lamps strictly tested by a spectroscope. In all workshops which have to serve as dark rooms lighting is only provided by a few red lamps strictly tested by a spectroscope.

For the application of the emulsion to the plates the sensitive gelatine is melted at $30-35^\circ$ C. and spread on to the plates by machinery. Whilst washed, dried and prepared plates pass along the conveyer under the machine, the emulsion contained in the vat is spread over the whole surface and on one side in a perfectly uniform manner. The plates are then removed on moving frames, washed on the glass side in hot water and thereafter led to an ice-cooled bench. After passing through a drying trough the plates receive a final drying and are then cut into the desired sizes. The plates, after cutting, are removed on a conveyer under the examining room, where women workers examine them with a view to finding out defective cutting or faults in the sensitive layer. The plates, after revision, are wrapped in black paper and placed in cardboard boxes. They then leave the dark room and arrive in the packing department where packing and labelling is effected mechanically.

In all workshops where prepared or emulsified plates are present there must be absolute freedom from dust, gaseous products and as far as possible from microbes. Adequate plant for air purification is indispensable. The air passes over layers of pumice stone impregnated with a special liquid calculated to absorb the carbon dioxide, sulphuric acid and other gaseous impurities. It is then heated, passed through a cloth filter and sent into the workrooms with provision for avoidance of draughts likely to cause discomfort. Further, the air must have a constant temperature and humidity rate.

When films made of celluloid or acetylc cellulose are used in place of glass plates the application of the emulsion is similar to that used for papers. The same care is taken of the operations of drying, winding and cutting out. Nevertheless, prior to the application of the sensitised emulsion the surface requires to be prepared with a view to facilitating application and adhesion. For this purpose the surface of the film which is to be covered is dipped in a solution of celluloid. Recently, a proposal was made to use furfurol in this connection. This process resembles the "floation" process used in spreading photographic papers.

In the preparation of printing papers it is very rarely, and only under quite special circumstances, that such papers are intended for negative proofs. Mention will therefore only be made of papers intended for positive proofs. The paper furnished by fine-paper factories (stored, first of all, in well-ventilated workrooms where the temperature is carefully controlled) is subjected to preliminary preparation by means of earthy alkaline sulphates with a view to covering with a very thin layer any small defects in the paper and furnishing a pure white or slightly tinted background for the later application of the emulsion. In general, baryta is used; an extremely fine suspension, filtered several times, of barium sulphate chemically pure and to which a small amount of gelatine, a little colouring matter and certain chemical substances facilitating conservation have been added. The band of paper then reaches the drying room, where it is stretched over an endless belt and passes through several calenders, which gives to the baryta paper a good glazed surface. The later operations are only effected in workrooms lit artificially by red light, the temperature and humidity rate of which are strictly controlled. The preparation of the chloride or bromide of silver emulsion is in general similar to that for photographic plates, but it may be prepared with gelatine, albumen or collodion, etc., according to the type of sensitive paper required. The collodion solvents (ether, alcohol) are withdrawn by exhaust ventilation and recovered either for economic reasons or with a view to avoiding the risk of fire. The spreading of the paper is effected in the same manner as that followed in the case of plates.
The emulsion liquefied by heat is contained in a silvered receptacle placed above the machine. A tube attached to the base of this receptacle terminates in a horizontal silver tube, the length of which corresponds to the width of the paper to be spread and which is perforated throughout the whole of its length. The method of "flotation" of lengths of paper over a bath of emulsion at a constant level is also utilised. The paper after receiving the layer of emulsion arrives in the drying room where it is again wound on to a roll.

According to requirements, the paper is sent on to the cutting rooms or to machines which cut it into various sizes and count these automatically. The sheets, after careful sorting with a view to elimination of defective samples, are enveloped in red paper which is damp-resistant, and thereafter in black paper or envelopes. They may then leave the dark rooms and reach the final process of packing.

A brief reference suffices in regard to colour photography. This latter process has been so far obtained by colour selection on different plates, rendering impossible, however, photography of moving subjects. The discovery of the single autochrome plate certainly constitutes progress since it reduces the operations to one single process, but posing has to be longer than in the case of snapshots. Now, thanks to the English Finlay process, it is possible to take snapshots at 1/50-1/100 second in colour.

**Pathology**

It is known that gelatine serves as a favourable culture medium for the development of most types of microbes. It is further a very sensitive albuminoid substance. The whole series of operations constituted by the preparation of photographic plates and papers requires a constant temperature and humidity rate in the workrooms and an exceedingly pure atmosphere. In other words, the working conditions in the photographic industry are favourable to the health of the workers employed. It must, however, be added that as a result of the more extensive application of machinery in this industry the number of workers employed has been greatly reduced. It is only in course of preparation of films that there still exists a certain risk connected with the use of celluloid solvents.

Doctors have, however, for long stressed the detrimental effect on health of permanent work carried on in dark rooms necessitated by the photo-sensitive quality of the products used. Agasse-Lafont and Heim de Balsac found amongst 84 per cent. of photographic workers a slight degree of mononucleosis (40-45 per cent.), which they were inclined to attribute to manipulation of salts of silver, and similarly a slight degree of eosinophilia, which they attributed to the action of amylacetate and acetone fumes. L. Carozzi (1913), as the result of a series of examinations effected amongst workers in a photographic plate factory in Milan, was able to confirm the presence of mononucleosis and eosinophilia, though he found no marked diminution in the haemoglobin or in the number of red blood cells and leucocytes. Carozzi considers that the slight changes in the blood are merely the sign of oligochromia, which is common amongst workers; further, that the absence of daylight might be considered as practically harmless and that the air of the workrooms was likewise free from any serious objection as regards health.

Elizabeth Kruger (1924) has resumed this study and examined working women employed in dark rooms. She was not able to find any specific general symptoms and in particular no diminution of the haemoglobin. For this reason, Gerbis has sought the explanation of the poor health frequently found amongst these workers in the defective composition of the air, the absence of ventilation and the effect of certain products, namely, sulphuretted hydrogen, rather than by the absence of daylight.

Gerbis has often received complaints from small reproduction workrooms relative to the work effected in dark rooms. As far as spacious workrooms in modern plant for the manufacture of photographic plates, papers and films are concerned, the state of health of the staff — to a large extent women workers — is quite satisfactory, and the morbidity figure is usually low. It should, however, be remembered that the effect exercised by permanent work in a dark room on those unaccustomed to it may lead to a state of anxiety and nervous excitement which may, where complicating circumstances occur, even lead to panic. Amongst individuals with weak nervous systems the nervous tension resulting from permanent work in dark rooms is continuous and may even lead to states of depression with a sensation of pressure resembling constriction by a tight helmet (Gerbis).

Dr. H. Gerbis
(Berlin).
Photographers

It is scarcely possible to end this article without brief mention of the pathology of photographers called upon to handle and use photographic products (plates, films, papers, etc.).

It is chiefly developers which are responsible for a number of skin diseases, generally localised on the hands. Amongst predisposed individuals these may sometimes even attack other parts of the body.

Amongst developers the aminophenols (see that article) are those which present the greatest interest from the medical point of view. In 1898, Freund drew attention for the first time to the acetone solution of metol (sulphate and monoamethyl-para-amino-phenol), in 1925 W. Ermen announced that a kind of metol without a poisonous effect on the skin had been discovered, but despite this several cases were reported later.

Metol causes an erythematosus and eczematous form of cutaneous disease. The former, described by Freund, Krébich, and St. Weidenfeld, is localised principally on the fingers and hands and may cause a condition which is comparable to that of local asphyxia.

Stors has noted in one case symptoms of a general order: fever, weakness, irritation, etc., whilst the cutaneous manifestations also attacked the extremities. The nails are often affected.

The eczematous form similar to that caused by turpentine, etc., may be very serious, especially when in the case of a relapse the eczema becomes infected and spreads all over the body.

In a case studied by Freund the patient was a young girl who dipped her fingers in a solution containing borax, gold chloride, chloroplatinum, citric acid, hyposulphite of soda and ammonium sulphate. The skin disease attacked her face.

An enquiry carried out by Karasek (1911) in Chicago workrooms revealed 31 cases of dermatitis and ulceration due to metol.

Beers reported cases of dermatitis and eczema in 1908; Knowles (1913), 4 cases amongst photographers; and Hamilton (1921) one case affecting a photographer who suffered from dermatitis and eczema during the nine years in which he worked with metol.

In his report for 1929 the British Chief Medical Inspector of Factories records that, according to an investigation made amongst photographers, cases of dermatitis due to hypo acid in a solid form were encountered. On the other hand, cutaneous troubles due to metol might be, it is stated, avoided by washing off immediately any splashings of the developer with a weak solution of mineral acid. It is essential that no soap containing free alcalis should be used.

Pyrogallic acid colours the hands and nails dark yellow and even black; para-phenylenediamine ("Metacarbol") gave rise to the following symptoms in the case of a photographer: diarrhoea, vomiting and vertigo; quinone-dichlor-diamine to difficult to remove, of the skin; amidol (diaminophenol) and rodinal (potassic phenolate of para-midophenol) to eczema; handling of platinum printing paper has caused (according to the enquiry quoted by Karasek dealing with 40 Chicago workshops) 8 cases of poisoning characterised by violent irritation of the throat and nose, sneezing, coughing, bronchial irritation, respiratory troubles, eczema, etc.

The carbon or colour process has caused cutaneous troubles attributed to chromates (Burns, Edinburgh, 1904) and which Richardson, of London, designates "the bichromate disease".

Silver nitrate causes a form of disease known under the designation of argyria (see article "Silver"), typified by a blackish coloration running to deep black of the skin which is extremely difficult to remove, in the case studied by A. Reuss (1887) affected a photographer who showed also black coloration of the caruncula lacrimalis and part of the bulbar conjunctiva.

Account must likewise be taken of the harmful action of the skin and mucous membranes of other products handled by photographers: nitric, hydrochloric, and oxalic acids; chromates, especially in the colour processes, helio engraving and photo lithography (see article "Photo-Engravers"); mercury bichloride — often in 2-5 per cent. solution — cyanide of potassium — in a 2-10 per cent. solution — which causes serious dermatitis amongst workers engaged in galvanoplastie processes and photographic reproduction (collodion process); iron chloride; caustic soda; alcalis in general; nitrate of uranium; aurantia; solvents; salts of bromide and salts of iodine; etc.

A further cause of injury is related to the long hours spent in the dark room, which is often badly ventilated and in which the atmosphere is vitiated and which presents conditions of damp heat.

Retouchers have been found to suffer from syphilis and tuberculosis transmitted by the common use of brushes.
A bad habit which has given rise to infection is that of pointing the brush by placing it between the lips (Freund). This bad habit obviously represents a possible source of numerous types of poisoning.

It is necessary in conclusion to recall the use of very powerful lighting sources for reproduction work and their detrimental effect on the eyes. Duke Elder has reported cases of iritis amongst photographers due to exposure of the eyes to the action of sources rich in ultra-violet rays.

HYGIENE

It is not possible to suggest any special hygienic measures in the photographic plate and printing paper industry. On the other hand, the measures indicated in the article "Chemical Trades" should be recommended for adoption in the case of photographers as likewise those referred to in articles dealing with the various products manipulated by photographers.

LEGISLATION

Skin diseases (eczema, dermatitis) amongst photographers and likewise mercury poisoning are subject to compulsory notification in the Netherlands; forms of dermatitis due to chemical products receive compensation in Bulgaria, and mercury poisoning in Sweden. See also article "Occupational Diseases: Definition and Compensation".

***

Picric Acid

(Trinitrophenol, Trinitrophenic Acid)

CHEMICAL PROPERTIES

Pure picric acid C₆H₅(NO₃)₃·OH is in the form of rectangular foliate, elongated crystals, varying in colour from lemon yellow to reddish yellow according to the manner of production, odourless and with a very bitter taste. These crystals melt at 192.5° C., are slightly soluble in cold water, more readily soluble in hot water, ether, alcohol and especially in commercial petroleum spirit.

Picric acid, which is a powerful colouring agent, is a strong acid; it decomposes carbonates and even nitrates and chlorates in the presence of moisture.

It was first mentioned by Hausmann (1788) as arising from the action of nitric acid on indigo, and Welter obtained it later by reaction of the same acid on silk, while Laurent prepared it from phenic acid without it. It was first used industrially by a silk dyer at Lyons.

In commerce a less pure (sulphonated) variety is known. In compressed form or in a fused state it is explosive and must be handled, packed and transported subject to the rules for explosives.

Picric acid [C₆H₅(NO₃)₃·NH₂·OH], which is got by reduction from picric acid, has red crystalline needles melting at 168-196° C. It is used as a colouring agent, chiefly with picrate of ammonia, giving a deep red colour. It is also used in photography.

Picrates are metallic salts yellow in colour with a bitter taste generally insoluble or slightly soluble in water, alcohol, ether, except the potassium salt which is very soluble and easily crystallised. These salts are more highly explosive than picric acid itself. The picrates of calcium and sodium catch fire by simple friction. They are chiefly used in combination with other chemicals such as ammonia and potassium.

INDUSTRIAL OPERATIONS—USES

Picric acid is prepared from phenol. 100 parts of phenol are mixed with 500 parts of sulphuric acid and the mixture kept at 100° C. for about an hour. The sulpho-phenol thus obtained is poured on to a mixture of nitric acid and nitrate of soda at 28° Bé. Sulphonation is usually carried out in cast iron receptacles and the nitration in stoneware vessels or brick-lined cast-iron basins. They are mostly provided with covers, each having a chimney leading to condensation and recuperation chambers. Great heat accompanies the reaction and nitric acid fumes are liberated. The temperature in the nitration vessels must be kept above 110° C. for a fairly long time, after which it is allowed to drop, the mixture being then diluted with water. It is left for 24 hours, then the mother liquors are decanted and the picric acid recovered and poured into double-bottomed tubs and washed with water. It is subsequently heated and dried at about 50° C. and put through a sieve.

Picric acid has been, and still is to a reduced extent, used in the dye industry in the preparation of certain artificial organic colouring matters. It is also utilised with other chemicals in the production of certain sulphur blacks (although these are rather unstable).

Picric acid was widely used during the war in the manufacture of explosives. The pure acid was used for filling shells with a mixture known
in Italy as pertite, in France as melinite, in England as tydallite, in Japan as shimoe. It is now, however, frequently replaced by trinitrotoluol for this purpose. It is also used in combination with other chemicals such as nitrotoluol to form explosives and is used in the manufacture of fireworks and tear gas (chloropiric). Picric powder makes a special variety of semi-smokeless powder. In laboratories it is employed for chemical analysis (reagent for albumin and alkaloids), and microscopic analysis, and to a lesser extent as a medicament, and in the photographic industry. It was formerly the practice to add it to beer to give a bitter taste and it is still sometimes fraudulently employed to colour certain foodstuffs (butter etc.).

Poisoning may occur among chemical workers (preparation of picric acid), munition workers (shell filling, manufacture of tear-gas), dye workers, woodworkers (mordanting) photographers, firework makers, laboratory workers, chemists, etc.

TOXIC ACTION

What is known of the toxicity of this product is based on observation of cases of acute poisoning, for so far laboratory research has not yielded exact knowledge on this point. According to Kobert and Erben picric acid, like nitrated substances, has a tendency to attack the red blood corpuscles and to form methemoglobin; it also has a strong coagulating action on albuminoids and marked caustic effect on organs in which acid is present — the stomach for instance. But since picric acid is easily changed in the system into the less toxic and less irritating picramic acid, this latter effect is ordinarily attenuated. Though certain authorities have found alteration in the number of red corpuscles (diminution) with increase of white corpuscles, others have only found slight eosinophilia without any modification of the blood.

Poisoning takes place principally through inhalation of dust and more rarely of fumes. The dust soils the hands and thence the food and can thus enter the system by the digestive tract. Absorption of picric acid through the unbroken skin (as with other nitrated substances) can be admitted theoretically, but actual occurrence may be doubted.

The dose poisonous for rabbits has been calculated experimentally by Eulenbert and Koizumi at 0.33 grm. per kg. (acute poisoning) and from 0.0045 grm. gradually increasing to 0.045 grm. per kg. for chronic poisoning. In 1918 Ilzhofer induced fatal acute poisoning in cats with a single dose of 0.5 grm. per kg. of an aqueous solution of picric acid, and death on the third day by administering two doses of 0.2 grm. per kg. When the dose was limited to from 0.05 grm. to 0.1 grm., repeated several times in course of a week, red fumes in Germany unaccompanied by any other important phenomena resulted. The formation of methemoglobin was never observed. Ilzhofer is of opinion that picric acid is more poisonous than nitroxylenol or nitronaphthaline.

STATISTICS

Statistics relating to occupational lesions and poisoning due to picric acid are very limited. Cases of dermatitis were reported in Great Britain in 1902, but it was particularly during the war that cases of cutaneous and mucous irritation and digestive disorders were reported and made the subject of careful study by experts. Fatal cases due to picric acid are much less frequent; three deaths were reported in 1906, one of which was the case described by Christnacht (1917) as having occurred in an explosives factory, while a second took place in Germany during the war. Slight cases of dermatitis have been reported more recently (1919-1922) chiefly in lamp wick factories. In one picric acid factory, however, no case was reported in the course of twenty years. The third fatal case was that of a worker who fell ill after emptying a receptacle containing liquid picramic acid and died after a few hours. It must be remembered that serious cases, some fatal, have been caused by nitrous fumes (during the nitration of phenol).

SYMPTOMS

A few minutes in a workroom where picric acid is being handled suffice to produce a bitter taste in the mouth and shortly afterwards the hair and the nostrils look yellow. This change of colour is quicker with blond than with dark-haired workers. The coloration of the exposed parts of the skin which is typical, is particularly marked on the palm of the hands. Yet despite this the general health of the workers is good and it may be said that the picric acid industry is not as unhealthy as was first thought (Koelsch). The quality of the acid and particularly its degree of purity, as well as individual susceptibility, largely determine the clinical picture.

The use of picric acid as a medicament, and its popularity with
malingerers anxious to escape military duty during the war, but especially cases met with in munitions factories, have brought to light the symptomatic poisoning of picric acid poisoning, but little known prior to 1914. Inhalation of this product rapidly causes — besides the characteristic yellow colouring of the skin and hair (head and beard) and mucous membranes — sneezing, sometimes violent catarrh, stomatitis, gastric pain, and vertigo. The so-called chronic form is accompanied by a bitter taste in the mouth, a lack of appetite (at first the appetite increases), a dry cough, accelerated breathing, anaemia — a state which rapidly improves and finally disappears if the victim is removed from contact with the product.

In the urine, poisoning is characterised by the presence of albumin, blood, haemoglobin and casts. Picric acid is eliminated in the form of picric acid into which it is perhaps transformed in the liver.

Picric acid reacts on the skin by provoking a scarlatiniform erythema, chiefly affecting the face, the neck and the limbs, and causing itching of the skin. In serious cases there is rise of temperature, headache, vertigo, accelerated pulse, vomiting, diarrhoea, and collapse.

In the industries in which workers are brought into contact with this product generally the only symptoms noted are dermatitis (especially in summer), conjunctivitis, and more rarely bronchitis. The bronchite meliniteuse (lydite bronchitis) mentioned by Regnault and Sarlet due to the irritating action of acid picric may be recalled here.

Cases are now much less frequent than formerly, and chronic poisoning and picric jaundice as described by certain authorities are doubtful (Curschmann).

**Demonstration**

(a) In the urine. — Add to 100 c.c. of urine 10 c.c. of a neutral 10 per cent. solution of acetate of lead, filter, add 20 c.c. of sulphuric acid at 25 per cent., filter, shake the filtrate with the addition of 5 c.c. of chloroform or ether, decant, add 5 c.c. of ammonia at 10 per cent. A red colour proves the presence of picramic acid. The following reaction may also be employed: acidify the urine with hydrochloric acid and mix it with ether, add to the ether extract (yellow) a slight quantity of caustic soda solution (lye); the ether becomes discoloured and the lye assumes a red colour.

Kohn Abrest advises the following reaction: treat 20 c.c. of urine with 10 c.c. of Denigès reagent (10 grm. red mercury oxide, 200 grm. water, 40 c.c. sulphuric acid) filter after 5 minutes; shake the filtrate with 5 c.c. of chloroform, separate the former, mix again with about 4 c.c. of chloroform, shake, leave it to settle, decant the chloroform and mix the two chloroform solutions, filter them if necessary, add ½ c.c. of water, put them in a test tube and drive out the chloroform by standing in water and heating the water. The presence of picric acid is shown by golden yellow colour of the liquid. It is advisable to repeat the reaction several times as a check on the test. Another method is to dip into the liquid obtained as above some strands of white wool or silk and discover whether the yellow colour imparted to these resists vigorous washing and changes more or less to a reddish tone when the strands are brought into contact with a solution of potassium cyanide to which potash or soda has been added and the whole slightly heated.

(b) In the blood. — Fifteen drops of blood are mixed with 3 c.c. of a 0.5 per cent. solution of sodium chloride which is left to stand for twenty-four hours at the temperature of the room, the mixture being stirred occasionally; a yellow hue, even with very slight, proves the presence of picric acid. The addition of an equal quantity of a methylene blue solution (1 : 50,000), the whole being then shaken, will indicate the presence of the product by pale to dark bottle-green colouring.

**Hygiene**

Though in practice cases of occupational poisoning are very rare, it is nevertheless advisable to apply the well-known precautionary measures against dust. It is indispensable that the grinding and drying of picric acid should be effected in closed and airtight apparatus. Dust elimination at the workplace should be effected by a downward or sideward drawing exhaust, the optimum rate for the air current being exactly determined (very light dust). It must be admitted that mechanical elimination of dust in this special case presents a problem which still awaits a satisfactory solution. The workrooms should be cleaned daily and all tools and implements maintained in a clean condition.

Manipulation and transport as well as packing of this product in the explosives industries should be subject to the usual precautions taken in regard to explosives.

Measures of personal hygiene comprise powdering of the face to prevent yellow discoloration of the skin; washing of the hair with a hot and concentrated alkaline solution and in close (it is preferable to wear the hair very short). The wearing of rubber gloves and impermeable overalls has been recommended (Great Britain). A
method to be recommended is the manipulation of picric acid in cupboards provided with adequate exhaust ventilation and having windows to permit of controlling the work in progress, or two apertures for inserting the hands.

The presence of metallic lead should be prohibited in places where picric acid is handled.

During the war several factories had all applicants for work medically examined and had their workers periodically examined. Milk was also distributed to the workers. Persons showing signs of poisoning should be immediately removed from departments where the product is present.

**LEGISLATION**

Exclusion of women from the manufacture of picric acid is enforced by legislation in Argentina, France, and Switzerland. For the Netherlands see article "Acrolein".

Compensation for injury caused by picric acid is provided for in Finland and Switzerland.

Pitch

(Coal Tar Pitch; Tar Pitch)

**PROPERTIES**

Pitch is a solid substance with conchoidal fracture, brilliantly black, but at the same time smooth and sticky, constituting the residue from distillation of tar, or rather of tars, because the composition of these varies with the different kinds of coal from which the gas is extracted. Pitch dissolves partially in petroleum ether, petroleum benzine, alcohol (in small quantities), etc.

In addition to hydrocarbons, heavy oils (naphthalenes and anthracenes), light oils (benzenes and phenols), the tars contain a certain quantity of fixed carbon.

The hydrocarbons and oils are separated by fractional distillation; the black mass remaining at the bottom of the stills is pitch.

The amount of pitch collected from the tars varies between 30 and 80 per cent. This residue, itself very variable, is a mixture of anthracene, chrysene, pyrenes, resins, gums, coke, etc.

Pitches are divided into different categories; according to their melting point they can be distinguished as soft pitch ( fusible between 40° and 50° C.), hard pitch ( fusible between 70° and 100° C.), and semi-soft pitch with intermediate properties.

The proportion of pitch in the agglomeration of smalls can be ascertained by the simple means of breaking up a small sample. Those in the trade easily learn to gauge, by taste and plasticity, the quality of pitches (De Vulilch).

**USES**

Pitch is largely used in the manufacture of patent fuel (briquettes), artificial asphalt, impermeable pasteboard, varnishes for wood and metals, lampblack, insulating materials, etc.

When hot pitch, completely free of volatile matters, is mixed with siliceous materials of different degrees of hardness, a special product is obtained, known in commerce under the name of "Prodorite". This mixture can be moulded; it serves for the manufacture of pipes, blocks, etc., which can be joined with an impermeable cement of the same nature. It can be reinforced by steel, like cement. It is used to make chimneys proof against acid fumes, and for impervious floors, for electric accumulator rooms, vats, receptacles, etc., which are required to be resistant to acids, heat, pressure, etc.

Pitch (with tar) is used as paint in the construction of ships, the manufacture of accumulators, in the barrelling department of breweries, in the making of brushes (in the form of glue, either mixed or not with asphalt), in the making of lacquers, artificial stones (finely ground cork, mixed with molten pitch and compressed under a vacuum), etc.

Its use in the manufacture of patent fuel is very important. This consists in mixing and pressing coal dust with a certain quantity of pulverised pitch (8-10 per cent.) which is converted, on heating, into a paste and forced through a press into quadrilateral moulds and then cut into briquettes.

The mixing of the two powdered materials is done in an apparatus charged automatically; the paste comes from a closed pug mill provided with
mixing arms where it is brought to the temperature for the melting of pitch by means of steam jets.

The paste is then submitted to considerable pressure, and the continuous charge thus obtained is cut automatically by a rotating table pierced by openings, or simply by hand by means of a knife.

The briquettes are then filled on to wagons (work generally done by women on the Continent).

As soon as the mixture of the powders is effected, the operations are carried on in an enclosed apparatus and in a moist condition—that is, without evolution of dust. It is to be noted that persons employed in these operations do not show the characteristic lesions set up by pitch.

**Sources of Danger**

The hands of the charger are always in contact with the briquettes, that is, with tarry matter. Further, all around the machines and at the point of departure from the press a tarry smell is felt, obviously coming from the pitch. These gases and vapours do not appear to have an appreciable effect on the health of the workers; at any rate, no specific action either on the skin or the eyes or respiratory tract can be attributed to them.

Careful investigation of methods of work convinces one that only the workmen exposed to pitch dust are subject to these occupational injuries, generally designated as “pitch effect” (maladie du brai). It is especially the means of conveyance (elevators, endless belts) which create the very fine dust. Dipping or hacking out with a pick and crushing of the pitch, which reaches the factory in large lumps and sometimes even in cylindrical masses, raises quantities of pitch dust, which remain in suspension in the air for a long time. Digging is done generally in an enclosure or hangar, or even in a separate part of the building more or less distant from the machines. The pitch which has been dug out is conveyed to the disintegrator on trolleys pushed by hand; charging and discharging these raise quantities of dust, but it is especially at the point where digging is done that it is thickest and most injurious. At the moment of breaking up the pitch with the pick a characteristic odour of hydrocarbons, recalling that of pyridene, is evident.

Pitch dust floating in the air alights on the skin, the hair, the beard, and the mucous membrane of the eyes, nose and throat.

The injurious effect of these dusts depends for the most part perhaps on their chemical composition, but, by reason of the physical structure of the particles (sharply pointed, toothed and angular) their power of inflicting injury must be admitted (see fig. 76).

**Statistics**

In Germany the question of dermatitis and tumours among workmen manipulating pitch has been followed with the greatest interest. At Oppeln, in 1894, cases of conjunctivitis and dermatitis accompanied by the formation of crusts were reported among workers of a recently erected patent fuel factory. In Upper Silesia these lesions were already known, and also in Westphalia and Rhineland, where enquiry, made in 1895, showed that sensitiveness to the action of pitch varies in different individuals, and was most marked among young subjects with delicate skins and of a scrofulous type. Measures taken for individual cleanliness and general hygiene, efficient dust removal, especially in drying and pressing departments, have diminished the frequency of cases. The report of the enquiry of 1898 attributes these lesions to the presence of traces of phenol in the pitch. In 1901 it was stated that the workmen affected had been manipulating finely divided English pitch. In 1909, L. Zweig, of Dortmund, described three cases of pitch (or tar) tumours among patent fuel workers. He was of opinion that these substances exercised an action analogous to that of paraffin and lignite tar, causing not only eczema, but tumours also. Nevertheless the number of those attacked by the latter in relation to those exposed to risk was fairly low. He admitted, however, that these substances favoured or accelerated the development
of tumours in those who were predisposed. The number of occupational lesions reported in Germany is very small. Thus during five years only two cases a year were reported among 2,500 workpeople, i.e. 0.08 per 1,000. Of these the cases the lesion was located five times on the scrotum, four times on the face, and once on the forehead. In the cases of pitch cancer were reported in Hamburg.

In the United States, according to A. Hamilton the question has little importance, as the patent fuel industry is insignificant. Davis (1914) reported a case from use of an industrial oil (paraffin?) and a few cases have been collected by McCord and Kilker (1921) among 17 workers employed in treating wood with tar, pitch, and chloride of zinc.

On the other hand the matter is of great importance in Great Britain, where dermatitis and tumours are more frequent than elsewhere — no doubt because of compulsory notification by medical practitioners. These lesions have even been reported there among workers employed in discharging pitch from vessels and from trucks. The lesions are situated on the most different parts of the body: face, hands, scrotum, etc. Generally the lesion follows a benign course, leaving only a superficial cicatrice. But when the lesion is localised on the scrotum, not infrequently it becomes cancerous, as in this situation no doubt the linen impregnated with pitch irritates the parts. Operative interference, however, generally prevents or retards recurrence.

Unfavourable sites also are the eyelids and eyes (conjunctiva), and blindness is fairly often a sequel. Dermatitis and warts set up by pitch have been included in the list of diseases scheduled for compensation since 1905; since which time scientific researches on the subject have been very numerous. An enquiry in 1907 among the briquette makers of South Wales brought to light 38 cases; but previous to this no case had been reported during twenty-three years among the workmen making briquettes with tar and pitch. Hilditch, Inspector of Factories at Swansea, attributed these lesions to the action of crude anthracene, and Legge and Owen Edwards examined 277 workers in 1909, finding in the majority of them symptoms of irritation of the skin, enlarged sebaceous glands, and ulceration set up by the pitch. In 1911 a public enquiry was conducted under the Factory Acts by Mr. W. A. H. Lush, and it came out in evidence that the action of the pitch differed considerably according to its origin. The workers stated that pitch from Margport and Goole was much the most irritating. The yellow staining of their linen was said to be due to the presence of anthracene in high quantity — so much so that either anthracene or phenol was believed to be the cause.

Lush in his report recommended special clothing to protect the workers' skin against contact with pitch dust; use of goggles; means, other than soap, for ridiccling the skin of pitch without causing irritation, and medical supervision.

Ross and Cropper conducted researches from 1910 on different kinds of pitch in order to find the substance setting up the irritation. Coal tar pitch they found the most irritating, while blast furnace pitch was much less so. This view was found to be the case in actual practice by Legge. The acid sweat was believed by the experimenters to dissolve out the auxetic substances in the pitch which favours the development of new growths.

The employers in 1911 organised a voluntary periodic medical examination, and it is owing to this that detailed statistics for workers in briquette factories are available. From 1911 to 1919, 158 attacks (3 deaths) were reported among workers coming into contact with pitch. From 1920 to 1922 the cases numbered 79; in 24 of them the ages varied from 40 to 50 years, in 24 between 30 and 40 years, and in 8 over 60 years of age. Duration of employment had been in 16 cases less than 10 years, in 18 from 10 to 20 years, in 20 from 20 to 30 years, and in 12 from 30 to 40 years. The lesions were situated on the face and neck in 43 cases, on the scrotum and groin in 20, on the hands and forearms in 6, and multiple in 8; in 3 cases the site was unknown. In 1923 the cases reported numbered 85 (2), in 1924, 23 (1), in 1925, 25 (3), in 1926, 27 (3), in 1927, 34 (1), in 1928, 32, in 1929, 53 (3), in 1930, 44 (1), in 1931, 41 (2) and in 1932, 35 (1).

In Italy the cutaneous lesion among workers in a briquette factory at Ribolla were at one time so serious as to lead to temporary suspension of work.

The first enquiry into this subject was undertaken in the Netherlands in 1913, and had reference to only two patent fuel works, one which employed 47 persons (15 were under 17 years of age) and the other 8.

Irritation of the sebaceous glands was detected in 28 cases and furunculosis in one, on the face and forearm; in 7 there were cutaneous proliferation, and in 11 acute or chronic conjunctivitis.

Subsequently the personnel in all the patent fuel works were subjected to medical examination once or twice a year.

The results are given in the report of the Inspector of Factories for the years 1913 to 1924, and are shown in the table on page 654.

In 1913 and 1907 a medical examination of all the workmen employed in three factories revealed in the same factory 2 workers suffering from lesions due to pitch.

In 1913 one of these men showed cutaneous proliferations localised on the scrotum, of which one turned out to be sarcomatous. Four years later the same man had developed a tumour on the right wrist, which healed after an operation. The other man (with forty years' duration of employment) had an epitheliomatous ulcer on the scrotum. He had undergone an operation the year before for a similar condition on the same place.
The idea or associating pitch cancer with that of chimney sweeps is not new; there is a still more intimate connection between accidents due to pitch and those due to tar. Tar itch, dermatitis due to pitch, takes on many forms, varying from a simple acne to eczema and psoriasis. It occurs usually on the upper limbs, but is found also on the scrotum.

The carcinomatous degeneration of certain skin lesions has been observed by several authorities, among others by Volkmann, who has described one case of scrotal cancer and one of the eyelids due to the injurious action of tar. Mention only need be made of the innumerable instances of experimental cancer produced in mice by painting the skin with tar.

Chimney sweeps' cancer, like that occurring in persons employed with pitch, starts no doubt from the irritative action of various ingredients present both in pitch and soot, as well as in tar.

The noxious substances are believed by some to be phenol and naphthaline, by others creosote.

Bayet, interpreting the pathogenesis of pitch lesions, considers the morbid picture is not a single entity, but should be classified thus:

(a) the acute symptoms, exacerbated by light, Bayet believes, are the result of irritation by certain constituents naturally present in pitch, perhaps anthracene oils, an irritation analogous to that set up by a number of substances (turpentine, varnish, resin). It is natural to explain the matter in this way, but it should be made the subject of experimental verification.

(b) in the case of acne-like outbreaks he thinks it necessary to attribute to the action of tarry substances, and considers them to be similar to the well-known tar acne.

(c) in the case of pigmentation and hyperkeratosis, warts, and epitheliomata, he arrives at the conclusion which he was the first to formulate (in 1916), i.e. that they strongly resemble chronic arsenical poisoning.

Really, in Bayet's opinion, the third group is the one that should be considered as characteristically the pitch effect.

In a subsequent work this authority has confirmed this view, stating that, considering all the facts of the case as outlined above, the clinical picture observed in pitch workers in all the essential aspects, as well as in the details, resembles that of arsenical poisoning.

This conclusion has been confirmed by Slosse, who showed the presence of arsenic in the air of the factory on the one hand and on the other in the hair, blood and urine of the operatives in notable amount much in excess of what was physiological. An important point to remember from the point of view of prophylaxis is that the arsenic found in the air is not there in the form of vapour but of dust.

(b) the acute symptoms, exacerbated by light, Bayet believes, are the result of irritation by certain constituents naturally present in pitch, perhaps anthracene oils, an irritation analogous to that set up by a number of substances (turpentine, varnish, resin). It is natural to explain the matter in this way, but it should be made the subject of experimental verification.

(b) in the case of acne-like outbreaks he thinks it necessary to attribute to the action of tarry substances, and considers them to be similar to the well-known tar acne.

(c) in the case of pigmentation and hyperkeratosis, warts, and epitheliomata, he arrives at the conclusion which he was the first to formulate (in 1916), i.e. that they strongly resemble chronic arsenical poisoning.

Really, in Bayet's opinion, the third group is the one that should be considered as characteristically the pitch effect.

In a subsequent work this authority has confirmed this view, stating that, considering all the facts of the case as outlined above, the clinical picture observed in pitch workers in all the essential aspects, as well as in the details, resembles that of arsenical poisoning.

This conclusion has been confirmed by Slosse, who showed the presence of arsenic in the air of the factory on the one hand and on the other in the hair, blood and urine of the operatives in notable amount much in excess of what was physiological. An important point to remember from the point of view of prophylaxis is that the arsenic found in the air is not there in the form of vapour but of dust.

Mention only can be made of the theory of H. C. Ross on malignant disease as due to the products of the decomposition of living matter and the effect in hastening it of kinetic and auxetic substances. Neither can more than a reference be made to the view that use of formaldehyde might neutralise the noxious ingredients contained in the tar.

Burkhardt (1920) has raised objections to this view, and has promulgated another, namely, that tumours of the bladder in aniline workers, for example,
and new growths observed in patent fuel workers may be due to the action of an organic compound present in the coal tar pitch, but which has not yet been identified.

If under the term "pitch effect" are included not only the symptoms of pigmentation, hyperkeratosis and cancer attributable to arsenic, but also the acute irritative action, it must be acknowledged that the etiology of these latter does require further elucidation.

Merely to say that pitch acne resembles tar acne does not advance us far in the search for the cause; to say that the acute symptoms are due to carbolic acid or anthracene oils is only to give a ready answer; as a matter of fact, carbolic acid being the most valuable constituent in tar, is extracted to the furthest extent possible, and is only found in very small quantity in pitch; on the other hand the content in anthracene is very variable.

In addition to the undeniable chemical action account must be taken of the physical constitution of the dust and of the opinion of Herman that insufficient attention has been paid to this aspect. Thus microscopical examination shows
these dusts to be capable of producing wounds. When falling on the surface of the skin they penetrate it readily as a consequence of the movements made in the course of work or by friction exercised by the skin. To set up conjunctivitis blinking of the eyelids alone is enough. Lastly, having regard to the thin skin of the scrotum and the friction to which the genital region is subjected in walking and working, it is not surprising that this should so often be the seat of election for injury from pitch dust.

Once having penetrated the tissues these dusts act mechanically and chemically, but it would be a mistake to suppose that they are quickly dissolved or that the irritation has no other cause than the chemical substances set free by this solution.

In the cores of an acne spot already old, Herman has found pitch dust with characteristics like those shown in fig. 76.

Possibly the course of events may be somewhat different in the case of eye injuries both physiologically and anatomically; but Herman wishes to bring out the fact that the action of pitch is not exclusively due to chemical action.

There is no doubt, on the other hand, that the effects of pitch often become complicated as the result of scratching and subsequent secondary infection. The curious fact of exacerbation, of the burning sensation of the skin from solar radiation has not yet been satisfactorily explained. According to Herman the idea of the melting of the pitch particles by the sun's heat must be rejected as the phenomenon is instantaneous. Sun heat can only act gradually and as a result of the warming of the surrounding air, but there is no doubt that warm air and hot water can themselves increase the sensation of burning.

It is more logical to admit the action of the luminous (and perhaps chemical) rays of the solar spectrum. These rays excite the nerve endings in the skin: this increase in the excitation of the nerves already initiated by the presence of pitch dust may help to explain the increased tenderness felt.

Interesting results might be expected from placing different coloured glasses before the face of workmen exposed to the sun, in order to determine the action of the different colours of the spectrum.

**Symptoms**

The effects of pitch comprise a heterogeneous ensemble of different lesions and symptoms which Bayet has classified in three groups:

1. **Acute irritative symptoms:** these consist of a pricking and burning sensation on the face, during and after contact with pitch. This sensation is only produced when the sun shines.

2. **Symptoms mainly of the hair follicles and sebaceous glands:** these comprise comedones, pustular acne, sebaceous cysts (tar acne).

3. A third group comprises as the principal symptom pigmentation, hyperkeratosis and cancer; as secondary symptoms chronic inflammations and cutaneous atrophies, telangiectasies, and xeroderma.

The use of pitch in painting has caused cases of poisoning due, it is believed, to small quantities of heavy hydrocarbons contained in the paints. Such symptoms as loss of consciousness, epileptiform seizures, and small rapid pulse have been noted amongst these workers. Ulceration of the nasal mucous membranes has also been found in the workmen making patent fuel (Oliver), etc.

So far as cancer specially is in question, Bayet assigns to it the following characteristics:

(a) it almost always develops on the site of a hyperkeratosis (wart or thickening of the epidermis);

(b) the seat is mostly on or near the scrotum;

(c) it is frequently multiple;

(d) it often occurs in those who are relatively young (among 9 pitch cancers 4 affected workers who were under 40 years of age).

An enquiry conducted in 1916 in several patent fuel works in Hainault and Liège enabled Herman to observe the correctness of the above view.

All the workers exposed to dust—but only these—experienced the burning sensation on the face and noted how this was suddenly aggravated by exposure to the sun's rays.

On the other hand the electric arc, deprived as it is of all heating properties, as ordinarily used, causes no aggravation of the symptoms.

It is undeniable, however, that to be in an overheated atmosphere, or, further, to wash the skin with hot
water, does increase the burning sensation in the face.

Herman has been able to establish the fact that the kind of pitch used plays a part in the seriousness of the effects. Thus the pitch worked during the last two years is more injurious than that worked in the years preceding, although it comes from the same places.

The signs of acne seen among a large number of the workers were very polymorphous; but it was generally observed that the acne spots were inclined to become hard and indurated.

In one case, however, Herman noted suppuration of almost all the pustules. The man in question was very dull mentally and took no care in the matter of personal cleanliness; infection of the boils following on scratching

Fig. 73. — Cancer of the Parotid Region.

Fig. 77 is a photograph of a workman employed for thirty years in a patent fuel works. Acne spots of various sizes are distributed on the back, shoulders and loins; they are seen too on the neck, where a marbling of the skin can be observed produced by a special pigmentation of the integument.

The skin of the scrotum presents a quite special aspect. Whitish, rather prominent maculae are scattered pretty uniformly over the surface. About
the size and shape of a lentil when isolated, they sometimes form confluent plaques covering a fairly wide area. Although raising of the skin is not pronounced, there is nevertheless a proliferation of the skin similar to that of a wart.

Fig. 78 represents a workman employed in handling pitch for 32 years. Fifteen years before the appearance of the epithelioma over the parotid region he had undergone an operation for the removal of warts on the scrotum.

The illustration shows well the base and edges of the ulceration with extensive epitheliomatous proliferation of characteristic aspect. To be seen also are the hyper and hypopigmentation of the skin of the face.

The pigmentation is not always confined to the skin; sometimes the hair and beard change their colour. Herman noticed amongst others a workman whose whole hair had taken on a curious yellow straw colour. In 1920 Scholberg, of Cardiff, examined 213 patent fuel workers and established the presence of two kinds of warts among these workers: (a) one, pendulous, which ordinarily causes no trouble, but if situated, as it often is, on the upper eyelid, annoys the workman; and (b) a flat form, with large base, appearing either singly or in groups, and often passing unnoticed, but which develops rapidly, degenerating, in the absence of treatment, into a cancerous condition. This form, however, is the less frequent of the two.

Lastly, besides the skin lesions, mention requires to be made of the eye changes. Moret has divided them into two groups: (1) lesions produced by the accidental impact of pitch into the tissues (these are rather in the nature of a traumatic injury) and (2) symptoms of irritative conjunctivitis and sometimes a special tattooing of the cornea.

Bayer refers to a hyperpigmentation of the conjunctiva like that met with in arsenical poisoning.

Prophylaxis

Should the discovery of Bayer and Slosse as to the rôle of arsenic in the production of the lesions of pitch he confirmed, the fact that it is not as vapour that the poison is present in the air would leave Herman's conclusion (1916) as holding the field, namely:

In the actual state of the question preventive measures against the effects of pitch are summed up in an effort to control the dust.

This proposition, though easy to state, includes a number of desiderata which it is not always easy to comply with.

So far as complete suppression of dust is concerned, it has been shown that this dust is only made in patent fuel works in the processes carried on between the point of discharge of the pitch from the wagon and the pug machine. If dust envelops the whole establishment, it is either badly kept or badly organised.

The ideal step would be to make the contents of the wagon pass into the disintegrator in a closed apparatus. This would necessitate suppression of hacking out or digging with picks and conveyance of the broken-up pitch on trolleys to the breaker.

No factory has yet been able to do this, and before it could be done it would be necessary to have a series of new machines; but there is no reason for thinking that the breaking up and mechanical transport of the pitch to the breaker are impossible automatically and in enclosed apparatus. It is a matter for the good-will of the employer, coupled with ingenuity on the part of the engineer.

Damping the pitch to avoid dust is attended with such serious technical difficulties as to cause its rejection; the pitch ought not to be wetted before breaking and mixing with coal dust. No ventilation, however powerful in itself, could remove the dust effectively.

Paradoxical as this may appear, it is easier to ventilate a closed chamber than an open shed: a draught of air produces eddies without much benefit; exhaust ventilation is hardly possible under the ordinary conditions of work. This is not, however, to say that patent fuel factories ought not to be effectively ventilated. It is easier to ventilate an enclosed apparatus than an open shed: a draught of air produces eddies without much benefit; exhaust ventilation is hardly possible under the ordinary conditions of work. This is not, however, to say that patent fuel factories ought not to be effectively ventilated. The ideal, therefore, is to strive for as the best means of suppressing dust is to carry out digging and conveyance of pitch in an enclosed apparatus. While waiting for this, attempt must be made to protect the skin by the use of different isolating substances; vaselines, starch, potato starch, a paste of clay or Fuller's earth, oils, etc. These measures are, unfortunately, precarious, because generally the methods of protection get removed during the work. Their protective action is moreover incomplete, but they are, however, of distinct assistance.

In view of the severity of the eye accidents, the wearing of goggles is important; but most of them only protect the eye from harmful splinters. The dust gets in easily between the glass and the conjunctiva; closely-fitting
goggles, like those worn by automobile chauffeurs, must be used. The use of a helmet provided with glasses would place the head, eyes and neck beyond the risk of dust.

The use of respirators or other things of this kind are of little use owing to the difficulty of breathing which attends their use during work. The clothing of workmen exposed to dust ought to be closed at the neck, wrists, and ankles. Daily use of douche baths is indicated.

In view of the frequency of lesions to the genital region, workmen informed of this ought to wash their hands before micturition.

Workmen who are suffering from the effects ought to be temporarily removed from the dusty atmosphere.

**Hours of work.** — Regarding 8 hours as the maximum, hours should be divided in such a way as to allow time between two shifts for necessary attention to the skin. The influence of the sun’s rays where digging is done in the open air should be avoided by a suitably arranged roof; one factory has used with success a moving roof fixed on rails, which can be taken, as it is required, to that part of the pitch bed where digging is in operation.

Treatment is a matter for the medical man, and must be left to him.

Truth to tell, the necessity for official regulations has already been felt in certain countries. Thus, in 1910 draft regulations were prepared by the British Home Office for the manufacture of patent fuel with pitch, as an injurious occupation, and such measures were asked for as the installation of baths and washing and cloakroom accommodation, provision of protective goggles, and hermetically-closed apparatus for disintegrating, mixing and conveyance of the pitch and coal dust.

The draft regulations were not, however, accepted, and the matter was left to voluntary adoption by the employers of such of them as they cared to introduce. The periodic medical examination, to which the workers were asked to submit voluntarily, has not proved successful. Thus, the number of workers examined at Cardiff fell from 119 in 1919 to 94 in 1920, 39 in 1921, 5 in 1922, 3 in 1923, and 6 in 1924. Results were no better in Swansea, as shown by the fact that, as compared with 158 workmen examined in 1920 (with 10 cases of epithelioma), 9 only presented themselves in 1921 (4 cases), 12 in 1922 (5 cases), 6 in 1923 (1 case), and 7 in 1924 (1 case).

It is true that at first the workers were very loth to avail themselves of the washing accommodation and baths in the factory, even when they were installed, because they complained that the action of the wind or sun on the skin immediately after a bath or wash caused severe pain and persistent irritation; but that is only true if the skin is already affected. It cannot be accurately stated that to rid a healthy skin of an irritating substance is harmful, as the baths are preventive and not curative.

The workmen themselves refused to adopt the prescribed means of cleanliness. The same arguments were adduced in the campaign against ankylostomiasis, when the suggestion of installing douche baths in coal mines was raised. Generally, every industrial measure calls for sacrifices on the part of the employer and for goodwill on the part of the workmen, and any lack of the latter does not constitute an argument against the application of desirable sanitary measures. Effort must be made to get workpeople to acquiesce in the measures of personal hygiene prescribed.

Another objection on the part of the employers is that the casing-in of the elevators involves considerable danger of serious explosion from the fine dust. But this danger must be appreciated at its proper value. A mixture of air and dust can be explosive, but in the present instance this eventuality is not based on facts derived from observation but on a priori grounds.

**Legislation**

Employment of women and young persons is limited to the same extent as in the case of tar. The employment of women and young persons under eighteen years of age is prohibited in the Netherlands in factories where patent fuel is made with pitch in closed workrooms. Compulsory notification of epitheliomatous ulceration due to pitch is required in Great Britain, France and the Netherlands for the following symptoms affecting patent fuel workers: skin affections (eczema and dermatitis), epithelioma and malignant tumours; pulmonary affections; conjunctivitis; inflammation of the tendon sheaths and sub-cutaneous cellulitis, ulceration of the cornea, and conjunctiva.

**Bibliography**

Plaster

Plaster is prepared from plaster stone or gypsum, a hydrated calcium sulphate (SO₄Ca₂(H₂O)₆), which abounds in nature.

Where present in the form of rhomboedral crystals it goes under the name of selenite; when in compact masses with dicalcium or gypsum, a hydrated calcium sulphate of Prof. M. Herman.

Technical Data

Gypsum brought from the quarry is subjected for from twelve to twenty-four hours to the gradual action of heat in kilns, which are of three predominating types: (a) open-air kilns, (b) continuous kilns, and (c) metallic revolving kilns.

(a) The open-air kiln heated by wood or charcoal resembles a bread oven. Small arches are constructed at the base of the kiln with the largest pieces of gypsum, and smaller pieces and dust are heaped on top of these. Calcination is very slow; the product obtained contains over-baked plaster incompletely dehydrated gypsum and plaster baked to the required extent. This mixture provides, however, very good plaster. This kiln is of course not continuous.

(b) The continuous kiln is loaded from the top from time to time. The baked plaster is withdrawn at the base of the furnace. There are various types of kilns, but that most commonly used is bottle-shaped, the internal cavity constituting the hearth. The plaster circulates in the annular space between the double walls. The fuel is therefore completely separated from the plaster, which fact enables a very pure product to be obtained. The steam coming from the gypsum is liberated at the top of the kiln and the gases from the hearth are directed outside by tubular piping which passes through the double walls. Plaster stone, after crushing, is fed into the kiln by mechanical apparatus. The withdrawal is generally effected by shovelling. Certain types of these kilns are gas-heated.

(c) The revolving metallic kiln is heated by means of currents of hot air. Interior partitions arranged as baffle plates assure adequate stirring and mixing.

Withdrawal from the kiln is generally effected by hand or by shovelling subsequent to breaking, with a pick. For picking up the stones which are still hot, the workers are in the habit of wrapping rags around their hands to avoid burns.

At a first sorting, defective parts (not sufficiently baked or overbaked) are rejected. The others are sent to grinding which is effected in various ways according to the ultimate destination of the plaster—in ball mills or revolving mills (grind stones turning in a trough). The material is withdrawn by shovelling.

Bolting is only effected in the case of plaster of better quality intended for
The charging here is generally done by shovelling, but there exist certain entirely closed systems in which charging is also automatic and is effected by means of an endless screw or by a chain pump.

Plaster is finally stored. Automatic loading is gradually replacing hand work with a shovel, but more usually bagging takes place by means of more or less perfected apparatus analogous to that used for cement.

The industry comprises also preparation of artificial calcium sulphate by precipitating a soluble calcium salt (solution of calcium chloride) by sulphuric acid. It may also be obtained as a by-product in various branches of the chemical industry.

**Use**

The greater part of the plaster produced is used in construction. It is also used in sculpture, for moulding, in the manufacture of various objects (lighting and electrical apparatus, ornaments, etc.), which are plunged into stearine or paraffin, dissolved in ether or petrol, and colouring substances (gum, gamboge, dragon's blood) used to imitate sea foam. When the plaster has been mixed in a solution of glue and a small quantity of sulphate of zinc stucco is obtained, which is less absorbent than plaster and which takes on a beautiful polish and is used in the manufacture of mouldings and ornaments. Amongst other mixtures should be mentioned Paros cement, English cement, etc.

Plaster is likewise used as a raw material in the manufacture of sulphuric acid (see that article), as a loading material in paper pulp, in agriculture for manure and in the wine industry for the purpose of clarification. It is also used in pharmaceutical and surgical work.

**Sources of Risk**

Sources of risk consist for the most part in the escape of gases from the kilns (carbon dioxide, carbon monoxide, sulphur dioxide) and in the presence of dust from the plaster.

The gases in question are only of relative importance, for the kilns are situated in sheds open to all winds and once they have been lit the presence of workers on the upper platform of the kiln is no longer necessary. During emptying of the kilns, however, if the fire is not completely extinguished and the kiln cool the workers may be exposed to emanations of gas which are, nevertheless, rapidly dispersed by energetic ventilation of the sheds. From the health point of view the bottle-shaped kilns appear to be superior to open-air kilns, for their gases contain little carbon dioxide and no carbon monoxide or sulphurous fumes (Hébert, Mauté and Heim de Balsac). They ought, nevertheless, like the others, to be placed in open sheds.

Plaster dust, on the other hand, represents a much greater danger. According to Hébert, Mauté and Heim de Balsac, the most dangerous operations are the withdrawal from the furnaces of the fired plaster (breaking away of masses of plaster), the loading of barrows and the emptying of these, besides the troughs of crushing machines and the loading by shovelling of these troughs. It is the type of mill used in France and known as "Marie Salopes" which raises the greatest amount of dust. Grinding, charging of bolting machines, bagging, bagging and loading of wagons, are likewise dusty operations.

In course of the enquiry in question, the average content of the atmosphere in plaster dust varied from 0.075 grm. (discharging) to 0.400 (charging of the grinding mills) and 0.800 (storing) per cub. metre of air. According to this enquiry the quantity of dust inhaled daily by the workers engaged on the various processes of manufacture might theoretically be estimated at 0.114 grm. (emptying the furnace and loading the barrels), 0.581 grm. (bagging by means of hoppers), 0.710 grm. for emptying of the barrows into the grinding mills and up to 1.032 grm. during emptying of the barrels into the mills (Marie-Salopes).

**Statistics**

Statistics dealing with morbidity of plaster workers are relatively few and not of recent date. These workers constitute a floating population which may be entirely changed at any moment.

The enquiry conducted by Hébert, Mauté and Heim de Balsac (1909), covering 158 workers in plaster factories near Paris, did not succeed in establishing in an objective manner the effect on the mucous membrane of the nasal mucous membrane of the workers engaged in bagging. The morbidity in question is therefore of slight importance. Amongst 158 workers examined, varying from fifteen to fifty years of age, those who conducted the enquiry found dryness of the skin (158 cases), tuberculosis (6), dryness of the nasal mucous membrane with diminution of the olfactory sense (2), chronic catarrhal laryngitis (2), epistaxis (1), chronic catarrhal pharyngitis (1).
Further, amongst workers engaged in bagging there were 100 per cent. of cases of conjunctivitis, chronic rhinitis and redness of the pharynx.

**Pathology**

Numerous experts (Ramazzini, Fourcroy, Layet) consider that plaster dust represents a source of clearly defined occupational affections. Yet medical experts of the present time not only affirm it to be harmless (Hirth, Roth, Sommerfeld), but some even attribute to these dusts certain curative properties in the case of infectious pulmonary lesions, notably tuberculosis (Sommerfeld, Hacker).

According to Heim de Balsac, plaster dust does not cause occupational disease except in the case of workers engaged in bagging, all of whom, after a certain length of employment, suffer from chronic conjunctivitis.

The harm caused by plaster dust is connected especially with its strong tendency to absorb water, which causes it to become attached to the mucous membrane and form agglomerations in clogging thereof. It is for this reason that the descent of these dusts into the deeper respiratory passages encounters obstacles. Yet swallowing with the saliva and with food is on the other hand extremely easy.

Plaster of Paris, which is not in a state of fine subdivision, would appear to have a greater effect on the mucous membrane of the respiratory passages than the finely sifted plaster in the form of impalpable grains.

It has also been noted that constant contact with grains of plaster provokes inflammatory reaction of a mechanical origin, which is more or less severe, on the mucous membrane, on which it accumulates in considerable quantities.

It has nevertheless been established by experimental research that respiration of air charged with plaster dust is not injurious. The considerable solubility of plaster in water would lead to the supposition that its crystals have a tendency to dissolve when in contact with the mucous membrane, the soluble sulphate thus becoming absorbed and eliminated without accumulation in the system.

This does not hold good of dusts from polishing of stucco, which have been found encrusted in the mesenteric glands of workers handling stucco (the "adeno-gypsosis" of Robin), dusts which are insoluble by reason of the presence of particles of alumina and of insoluble mineral colours which the stucco contains.

These facts explain why the pathology of plaster workers is not very specific. It is reported that the skin of the hands is generally very dry, wrinkled and covered with cracks in the epidermis (Heim de Balsac) and at times ulcerated (Patisier). There is sometimes noted erythematous dermatitis (Roy) or eczematous dermatitis (Layet) amongst workers engaged in slaking plaster. Heim de Balsac reports a case of ichthyosis with desquamation localised on the external side of the arm and the upper part of the body.

There have also been reported cases of coryza and chronic rhinitis, dryness of the nose with diminution of the olfactory sense and the sense of taste and at times epitaxis, redness and dryness of the nasal mucous membrane and bleeding on the slightest contact (workers engaged in bagging). As regards the eyes, the most frequent injuries are chronic conjunctivitis, the intensity of which is said to be proportional to the length of employment (Heim de Balsac), marginal blepharitis, opacities on the cornea, which Heim de Balsac, however, did not observe.

Of less importance are respiratory lesions: pharyngitis (Layet) with redness and at times dryness of the throat, difficulty in swallowing, pharyngeal expectoration, benign chronic catarrhal forms of laryngitis with roughness and hoarseness of the voice, rarely of a granular type (Layet).

The pulmonary lesions indicated by older authorities would appear to have been attributed to plaster as a result of faulty interpretation. At the present time it is considered that plaster dusts do not cause pulmonary disease because they do not reach as far as the pulmonary parenchyma.

There have also been reported "stucco boils", from which the plaster workers who prepare wall and ceiling decorations suffer not only on the face and arms but often over the whole body. The plaster or stucco used is mixed with substances of vegetable origin, chiefly starch dextrine, etc., or other products such as asphalt, pitch, tar, in order to render the product applied impermeable, and these stick to the skin during perspiration and in the long run set up irritation and, as a result of obstruction of the orifices of the sebaceous glands, a type of folliculitis.

**Hygiene**

Measures dealing with the situation of plaster factories, as well as their construction, ventilation and installa-
tion, the working of kilns, etc., are similar to those already described in the article "Lime".

The most important measures relate to dusts raised during the operations of grinding, bolting, bagging, etc., which ought to be conducted under systems of localised ventilation or in a closed apparatus with automatic feeding devices. The transport of plaster between these various operations should also be effected automatically in a closed apparatus (see article "Dusts, Fumes and Smoke").

Precautions should be taken against noise, and likewise measures connected with the personal hygiene of the workers.

LEGISLATION

In Argentina women are excluded from operations exposing them to plaster dust. In Belgium young persons under sixteen are excluded from plaster-grinding mills where the dust is not evacuated by mechanical means. In Canada (Quebec) boys under sixteen are excluded from grinding and from crushing mills. In France young persons under eighteen are excluded from grinding mills and from kilns. In Italy boys under fifteen are excluded when dust is given off freely. In Spain boys under sixteen are excluded, and in Spain and Italy women under twenty-one years are excluded where diffusion of dusts in the workroom is not adequately prevented, etc.

There is no special legislation dealing with plaster factories. An Order of the Préfect de Police de Paris of 1 August 1930 prohibits manipulation of plaster in bulk and bagging of plaster in Paris, in the Department of the Seine, and on the municipal canals.

Measures against dust, which naturally come into play in this connection, are those issued under national codes of industrial hygiene.

BIBLIOGRAPHY

PLASTIC EARTHS

French: Terres plastiques. — German: Plastische or Feuerfeste Tonerde. — Italian: Terre plastiche or refrattarie. — Spanish: Tierras plasticas.

Amongst types of underground work, not the least interesting from the technical point of view, or from that of its effect on the worker's system, is the getting of plastic earths.

Whilst inhalation of schist or coal dust is apt to set up bronchitis, sometimes leading to pulmonary tuberculosis or even pulmonary disease in the absence of tuberculosis, amongst slate and coal miners, those engaged in plastic earth industry (as far as mining is concerned) may not assume in Belgium the same importance as coal-mining, it nevertheless gives occupation to an average of 954 workers in underground mines (365 at surface work) and 188 in open quarries.

Plastic earth is necessary in all refractory industries since it serves for the manufacture of crucibles (plate glass works, crystal, and zinc manufacture); smelting of ores or other products, sagger (firing of tiles in the pottery and china industries); making of special bricks (construction of tanks in the glass industry and lining of cupola furnaces in steel foundries), etc. The composition of plastic earths, which belong to the group of clays is as follows: silica-alumina — with traces of ferric oxide, calcium oxide, magnesium oxide and organic matter (of the lignite variety).

According to their content in alumina (which is of special importance) they are classified as lean earths (from about 13 to 18 per cent.), semi-lean earths (20 to 24 per cent.), and fat earths (up to 28 and 34 per cent.). Each of these divisions may be subdivided in its turn into first, second and third grade, according to colour, homogeneity and purity. The first grade is characterised by perfect colour and homogeneity, and is at the same time very pure (these constitute highly refractory earths). The second grade is characterised by its irregular colour (presence of marbling) and less homogeneity and purity. The third grade is also characterised by irregularity as to colour (yellow striation, traces of iron), and a much less homogeneous texture.
These earths are capable of withstanding very high temperatures (up to 1,690° - 1,730° C.), i.e. above the melting point of materials which may be contained in crucibles, tanks or furnace linings made out of these earths.

In the triangle formed by the Andenne-Namur-Ciney district where the principal mines in Belgium lie, there may be noticed small thatched huts scattered throughout the fields in groups of 2-3-10, each of which is situated on a pit of slight depth (about 20-50 metres) giving access to the galleries leading to the heading or working face.

Each pit generally gives employment to five workers, two at the surface and three below ground — two getters and one barrowman. A winch worked by the men at the surface, but sometimes driven by a horse, is used for lowering and raising workers, as well as of the blocks of earth obtained.

The air of the pits becomes vitiated by respiration, perspiration and excreta, by gas and smoke from carbide lamps when these are not burning well, by emanations from the wooden pit props, and gas from pockets made in former workings (inflammable gases which explain firedamp explosions often occurring in these mines). This air is renewed very inadequately and under great difficulty, with the result that during heavy or stormy weather, the workers may be obliged to leave the working face and return to the outer air.

Ventilation is effected by means of communicating shafts and zinc piping running from the bottom of the pit towards the top of the thatched roof of the hut and ending in a revolving chimney cowl.

In order to stimulate this rudimentary ventilation, a worker at the surface sets going from time to time a small hand ventilator, or sets on fire a bundle of straw at the entrance to the shaft.

It might be expected that in such an atmosphere the workers in these mines would suffer from very pronounced anaemia with a palor and breathlessness. Without a doubt their general appearance, their sagging gait and more or less leaden countenance certainly denote the harmful effects of hard work executed in a vitiated atmosphere and often in a bad posture. These workers usually look older than their years.

Fortunately, however, living in rustic and wooded surroundings, the life led out of working hours neutralises to a great extent the harm wrought by the unhealthy working conditions.

Standing, kneeling, crouching or lying on one side or the other, the getter,
On the right, cutting round the block with the scraper (instead of the tool).

On the left, inserting the tool into the earth to cut round the block to be detached (the worker is kneeling in order to enable a photograph of the tool to be made); on the right, the worker is cutting round the block and detaching it by means of the hoe.
Fig. 82. — Cutting the block by means of a steel wire.

Fig. 83. — Placing it on the truck.
armed with his "tool", that is to say, a sort of iron knife with a broad double-edged blade or a kind of elongated trowel with a double handle, drives it by means of violent and repeated blows into the sticky earth which is difficult to penetrate. In this way he manages to make an incision round a block in the mass which he then proceeds to detach and loosen with his hoe.

In making these efforts he breathes deeply, and then with a sharp outward breath he drives the tool into the earth. The effort is of necessity violent on account of the cohesive and gluey nature of the earth, and they are also subject to frequent repetition. In incision the worker has to give six blows with the tool, and driving it home once to the required depth necessitates six successive blows or, in all, thirty-six blows or efforts for each block cut out.

To complete the operation the worker uses his hoe in conjunction with his tool. This hoe requires to be driven in eight or nine times per block, and each of these successive operations requires five or six successive blows at the same spot or, in other words, forty efforts to detach each block. It is true that these efforts with the hoe are made rather at the expense of the arms, but it is nevertheless true that the respiratory system is called upon to furnish a perceptible part of the effort,

In making these efforts he breathes deeply, and then with a sharp outward breath he drives the tool into the earth. The effort is of necessity violent on account of the cohesive and gluey nature of the earth, and they are also subject to frequent repetition. In incision the worker has to give six blows with the tool, and driving it home once to the required depth necessitates six successive blows or, in all, thirty-six blows or efforts for each block cut out.

To complete the operation the worker uses his hoe in conjunction with his tool. This hoe requires to be driven in eight or nine times per block, and each of these successive operations requires five or six successive blows at the same spot or, in other words, forty efforts to detach each block. It is true that these efforts with the hoe are made rather at the expense of the arms, but it is nevertheless true that the respiratory system is called upon to furnish a perceptible part of the effort,

It is true that these efforts with the hoe are made rather at the expense of the arms, but it is nevertheless true that the respiratory system is called upon to furnish a perceptible part of the effort,
to a series of efforts of deep inspiration and expiration, the pathogenesis of which has already been described in detail in the article "Effort".

An enquiry made by Dessent, of Namur, amongst these workers led him to remark, after examining a certain number, on the similarity of the subjective, objective and clinical symptoms affecting them.

Out of 28 workers examined, 21 complained of respiratory oppression, and in all or almost all cases Dessent found that the chest was to a certain degree barrel-shaped with increased distension and sonority on percussion and sounding, and expiration longer than the normal. These signs were met with, of course, in varying degrees according to the individual predisposition of the workers, the number of years they had spent in the pits in their ages. The conclusion is that the workers in question are prematurely aged.

The 7 workers who were free from respiratory oppression showed no other symptom of pulmonary emphysema; these exceptions may be explained by the fact that 4 of them were still young — under the age of forty though they had been employed for twenty years in the pits — whilst three others aged between fifty and fifty-nine had only worked for periods of one, six and ten years and had previously followed the occupation of quarryman or stone-cutter.

Amongst the 21 workers the difference between deep inspiration and expiration ranged from 7 to 10 cm., and those in which the difference attained 10 cm. were precisely the youngest (forty-one, forty-five, forty-six and forty-seven years of age). In the other cases the difference reached 13 cm.

The majority of the workers complained also of rheumatic pains varying as to site and intensity; these may be attributed to time spent in a cold, damp atmosphere. None of these workers was found by Dessent to suffer from eye trouble or nystagmus.

There is another method of getting the product (fig. 80), in which the worker, instead of a tool or a knife, uses a metal instrument (known as a scraper) to detach the block.

He draws two vertical lines, the depth of which he increases, and joins these parallel lines at a distance of about 50 or 60 cm. by horizontal lines of a given height, and completes the work by detaching the blocks by means of his hoe and causing them to yield. In this method the worker is no longer obliged to work "on his stomach". The arms and especially the muscles of the dorsal lumbar region are brought into play. In this way less strain is put upon the chest than in the first method described above (fig. 79).

According to Dessent, the plastic earth getters do work which is at least as trying as that of coal miners. They are prematurely aged and their working capacity from the age of fifty-five onwards is considerably reduced. Without doubt they do not all or almost all die towards the age of fifty or fifty-two like slate workers; they do not suffer like coal workers from pulmonary anthracosis likely to lead to phthisis; yet all of them suffer from chest affections, and the pulmonary emphysema which attacks them may lead to aggravation of the slightest affection of the respiratory passages, causing simultaneously cardiac insufficiency, especially of the right heart. Workers engaged in getting plastic earths should therefore be placed in the same category as regards sickness and old-age insurance as slate workers and coal miners.

Another very important question to consider is the improvement of the present conditions under which these workers are obliged to work.

Modern technique, with a little humanity could speedily give excellent results.

The ventilation should be improved to secure evacuation of vitiated air and the provision of pure and periodically renewed air for the worker in the pit. An improvement of the kind would rapidly counteract the poisoning and anaemia generally suffered by these workers. The first method of getting should also be abolished and replaced by the second, or at least the second should be extended by education of the workers and as industrial requirements allow. It is also essential that electric lamps which are less unhealthy than carbide lamps should be introduced.

Platinum

French: Platiné. — German: Platin. —
Italian and Spanish: Plátino.

Platinum (symbol Pt) and likewise the other metals of the same group (ruthenium, rhodium, palladium, osmium, iridium) are found only in their natural state mixed with each other and often with gold or iron. These
metals offer some difficulty as regards complete isolation since their salts possess many similar properties.

Platinum is at present almost exclusively extracted from the sandy deposits of the Ural Mountains (U.S.S.R.). This sand, subsequent to levigation, leaves a grey mass containing 75 to 85 per cent. of platinum and a small quantity of 5 or 6 per cent. of other metals of the platinum group and sometimes of gold, when separated by amalgamation. Platinum is also encountered under the form of arsenide (sperrylite) in copper or nickel ores (Canada).

Platinum in the pure state has a silvery aspect, but when finely subdivided it has a black colour ("platinum black"). It commences to melt at 1,755° C. It is malleable, very ductile, and resistant to air even when hot. In the cold state it resists effectively the action of all chemical agents but less so than platinum is on the other hand attacked when hot by several chemical products: alkaline hydrates, phosphorus, cyanides, sulphides, halogens, etc.

In Russia, the sand after levigation and sifting (with a view to the removal of the heavy and precious parts) is subjected to treatment by the wet method (Wollaston), which consists in treating the mass with aqua regia. The residue contains osmium, iridium and a solution of chlorides of platinum, iridium, rhodium and palladium, which with caustic soda form when hot IrCl₃ and soda hypoehlorite.

Ammonium chloride is added and chloroplatinate of ammonium is separated which, when hot, deposits spongy platinum. The spongy platinum is transformed into compact platinum by melting in a refractory crucible placed in a simple furnace heated by an oxy-hydrogen flame. It is then cast in bars which are subsequently hammered and drawn out into sheets or very fine wire.

When gold is present, the mass, after sifting, is submitted to an amalgamation process for separating the metal. Purification by the dry method (Deville and Debray) consists in heating the ore with lead and galena. The lead takes up the platinum, which may be liberated later by cupellation.

The platinum obtained in general contains iridium which is left in the case of commercial platinum. Chemically pure platinum is rarely prepared.

It is used in the manufacture of laboratory apparatus and articles (crucibles, wires, fine sheets, etc.); in the jewellery industry, in dental processes, in the preparation of "pallo-

rium", an alloy of gold, and of metals of the platinum group, with even greater resistance than the latter and costing much less; in the chemical industry (under the form of "platinum asbeslotts") for catalytic processes; in electro-technical work (for contacts); for the manufacture of platinum salts (chloroplatinate of potassium, used in photography; platino-cyanide of barium, for the manufacture of fluorescent screens; radiography), etc.

Platinum is not toxic. Though largely utilised in industry, it has never given rise to injuries of an occupational origin.

In the course of purification by the dry method, the workers are exposed to the action of lead fumes (lead, galena). In treatment by the wet method, the aqua regia liberates irritant acid fumes, whilst in the course of the operation there may also occur liberation of osmium fumes.

Medical literature contains particulars of the case of a worker who on opening a bottle containing platinum-oxide of ammonia and nitrooxide of platinum developed erysipelatoid patches on his face with a sensation of burning and itch, and as a result of contact with small quantities of the product, similar lesions on the fingers (Lewin).

Oxide of platinum has also caused eczema of the hands, the forearms and lesions on the nails.

In a platinum refinery, platinum in a spongy state melted in a refractory crucible liberated white fumes, whilst the flame rising from the crucible (heated with an oxy-hydrogen flame) turned greenish. The workers and the chemist who were supervising the operation paid no attention to this phenomenon, being of the opinion that the cloud which arose was due to the ammonia salt contained in the crucible and the greenish colour to impurities in the copper. Some hours later however the workers complained of headaches and general discomfort. The chemist in his turn two hours later suddenly experienced discomfort: weakness, attack of vertigo, remarkable acceleration of respiration and of the pulse. His breath smelt very strongly of garlic and this odour persisted for ten weeks. The platinum had been prepared from the residues of gold-bearing ore from Russia and Siberia containing tellurium (see article "Tellurium").

From the point of view of hygiene, work on platinum demands the same precautions as those issued for the extraction, casting and refining of metals: cement flooring of the work-
PNEUMATIC TOOLS

rooms, ventilation of the workrooms, precautions relative to the catching and evaporation of acid and toxic fumes; treatment of the ore and residues under large hoods with adequate exhaust ventilation; measures of prevention against the risk from lead poisoning are also necessary. Waste water requires to be neutralised before being allowed to enter drains or to run outside the factory.

Pneumatic Tools
(Compressed Air Hammers, etc.)

French: Marteaux pneumatiques; Outils à air comprimé. — German: Lufterduckhammer; Pressluftwerkzeuge. — Italian: Martelli pneumatici; Utensili ad aria compressa. — Spanish: Herramientas neumáticas.

TECHNICAL DATA

The advantages to be gained from the use of compressed air as motive power suggested its employment for a variety of tools and machinery ordinarily worked by hand. A remarkable increase in output and power is thereby attained. These tools are thus analogous to machine tools, but have the advantage over real machines of simplicity in construction, lightness, and size. They can thus be easily carried and manipulated under conditions and in surroundings where machines could not be used.

They are known under the generic name of "pneumatic hammers" because compressed air was first applied to hammers: but afterwards it was applied to other implements involving some kind of percussion stroke, such as rams and chisels, as well as to tools having a rotary motion, as for example for drilling and polishing, and finally to tools of mixed function, both hammering and rotary, such as drills.

The field of application for pneumatic tools so far has been more or less limited to work on rocks, stone, earth, minerals (coal, lignite, sulphur, precious stones), wood, and metals, but they can be used on other materials.

The principal operations carried out are the following:

(a) with hammers: hammering and ramming metals, splitting, dressing or shaping blocks of stone, caulking and fixing metal sheets and parquet flooring (fig. 85);

(b) with rams: breaking of ground, sand (in foundries), cement (fashioning or moulding pipes, etc.), or concrete road making, reinforced concrete, fashioning stones or artificial blocks (figs. 86 and 87);

(c) with chisels: reducing the size of stones, cutting, dressing, roughing, chipping, grooving, lining, engraving, chasing, scaling (ships, boilers, gratings, etc.), scraping, scouring and freeing from adherent sand, steel pieces, caulking, etc. (figs. 88 to 92);

(d) with portable drills: perforating wood, stones or metals (fig. 93);
The possibility of executing the different jobs in question, or others which may in future be effected by pneumatic tools, depends partly on the shape of the extremity of the tool or of the part intended for the work (drill, wheel, etc.) and partly on the kind of movement (knocking, rotary, or mixed). All pneumatic tools, however, have one part in common, the valve box, which has the same object as that used in machines worked by steam.

This box contains a piston, on the ends of which compressed air alternately exerts pressure, causing a to-and-fro movement with a speed varying from 700 to 1,500 blows and more per minute.

By means of special arrangements, the alternating linear movement of the
piston can be converted into a rotary movement of the collar, which carries the drill or wheel, and consequently a to-and-fro, as well as a rotary, movement can be obtained immediately.

A flexible pipe connects the valve box with a reservoir of air, maintained under a pressure of 3 to 5 atmospheres by means of a compressor or vacuum pump.

The air as it passes through the valve box sets up a loud and disagreeable noise, comparable to that of an internal-combustion engine. Its entrance into the box is regulated or suspended by the workman by means of a valve, worked by a button or lever.

The rapid change of direction the air undergoes inside the box and the oscillations of the piston set up a rapid vibration of the tool, more or less powerful, which is transmitted to the body of the workman.
The shape, volume, and weight of compressed air tools vary much, according to the use to which they are put; they can be as heavy as 25 kg. or more. So far as the shape is concerned, the small hammers used for fine work on marble and other stones that are not too hard are cylindrical; the worker holds them with his fingers like a pen when writing in the position designated by medical men as "obstetric" (fig. 89). The hammers that are a little larger are grasped in the fist; other heavier tools have a handle, reminding one of the butt end of a revolver, when the
instruments can only be held by one hand (fig. 92); or if the workman must hold them with his two hands (fig. 93), they may take various forms — crank, horizontal bar, etc.

When light hammers are in question, the right hand supports and pushes the tool forward, while the left hand guides the drill (hammer or chisel) which is simply fixed to the part carrying the valve box. Heavier hammers have the drill screwed tightly so that it forms part and parcel of the tool. The weight of the tool falls more or less on the workman, on account of the position he has to assume to carry out his work. It amounts to practically nothing when the tool is directed from above downwards, and reaches its maximum in work from below upwards. Under these conditions, the tool often cannot be held by the hands alone for long at a time. It is for this reason that the workman applies the tool to the arm bend or to the thigh (fig. 96) or the shoulder, with his legs wide apart to increase his power of resistance and make a bridge. In many other cases the tool is suspended by means of cords or metal bars, as e.g., in riveting nails and scaling the bottoms of ships, ramming sand or concrete (fig. 91) or for certain operations in riveting (fig. 98).

In other cases, again, the tool is sometimes mounted on supports, or attached to metal columns firmly fixed in the ground or walls of the place (fig. 99). This position can often be adopted in work carried out in narrow spaces, such as the roadways in mines, holds of ships, etc., and especially in work entailing piercing. When this method of fixation is used, the pneumatic tool is converted into a real machine tool, acting without recourse to the muscular force of the workman. The latter has only to place the tool in position and regulate its action. In all other cases, use of the tool demands considerable expenditure of muscular energy, never less — and often much greater — than that necessary to execute the same kind of work with ordinary tools (see later). But production is many times greater, because to the muscular force is added another more powerful and regular force, continuous and unremitting, viz. that from compressed air.

Study of the Movements

Careful analysis of the method by which pneumatic tools work shows that the effect on the neuro-muscular system differs from that produced in the case of ordinary tools. Of the three principal elements to be taken into consideration — that is, the importance, the duration, and the rhythm of the effort — the importance of the effort only can be equal to, or sometimes even less than, that demanded from ordinary tools, whilst the duration of the muscular contractions, and especially the rhythm, are always increased in a remarkable way.

To show this it is sufficient to analyse briefly the movements necessary to execute different jobs with a chisel, which constitute the most typical and commonest example of work with pneumatic tools in their different shapes for chipping, cutting, roughing, chopping, grooving, lining, and caulking.

When a workman strikes the head of a chisel or drill with his hammer to chip or penetrate stone or metal, the blows follow one another at a varying rate. Generally the interval is greater the stronger the blow required; but the workman can always regulate the rhythm as he wishes. All the muscles of the arm rest simultaneously in the intervals between one blow and the next, and antagonistic groups of muscles rest alternately, the one when the hammer is raised and the other when it strikes its blow. Even contraction undergoes differing degrees and phases according to the different positions of the hammer. This is why in periods of activity alternating with more or less long periods of rest signs of fatigue are consequently absent or retarded.

In all mechanical work done by the muscles it is of great importance if fatigue is to be avoided that the rest pauses between the requisite contractions should exceed in length the duration of such contractions. In work with a pneumatic hammer, however, this rule is not observed; in work with an ordinary hammer it rarely is.

But when the workman uses a pneumatic tool, always supposing that the

![Fig. 99. — Compressed air boring tool supported by a vertical column.](image-url)
weight of the instrument and the resistance of the material worked are equal, the progress of the chisel over the surface or into the stone follows on blows so near one another that the muscles of the arm may be kept in a state of permanent contraction, either to counteract the jet of compressed air so as to obtain perfect and constant adhesion of the tool to the object, or to get up the necessary force to secure the complementary pressure indispensable to make the tool advance over the object in question.

In these circumstances, the importance of the effort is hardly ever higher than that required in the first case, but its nature is very different because the alternating movements in hammering, which bring into play different groups of muscles in the two acts of the raising and falling of the hammer, are replaced by permanent or static contraction of all the extensor and flexor muscles of the arm. The two forms of work, therefore, are almost as different in their effect on the muscles of the lower limbs as an upright position and a walking position. Further, the effort of the hand and arm muscles demanded by the permanent contraction is increased in a remarkable way by the continuous tremor, the result of the vibration of the tool. These two factors notably aggravate the causes of fatigue.

**PATHOLOGY**

Work with pneumatic tools is attended by certain morbid phenomena, which cannot, however, be considered as due to specific causes. On the contrary, they are the result of ordinary causes aggravated by particular conditions under which the work is done. When first using these tools, the workmen complained very often of the many different ways in which their health was affected, and these they attributed to the new type of tool. Gradually all these troubles became so rare, that it is difficult to admit to-day that there is any special pathology resulting from pneumatic tools. Practically the same phenomenon has taken place in regard to them as took place when pedal machines (sewing machines, pressing machines, etc.) were introduced — that is, the annoyance and injury reported when the workers first handled them lessened remarkably the more they became accustomed to them. The effect, however, may be most marked after the worker has used pneumatic tools for some time (Middleton).

The most outstanding sign is a vasomotor neurosis or numbness of the fingers, designated as "dead fingers" and reported by Lockera, 1911, at Rome, and since then by F. E. Barnes, at St. Louis (Mo.), among stonedressers — exclusively among those who hold the tool with their fingers stretched out. This neurosis is characterised by pallor, sensation of cold, tingling, and loss of sensation and movement of one or more fingers — phenomena always aggravated by cold. Blanching, however, may occur on cold mornings when the hands are immersed in cold water and before starting work. The tingling and loss of sensation cease generally after a short rest; the pallor is said to disappear even while work is going on, and is replaced by a slight hyperaemia, or sometimes by real cyanosis, which is often accompanied with sensation of warmth. In some cases, the loss of sensibility, or the "dead" feeling, lasts several hours, but no case of this symptom remaining permanently is known.

After work has ceased, a slight tremor of the hand is found, even some hours after.

Some workers, especially when commencing the use of pneumatic tools, complain of some diminution of muscular strength, of the arm feeling constantly asleep, of various digestive troubles, insomnia, headache, disgustitude, change of mood, etc.

These latter phenomena are evidently the same as those occurring in the first stages of fatigue of any kind. There is nothing characteristic about them, and they cannot be considered as symptoms indicative of anatomical or functional lesions of the neuro-muscular system. Even the phenomenon of "white fingers" must be attributed to local effect on the circulation, produced by muscular contraction and cold. It is the cause not only of the pallor and chilling of the skin, but also of the diminution in sensation and movement.

In November 1916, J. L. Miller, of Chicago, described in a stonedresser a clinical picture very like Raynaud's disease, which was attributed to the use of pneumatic tools. At the wish of the Stone Workers' Associations, the Labour Statistical Office organised an enquiry which was entrusted to Dr. Hamilton. She studied the question as affecting stonedressers in several centres, and was able to show that the troubles described by the workmen, which consisted mainly in affections of the circulation in the hand, particularly of the fingers ("dead fingers"), were very frequent. The concomitant action of cold
must also be admitted, because the troubles were most marked during cold weather. The fingers said to be most affected are the index finger and thumb, but other observers (e.g., Middleton) have found the ulnar digits of the left hand to be also affected. Continuous work with pneumatic tools provokes and aggravates the injury, which is not produced when work is done with small tools or when use is not made of pneumatic tools. The conclusions of Hamilton were that the lesion was due to three factors — long continued muscular contraction of the fingers holding the tool, vibration transmitted by it, and the action of cold.

In the report of the Chief Medical Inspector of Factories (England) for 1925, Drs. Bridge and Middleton give particulars of an examination of four masons, who used pneumatic hammers. They concluded from the enquiry that, under the present conditions of work as carried on in certain districts, the factors leading to the injuries complained of were as follows: pressure exerted by the instrument which hindered the circulation in the fingers (especially of the left hand), the action of cold due at least partly to the compressed air escaping from the tool and exercising more marked action by reason of the fact that the rate of the circulation was reduced, and in part to lack of heating in the workshops.

Certainly, such conditions might give rise to a measure of general discomfort, but no obvious data are so far available in regard to permanent affections acting on the system in general or on the nervous system of workers using the tools.

Thor Rothstein has studied 8 analogous cases, in which there was marked vasomotor disturbance localised in the hands and diminution in sensibility. N. A. Cary (Camp Douglas, Ill.), has described 8 cases of vasomotor troubles of the fingers among soldiers who had worked for from four to fourteen years with pneumatic tools as stonedressers. J. P. Leake, of the Public Health Service of the United States, undertook an enquiry among stonedressers in Indiana as to the injury set up by these tools. He found that the hands of the workers using them presented a hypertonicity of the vessels, which itself constitutes an exaggerated reaction against low temperature. This fact is said not to be serious, but is certainly a cause of lessened occupational activity.

Similar researches were made at the same time by Edsall. Medical men, on behalf of employers' associations, have studied the question and described or discussed certain cases. From a report by A. P. Herring, of Baltimore, the two tables on pages 677 and 678 are taken, which show that a differential diagnosis can be made between "white fingers", and neuritis, neurosis, Raynaud's disease, acroparesthesia, etc.

The very detailed study recently published (1926) by the Institute for Occupational Diseases in Leningrad, in regard to occupational diseases reported as occurring amongst the Russian boiler-makers using compressed air tools, is reviewed in the article "Copper Boiler Making".

The vibration set up by these tools would not appear to have any particular significance, nor can it be held to be an element capable of setting up specific troubles of sensation or motion. It is in fact known that vibration does not produce them in many other conditions under which it occurs, such as, e.g., railway travelling, driving a carriage, or work on or near machinery subject to marked vibration.

It must be considered, on the other hand, exclusively as a factor which may hasten or aggravate the manifestation of fatigue.

Although there is a great similarity in the pathology of "dead fingers" and cramp (forms of cramp belonging, too, to the vasomotor neuroses, showing themselves generally in the winter and associated very often with local effect on the circulation, sensation of cold, pallor, painful lowered sensation, etc.), no case has yet been described of muscular spasms produced when the necessary associated movements are carried out in holding and keeping in position the pneumatic tools with the fingers tense and contracted. This fact can perhaps be explained by the small number of workmen who hold the tool only with the fingers, either by the discontinuity of the movements (as with pneumatic tools alternates with that with ordinary tools), or because the muscles do not execute any movement of their own but are in a state of tonic contraction during the whole time that work is carried on.

Loriga has also enquired into the frequency and gravity of general effects produced by pneumatic tools, and has found that they depend on the individual worker, that is to say, on the greater or less personal susceptibility to fatigue. Among other troublesome effects, induced secondarily as a result of work with these tools, are:

(a) lesions due to pressure or repeated shock of the tool on the hands and other parts of the body to which the tools are applied as, e.g., callosities, hygromas, tenosy-

Novitis, and subcutaneous cellulitis;

(b) lesions due to forced or vitiated attitudes (kyphosis, scoliosis, deformities, etc.);

(c) pulmonary emphysema and arteriosclerosis of the extremities;

(d) affections produced by the noise on the organ of hearing and the nervous system;

(e) lesions due to the dust, of which the quantity ought certainly to be borne in mind when work takes place in a confined space (mine roadways, for example), because these dusts increase in proportion to the rapidity of the work.

### Hygiene

Prevention of the effects set up by fatigue depends mainly on limitation of hours of work, or alternation of work with pneumatic tools with other work, demanding less continuity of effort, or bringing into play other groups of muscles. Duration of rest pauses should be by so much prolonged as the importance of the elements increasing the intensity and duration of the effort is greater.

Among the elements should be specially mentioned:

1. **The form of the tool and the way in which it is grasped.** — Tools of cylindrical form, which are grasped only with the extended fingers, fatigue the groups of muscles entering into action more than those which can be seized with the full hand and than those requiring a special grip (tools with handle like revolver butt, with a crank, or horizontal bar). These, therefore, are to be preferred whenever possible.

2. **The weight of the tool.** — Effort increases not only with the real weight but also with the position in which the instrument is placed. The position from...

above downward is the most convenient; that from below upwards the most distressing. With tools of weight exceeding 15 to 20 kg., work cannot be continued for more than four to five minutes, when all the weight of the tool has to be supported by the body; rest periods exceeding the duration of the working spell should then be introduced.

(3) **Air pressure** — A high pressure increases the number and violence of the repercussions of the tool, and increases consequently the effort of resistance and propulsion which the arm has to sustain, as well as the vibrations transmitted by the tool to the muscles. Observations by Loriga indicate that the pressure of the air ought not to exceed \( \frac{3}{2} \) atmospheres to render continuous work possible. The vibration produced by high pressure can be lessened in great measure by holding the instrument with the hands covered with large woollen gloves, or inserting between the skin and the tool a suffi-
cient layer of very soft material. This measure helps to counteract formation of callosities, cellulitis, tenosynovitis, etc., which may be set up by the tools.

Heavy tools placed on supports often have a grip which is fixed to the support itself by means of elastic catches with the object of lessening the vibrations. This arrangement does not apply to less heavy tools held by the hand.

(4) The position of the body and the manner of holding the tool. — The degree of fatigue varies markedly according to whether the tool is held with the single hand or with the two together, or is supported by and weighs upon the arms, shoulders, and thighs. The degree of fatigue varies also according to the position of the body; that is why, when it is possible, the tool should be hung by means of cords or fixed by supports in the form of a column, or on wheels, or fixed on the ground or on the walls; that is to say, every means which circumstances can suggest should be used in each particular case.

The position in which the body is held is not in any case so prolonged as to cause fear of injurious consequence or any permanent deformity.

(5) Noise. — This is closely related to pressure of air, but the degree of discomfort varies noticeably according to whether the work is done in the open air or in enclosed spaces, and also according to the size of the latter. There must also be taken into account the kind of material to which the blows are applied (riveting sheet iron). Closing the external meatus of the ear with plugs of cotton wool, indiarubber or wax, etc., prevents not only damage to the hearing apparatus but especially the injurious influence which the noise exercises on the nervous system. All the tools should necessarily be provided with a valve capable of stopping the entrance of air into the valve box which emits the noise when the tool is not at work.

(6) Dust. — In addition to the effects described and as a factor in increasing signs of fatigue, the danger from the dust given off in the course of work should be mentioned, as the quantity so produced is always greater than that given off in hand work, because it is obviously proportional to the speed at which work is done.

The harmfulness of this dust is increased by several factors (work on stone, work in confined spaces) quite independently of its physical or chemical qualities.

These inconveniences can be diminished or avoided by using hollow drills allowing a jet of water under pressure to be directed, at the same time, on to the spot where the drill works; this has two advantages, softening the rock and total suppression of the dust, as this is at once reduced to a state of paste by the water.

This arrangement of a jet of water, however, is only applicable with hammers of considerable weight and volume. In other cases, the raising of dust can be largely avoided by moistening the materials, if this can be done without damaging them. In all other cases, the usual methods of prevention must be adopted, e.g. respirators, goggles, etc.

LEGISLATION

Compensation for diseases of the muscles, bones and joints due to work with compressed air tools (drills, hammers, pneumatic riveting machinery, etc.) is provided in Germany (1929) and Czecho-Slovakia (1932).

Podophyllin

Podophyllin is a resinous substance containing active principles of Podophyllum peltatum Linn. It is prepared by subjecting to alcoholic extraction the powder obtained from the rhizoma of podophyllin. The extract, after being reduced to a third by means of distillation, is poured drop by drop into a large quantity of water containing 1.5 per cent. of hydrochloric acid; the precipitate obtained is washed, dried at a low temperature and pulverised.

Podophyllin is an amorphous powder of a brownish or greenish yellow colour, with a slight 'odour' and a sharp and bitter taste. Insoluble in water, it is soluble in alcohol and slightly so in ether and chloroform. It contains podophyllotoxin, picropodicphyllin, podophyllin, etc., as well as a colouring substance which seems to be identical with quercetin. Podophyllin is a resinous substance identical with quercetin.

It is soluble in alcohol and slightly so in ether and chloroform. It contains podophyllotoxin, picropodicphyllin, podophyllin, etc., as well as a colouring substance which seems to be identical with quercetin.

Podophyllin is used as a medicament.

In contact with the eye, podophyllin gives rise to intense conjunctival hyperaemia, with lachrymation, but without increased mucous secretion. At times there is oedema, red spots on the eyelids which resemble papulae and a burning sensation of the eyes. In general symptoms affecting the cornea and iris are the most prominent features of the clinical picture. In the cornea there occur opacities which are barely perceptible. In other cases, on the contrary, there is a central opalescent whitish infiltration with superficial erosion of the epithelium. The characteristic symptom is constituted by irritis, which supervenes rapidly and violently, attaining its maximum evolution by provoking exudation in the anterior chamber, considerable diminution of sight and intense superorbital pains. This symptom complex ceases rapidly, however, and if the patient is removed from the action of podophyllin the affection generally clears up in eight to twelve days.

Sureau (1902) was the first to draw attention to the harmful action of podophyllin. Rocca Serra (1902) in his thesis has described in detail lesions affecting the anterior segment of the ocular globe and has undertaken research with a view to ascertaining what are exactly the anatomo-pathological alterations caused by podophyllin. These two authors, however, do not refer to more deep-seated symptoms or injuries caused by this substance. It was Chiari (1910) who, having met with three cases of injuries of the eye of an occupational character due to podophyllin, drew attention in the most serious of these cases to the occurrence, in addition to phenomena localised in the anterior segment of the ocular globe, of a bilateral diminution of sight and an absolute scotoma of elliptical form situated quite close to the "macula lutea."

Podophyllin and its active principle podophyllotoxin are readily dissolved by tears having an alkaline reaction. They destroy the corneal epithelium and injure the nervous cells by causing lack of sensibility of the cornea. The iris, on the other hand, acts as an organ of secretion and the podophyllin exerts on it a similar action to that exerted on the intestinal glands.

Deep-seated changes in the eye are perhaps due to a slow but continued action of the irritant liquid — that is to say, of the abundant lachrymal secretion containing a relatively great quantity of the toxic substance. The latter penetrates deeply into the tissues and gives rise to phenomena in the anterior part of the uvea as well as alterations of the retina and the optic nerve — alterations which may be ascribed to poisoning of the nervous element (Oblath).

Podophyllin dust has also caused irritation of the respiratory passages, which results in a cold amongst workers engaged in the preparation of podophyllin (Koelesch, Hessburg).

Poisonous Woods

Many processes in the wood industry (sawing, planing, boring, drilling, removal and utilisation of waste) give rise to wood dust, which is classified among the sharply-pointed dusts of moderate hardness. Every particle of this dust, according to Lehmann, would average about 10 microns in size.

Ordinary wood dust has attracted attention by reason of its purely mechanical action, but handling of certain kinds, especially woods coming from abroad,
requires still greater care because of the essential oils impregnating these which, when liberated in the dust, may affect the health of the workmen concerned.

Con structural timber of Europe or other temperate regions sometimes comes from trees (e.g. oak, beech, chestnut, and trees of the species yew and juniper) containing poisonous or injurious substances, but they are generally innocuous or contain such minute quantities of the toxic agent that very little trouble is attributable to them.

On the contrary, quite a number of foreign woods from tropical regions, much sought after because of their special qualities for coachmaking and fine cabinet making and for use in the dyeing and perfume industries, cause, according to their genus, either an irritation of the skin, mucous membranes, or symptoms of general poisoning. Although cases of dermatitis and toxic symptoms set up by foreign woods are frequent, their precise origin and a probable cause have not been accurately determined. Some reports even contain definite statements as to the impossibility of obtaining precise information as to the kind of wood used. This accounts for the fact that, in the majority of cases reported, the dermatitis is attributed to satinwood without specifying or even knowing the scientific name of the special wood in question. Again, the commercial name of the wood is unfortunately too often based on the country of origin or on some special qualities for technical purposes, qualities which are to be found in kinds of wood quite different from the botanical point of view.

The numerous foreign woods capable of setting up the lesions in question all belong to trees of tropical or subtropical regions known under the following names: scented wood, iron wood, yellow wood, courbaril, lignum nephriticum, bone wood, purple or violet wood, red or Brazil wood, satinwood, teak wood, greenwood, woods from Guiana and Cayenne, e.g. cumaru wood or tonka, Dipleryx odorata (Aubl.), or Brazil, Venezuela, etc., cocoz wood or Cuban grenadil (from Inga vera (Willd.) or according to some writers from Brya ebenus D. C.). The botanical name has only been given to those woods capable of setting up toxic disturbances and enumerated in the following list:

East Indian satinwood or Indian yellow wood (Bahamas) (Bois satiné des Indes orientales = Ost-indisches Satinholz — Madura satinholz; Legnosa seba = Madera sebana) comes from Chloroxylon swietenia D. C.; West Indian satinwood coming from Fagara flava (Krug and Urban) is identical with Xanthoxylum crinatum (Spreng.) and is obtained in Jamaica, San Domingo, the Bahamas and especially from Porto Rico; Asias satinwood or satinwood from Ferrula guianensis found in Guiana and another variety from Ferrovia vartegata is obtained in the Antilles; Black ebony wood (Bois d’ébène noir — Ebenholz — Ebony; Xylocera de Bois) comes from different species of Diospyrus africanus (Madagascar, Zanzibar), or Asiatic (Mo- luccas). or, according to others, from Mauba ebenus, West Indian mahogany, from Swietenia mahagoni, and West African from Swietenia or Khaya Senegalensis; South or West African boxwood (Buis africain — Afrikanischer Buchbaum); Gonjona Kamassi comes from Sarcococ- phus Diderrichtii; Macaribo boxwood from Tabebuia pentaphylla; Rosewood comes from Rhodorhista scoparia: Magenta rosewood from Benueo; Teakwood (Bois de teck or tik — Teak Holz — Legno di teck — Madera de teca) comes from the East Indies, from Tecloa grandis (Linn); fine teak (Bassia wood) comes from Bassia longifolia or latifolia.

The Japanese wood Tagayasan, the dust of which is sulphur yellow in colour, turns violet or brown on exposure to air; Australian mohwah wood or wood of Flinders Australis: cocloba from the species Polygonaca colorata; West Indian mahogany, from the East Indies, from Tecloa grandis (Linn); fine teak (Bassia wood) comes from Bassia longifolia or latifolia.

**TOXICITY**

Comparison suggests itself between the affections due to woods and those commonly known to be set up by the leaves of the anacardiaceae (Anacar- dium occidentale L., Semecarpus venenosa (Vlks.), etc.) and notably by those of the sumachs of North America (Rhus toxicondendron L., Rhus vernicifera D. C., Rhus venenata D. C., etc.) used for making Japanese lacquer — which set up an irritation of the skin accompanied by slight fever, itching, and a sense of tension in the head and limbs. According to the researches of Scheube, the emulsion of resin of Rhus vernicifera (Japanese lacquer) has no injurious action as soon as the lacquer dries and hardens, either because the noxious ingredient evaporates or because it is modified by the oxygen of the air; the latter reason seems the more probable. The severe symptoms produced by Rhus toxicondendron which has been frequently studied, most recently by Rost and Gilg, would appear to be connected with a poisonous oil called “toxicodendrol”, the chemical properties of which somewhat resemble those of “cardol” — a substance obtained from other anacardiaceae and possessing likewise an irritating action on the skin. The chemical constitution of Khaya Senegalensis and cardol are not known; they are supposed to be compounds of glucosine. Numerous experts have tried to obtain pure chemical combinations which would set up toxic symptoms characteristic of satinwood. Harvey Gibson,
of Liverpool, and Dixon, of Cambridge, (England), are said to have extracted an active principle from Conium Ka-
massa — an alkaloid which has an action on the heart similar to curare. In 1909 Auld extracted, from satinwood, coming from Chloroxylon swietenia, an active principle which he called "chlor-
 oxyloxine". Cash, of Aberdeen, also carried out physiological experiments in 1911 with this alkaloid. In the same year, Iwakawa isolated from Japanese tagayasan a substance like chrysoarbinne, capable of setting up digestive and renal lesions. The content in this wood of the substance varied from mere traces to 0.73 per cent. In 1913 Nestler isolated from satinwood a soluble substance analogous to stearine.

According to Gilg, of the Botanical Museum at Dahlem (near Berlin), the Chlorophora excelsa (Eth. and Hook) or Morus excelsa (Welm.) is generally known under the name of "muilwood" of West Africa. Experiments with this wood were made at the Hygienic Institute of Bremen which were not published, but which do not seem to have given definite evidence as to any irritating action on the skin.

Matthes and Schreiber, in the course of their experiments on six kinds of wood from the point of view of botany, chemistry and physiology [fine teak wood from the East Indies; teak wood from Tectona grandis; wood of Flindersia Australis; Lapacho wood (which comes from one of the Bignoniaceae of South America); the wood of Tecoma araliacea (of Brazil); and green wood (of Bignonia Lewcovylyon of Surinam)], could only obtain a characteristic alkaloid in the case of Flindersia, a wood used specially in the building of ships and for sleepers on railways. The alkaloid of Flindersia, which they called "flindersin", possessed neither an irritating action on the skin nor any striking noxious properties. The resin coming from the woods mentioned had no irritating action except when it was composed of non-saturated resinous acids in a free state. But this was not the case with Flindersia, which chemically belongs to the saturated compounds. It should be added that the piece of wood examined belonged to a botanical museum and its chemical composition may have been somewhat modified by the fact that it had been exposed for a long time to the action of air.

1 This alkaloid is said to have had the formula C₁₇H₂₁O₄N. Its amount varies with different samples of wood from mere traces to 0.07 per cent.

Lastly, it should be mentioned that among the chemical compounds to be met with in a large number of woods are notably Bapachonon and Lapas-
chol. The latter, discovered by Patern-
no, of Rome, in Lapacho wood, is described as an oxyynaphthoquinone of an amylene side chain. Cross and Manuelli later extracted from the same wood lapachenon. The irritant action of these two compounds, however, when present in several kinds of woods, disappears when in the pure state.

Fortunately, the persons who handle these kinds of woods are not all attacked and only those particularly susceptible to the action of the sub-
stances, still but slightly understood, which they contain become affected. This finding recalls similar observa-
tions with regard to the action of the primulas (Primula obconica) and other ornamental plants which cause an eruption sometimes — very profuse, but limited to certain individuals — of special susceptibility (see the "Cicatrices Gardens", "Skin Diseases", etc.).

Although other experiments have not given different results, the researches of Matthes and Schreiber quoted above support the view that any injurious action on the skin of workmen caused by irritating woods is essentially due to the fact that they contain non-saturated resinous acids in a free state.

STATISTICS

The first occurrence of skin lesions from the working of exotic woods was described in 1893 by Jones, who had come across them amongst the Clyde shipyard workers, and about the same time by Sternberg among the cabinet makers of Vienna.

In 1902, Oliver, in his book Diseases of Occupation, referred to cases of dermatitis dating some years back among Edinburgh cabinet-workers using satinwood, Californian sequoia, and rosewood; while the German factory inspectors reported some cases of illness at Hamburg from "locan-
dario di Campo".

In 1902, at the meeting of the British Medical Association, Dr. T. F. Young, of Liverpool, described certain symptoms in shipyard workers from boxwood coming from Tabebua pentaphylia (of the order Bignoniaceae).

Two years later, Jones described cases due to East Indian satinwood; and during the year 17 cases from coccoloba wood were investigated at Strasbourg.

In 1905, the army surgeon Bidie described cases set up by satinwood, and W. Evans the first cases from teak. The following year the Austrian inspectors enquired into dermatitis from coccoloba, while Veysey Smith, Inspector of Factories in Norwich, studied cases set up by Borneo rosewood.
Other factory amongst several workmen in the cabins (satinwood) yards engaged especially on cabinet work in Aberdeen, also reported among cabinet makers. Cash, of several cases attributed to satinwood were Japanese of "hag " reports such cases amongst workers hand- an obstinate and painful nature. In 1909, cases set up by satinwood from Jamaica. The subject of this dermatitis became so hypersensitive that she suffered from inflammation of the skin even when she worked with ordinary oak. Possibly particles of injurious dust may have stuck from inflammation of the skin even when they came into play at the moment of working on a harmless wood. In 1909, cases set up by satinwood from Brazil were similarly investigated by Sieghelm. Balban (1910) described cases in Vienna attributed to satinwood and Atlas ozimatiss wood. Hagemann reports 12 cases in Breslau set up also by "moule" wood from East Africa having a striking resemblance to teak wood. A report of the German Imperial Health Office (1911) charged the factory inspectors with obtaining data in relation to cases of this kind in the wood-working industry. Numerous cases attributed to satinwood, teak, mohwah, lemon, acacia, or coccoloba from the nine factory inspectors' districts have been regularly described in their annual reports. The action is limited to inflammation of the skin — sometimes of an obstinate and painful nature. Breme reports such cases amongst workers handling "moule" and East African wood. In 1911 also Iwakawa investigated cases of dermatitis and conjunctivitis from Japanese tagayasan wood. In Berlin several cases attributed to satinwood were reported among cabinet makers. Cash, of Aberdeen, also described cases he had seen amongs workmen in naval shipyards engaged especially on cabinet work in the cabins (satinwood). Coccoloba wood set up, in 1912, dermatitis amongst several workmen in a stick factory. Nestler reported on similar cases. Other cases set up by fresh teak wood were reported in 1913 in Berlin in the Wilhelmshaven yards (Dr. John) and by E. Franck. In Italy, in 1915, Devoto had charge of cases of dermatitis in the clinic for industrial diseases in Milan. In the years following the war the number of cases diminished, whether due to the improvements in the exhaust ventilation for removing the dust or diminution in the importation of exotic woods it is impos- sible to say.

**SYMPTOMS**

The symptoms caused by the dust of these different kinds of exotic woods can be grouped as:

1. Irritation of the skin.
2. Irritation of the exposed mucous membranes.

These different manifestations cannot with certainty, in the present state of knowledge, be accurately related, either to the channel of entry into the system of the noxious substance or to the differences that exist in the sub- stances themselves. Possibly, the principal factor may be the susceptibility of the person attacked.

The local or general symptoms can present themselves either immediately following contact with the dust, or later. Generally, local lesions appear first on the uncovered part of the body, most of them on the hands, fingers, forearm and face, and more rarely on the back, trunk, etc. The skin, at first red and oedematous, can then become covered with an eruption (vesicles, papules and even pustules). Certain woods cause fairly charac- teristic lesions. Thus, Japanese taga- ayasan gives rise to a brown or even a black pigmentation analogous to the lesions pin- boiled by burns from black powder. Certain writers describe also a characteristic lesion of the hand which has been called "crocodile hand" (Horand). The rash may disappear in a few days, but may recur two or three times in succession.

All these forms of dermatitis are accompanied by intense itching.

The dermatitis due to these woods presents naturally analogies with other industrial skin maladies (eczema), long known under the name of "itch", "cancer", etc. It would therefore seem desirable that research should be engaged in with regard to them. They do not appear often except in the presence of "general debility", nutritional disturbance (natural or acquired) capable of causing
general digestive disturbance, chlorosis, etc. (Neisser).

Persons who have suffered once from a skin disease (especially from eczema) and have recovered, are probably in condition of hypersensitivity (anaphylaxis), which gives to the eczema the characteristics of a true industrial disease. Wechselmann spoke of anaphylaxis for the first time in 1909. Without going into further detail (see the article "Skin Diseases"), it should be said that the dermatitis in question belongs to the ill-defined category of eczemas and erythemas without special clinical appearances. Sometimes they can, however, take on the special characteristics connected with the causal agent as regards localisation, morphology, etc. It is further possible that in the pathogenesis of these maladies the general state of the health plays a part at least equal to the state of the digestive system and the condition peculiar to each individual.

The eyes are also often attacked — conjunctivitis with intense lacrymation, and even irido-cyclitis and somewhat severe keratitis (by tagayasan).

The affection has its seat sometimes in the nose, giving rise to frequent sneezing and considerable nasal secretion.

The sufferers complain of anorexia, nausea, roteching, palpitation, vertigo, sweating, and chills. The respiratory tract is the seat of various phenomena: retrosternal oppression, dryness of the throat, cough, difficulty in breathing, asthma, air hunger, bronchitis. These symptoms are notably provoked by African boxwood (Gonioma Kamassi) which is said to be also responsible for headache, somnolence, general malaise, and, especially, slowing of the pulse and dilation of the pupil.

To the same wood is attributed a chronic action showing itself in a yellow tint of the skin and camphor-like smell of the breath. Experiments on animals are said to have caused death with the picture of paralysis of the respiratory centres.

Without giving other examples, it must be remembered that those cited are isolated observations insufficiently controlled, not only as to the origin of the wood, but also as to its botanical identification. Whether this is right or not, the symptoms occurred, in general, on the first contact with the kinds of wood enumerated; in a minority of the cases the sensitiveness of the sufferers to the action of the woods increased remarkably on each fresh exposure. Apart from an obvious Idiosyncrasy in certain persons, there is the possibility of acclimatisation to be considered on the part of the majority of persons exposed, always excepting those afflicted with asthma and bronchitis. In some cases, finally, an obstinate resistance to treatment has been observed.

Generally the malady lasts some weeks — in a few cases as long as six.

**Hygiene**

Seeing that the noxious effect is due to wood dust, it is of the first importance to provide exhaust ventilation as near as possible to the point of origin of the dust. The different wood-working machines should have suitable covers. The ducts connected with the covers should not enter the main duct at an acute angle. All sharp angle bends in the piping must be avoided throughout the system and powerful exhausts should be applied, so as to secure rapid air currents and ensure as complete a removal of the wood dust as possible. Should it be impossible to remove the dust in this way, all wood having irritating properties should be moistened before working.

Tools soiled by the noxious dusts, it should be remembered, may convey the irritating property to otherwise innocuous dusts.

The workers should wear overalls, in good condition and fitting closely near the neck; during and after work all exposed parts of the skin should be well cleaned, and specially susceptible workers should not be employed on woods with irritant action.

**Legislation**

The effects produced by West African boxwood (Gonioma Kamassi) are brought under the Workmen's Compensation Act in Denmark, Great Britain, British Columbia, Venezuela and Minnesota (U.S.A.). A judgment of the Imperial Insurance Office in Germany since 1911-1913 regarded these morbid conditions more as industrial diseases than as accidents.

Dermatitis and ulceration of the skin due to dust and liquids are likewise compensated under British law.

Postal, Telegraphic and Telephonic Services

**Telephone**

French: Téléphone. — German: Telephon.  
Italian and Spanish: Telefono.

**Sources of Danger**

The hazards of the telephone industry fall naturally into two groups: (1) those of the outdoor employees, and (2) those of indoor office employees.

(1) **Workmen employed in the open air** and especially linemen, trench diggers and cable layers may be exposed: to burns and shocks from the electric current, owing to crossed wires; to fractures, dislocations, contusions and sprains, due to falls while employed on elevated work; and to wounds from handling copper wire which may present sharp ends.  

Outdoor employees are therefore subject to dangers of accidental injury rather than industrial diseases. Nevertheless they are liable to rheumatism and to diseases caused by cold, while men who lay cables in the ground are liable to poisoning by carbon monoxide from the escape of gas.

At Chicago in one year alone 473 cases of electric shock were reported, two of which were fatal. Layers of telegraph lines formed the majority of victims of these accidents. Statistics cited by Hoffmann based upon 205 deaths among layers of telegraph lines exhibit 48.3 per cent. as due to accident, 18.5 per cent. to tuberculosis, 6.3 per cent. to diseases of the respiratory passages, and 3.9 per cent. to diseases of the urinary system.

(2) **Indoor employees**, however, merit more detailed consideration from the medical hygienist. It is extremely important from every point of view to safeguard the health of these employees, who are for the most part young girls about the age of puberty. Moreover, a telephone girl is not a real asset to the company which employs her until she has had a year's apprenticeship. Hence the economic necessity of maintaining her in good health to lessen as far as possible the labour turnover, which is as a rule very great.

In the United States a young telephonist commences her training in the school of the company, where there is ample opportunity to observe her health and secure the correction of defects or disabilities, such as poor teeth, or diseased tonsils. The maintenance of a high hygienic standard in the workrooms, known as "centrals," is a matter of the greatest importance; and it happens to be of equal importance for keeping in good condition the delicate electric apparatus and the health of the operators. The rooms must be kept scrupulously clean, free from dust, dirt and moisture which foul the switchboards and cause short circuits; they should be warmed in the cold season, well ventilated and lighted either by natural or artificial light. Proper seating adjustments admitting of change of posture to lessen fatigue, rest and refreshment rooms, good toilet and washing facilities; and lockers are all essential factors. In smaller stations, as e.g. those in villages, in which, although they are usually important offices, night calls are infrequent, provision may be required for sleeping quarters for the attendant.
A large telephone exchange where two or three hundred young girls may simultaneously be occupied is peculiarly difficult to ventilate. In the United States high vertical switch-boards are arranged in a "U"-shape, thus cutting off currents of air.

A sanitary inspector is employed to inspect periodically conditions in all company buildings, and also to make studies, in conjunction with the chief engineer, of the ventilating conditions.

The girls are seated close together in front of the switch-boards, whilst supervisors or "monitors" occupy the centre or walk about inserting plugs and "listening in".  

Pathology

Among the female personnel the following disorders frequently occur: anaemia, loss of flesh, typical nervous conditions, sthenia, insomnia, headaches, and symptoms of hysteria.

Work in large exchanges—or "centrals"—is often such as to provoke quite rapidly among predisposed workers an incapacity for reliable and sustained work. With young girls especially the strain gives rise to general weakness, which lowers the body resistance and paves the way for tuberculosis and diseases of the respiratory passages.

The harmful factors are not only excess of work, such as a too prolonged time-table with the multiple Siemens, but also imperfect hygienic conditions at exchanges, such as ineffective ventilation, bad heating, night work, no fixed hours for meals, etc.

It must also be borne in mind that in certain cases young girls (auxiliaries) are concerned unaccustomed to sedentary work which is tiring, nerve-racking and hurried; this alteration in life certainly influences the bodily system in a general way.

Diseases attributable to occupation are rare. But it can be stated that common diseases, such as rheumatism, neuralgia, myalgia, arthritis, rheumatic fever, angina, bronchitis, acute and chronic catarrh of the bronchi, pleurisy, cephalgia, giddiness, nervous excitement, etc.—which with a normal ear disappear after a period of rest—may become dangerous for a diseased ear.

According to Politzer and others the pathology of these symptoms is easily explained by defective hearing and by the neuropathic condition of some telephonists obliged to make a sustained effort of attention to catch the sounds. Most specialists are of opinion that the healthy individual who is neither neurotic nor overworked easily becomes adapted to continued and prolonged telephone work. But if the work is excessive it may cause a general nervous condition and sometimes troubles of hearing—as when the ears do not function together causing double hearing, or strong buzzing in the ear—a diminution of hearing, or shooting pains.

Braunstein was the first to examine 160 operatives at a telephone exchange (Munich) and although he was restricted to seeing only those who submitted voluntarily to the medical enquiry, he was not able to find any injurious effect from the telephone upon healthy hearing, but was only able to prove that this work is harmful in cases of ear trouble. Mancioli, of Rome, has raised the point of troubles being due
to a slight lesion of the labyrinth rather than to a nerve condition.

Blegvad, who examined 450 operators of the Copenhagen exchange, found very often (in 26.4 per cent.) retraction of the tympanic membrane in the ears to which the receiver is applied. The other ear only showed a very slight retraction or none at all. Sixty-six persons did not hear deep tones well on account of being accustomed to them. Nevertheless he did not find any effect upon chronic diseases of the middle ear, nor any diminution of hearing amongst other operators, nor the improvement in hearing of which some boast and which is due rather to middle persons did not hear deep tones well retraction often of the Copenhagen exchange, found very to rupture of shock to etc. contact with subscribers call at the same time, or mm, 1927). easily injure telephonists' ears men. to be more closely studied by medical drawn, it 

In conclusion and generally speaking it may be said that the call upon the hearing exceeds ordinary conversation too slightly to cause serious troubles, save a slight transitory fatigue of the vestibular apparatus. While observations made up to the present only permit very general conclusions to be drawn, it is a matter which deserves to be more closely studied by medical men.

The secondary noises (defective apparatus and lines; call bells, etc.) may easily injure telephonists' ears (Solo-min, 1927).

More serious dangers are caused by electrical discharges due to lightning, storms or the current.

The discharge may occur when two subscribers call at the same time, or just as the operators touch the metal part of the plug, or their lips come in contact with the metal microphone, etc. Generally the pain is not painful. However, on one occasion this shock to the ear was the cause of rupture of the tympanic membrane (case of Bernhardt). But as a rule it only causes an attack of nerves of such a kind that most observers are of the opinion that the very large number of telephonists who are victims of such accidents are neuropaths or anaemic and that their accidents (trembling, cramps, partial paralyses, muscular weakness, diminution of visual acuteness going as far as blindness, anaesthesias, parasthesias, vaso-motor disturbances, etc.) are due for the most part to hystero-traumatic or neuro-traumatic troubles, the discharge only very rarely passing through the body of the operator.

However, Trautmann (1927) found in a telephonist after an electrical discharge pupillary troubles on one side and anomalous reflexes. As accidents due to electrical discharges may be instanced two cases of paralysis which lasted several months and five of shorter duration caused by a storm at Lyons (1931).

Recent experience has shown that these violent noises produce their harmful effect upon the labyrinth by bone conduction rather than by air conduction. As a matter of fact protecting plugs placed in the external meatus to deaden excessive sounds are not of any benefit.

On the contrary it is notorious that with perfect apparatus and a good installation of aerial lines, operators do not suffer the inconveniences produced by sharp, strident, violent or sudden sounds.

The receiver readily warms the ear causing a local sweating with itching, frequently followed by boils, or eczema and even mycosis of the external ear. Miss Richardson (United States) states that a lesion of the skin due to a mechanical irritation of the plug may be the door of entrance for local infection, exceptionally for serious eczema. The same author expresses the opinion, which is very prevalent among American telephonists, that the metallic (brass) part of the plug may cause an occupational poisoning, even penetrating the skin. She affirms that the use of acetone for cleaning the signe marked upon the multiple has caused some cases of malaise among the staff, for they dry up the traces of acetone with their fingers rather than with a cloth. Miss Richardson has also reported some cases of neuralgia localised on the shoulder blade and of abdominal pains caused by the effort necessary to put the plug in the furthest holes.

McCord reports (1931) nyctagmus, deafness in one ear and nervous and

---

POSTAL, TELEGRAPHIC SERVICES
In 1919 out of 9,428 candidates 815, or 8.6 per cent., were rejected on account of physical unsuitability. Among those one-fifth were rejected on account of an unhealthy state of the respiratory passages, and 18 per cent. for insufficient development. However, at the present time a young girl, even of inferior physique, is accepted if she is considered capable of doing the work required of her. Then, in her status as an employee, an appropriate course of treatment restores her to the normal condition, that is to say, to the physical standard required for the work to be performed.

In 1919 out of 618 telephone apprentices 478 had to abandon their apprenticeship on account of bad health. There is no doubt whatever that if the telephone personnel were subjected to a very careful examination there would be fewer discharges, and the figures could be kept thus much nearer a maximum level.

Fumarola and Zanelli (1913) have also reported, among telephonists at Rome, cases of neuritis which take the form of neurasthenic hypochondria associated with anxiety, neuritis and vaso-motor troubles. The authors did not find any history of nervous affections in the families, but did find history of previous nervous trouble in the individual. They urge the necessity of a very careful medical examination on entering the service and also periodical examinations.

An enquiry made in 1923 by Dr. Trambizky regarding the health of telephonists of the towns of Kharkow enabled him to report that the variety of sounds emitted by a telephone apparatus had a definite action upon the ear, which, according to him, results in an amelioration of deafness. Even a superficial examination confirms the existence of nerve diseases which have so frequently been reported among telephonists.

G. Zerba (1925) does not consider that the sickness among telephonists and telegraphists is so negligible as is generally allowed. The figures collected in the telephone and telegraph exchanges of Karlsruhe and Heidelberg show that the female personnel is much more affected than female clerks, both from the point of view of gravity and the duration of the diseases. Although he considers it necessary to bring forward a greater wealth of evidence before drawing conclusions, he gives meanwhile the following figures (for the period 1920-1923 for Heidelberg):

<table>
<thead>
<tr>

According to L. Dublin tuberculosis and pneumonia among these workers should be considered as their most important occupational diseases.

**Prophylaxis**

The prevention of sickness among the personnel of telephone exchanges depends upon the installation of the system (wires), upon the individual, and upon the internal administration of the service.

As regards the installation, among other measures the use of fuses against high tension currents is advised; also the insulation of microphones and receivers during storms, etc.; but especially a greater use of subterranean cables in the place of aerial lines; and the use of receiving apparatus which is lighter and more efficient and which allows good aeration of the ear and an effective protection of the labyrinth.

As regards the individual, endeavour should be made to eliminate neurotic-holic persons, those predisposed to nervous diseases generally, and those who during their apprenticeship show that they do not possess the qualities necessary for the work demanded.

The psychological qualities considered necessary are the following; good hearing and eyesight; auditory memory; sense of distance; sustained attention; rapid reaction; calm disposition; smooth temper. The physician will determine the physical defects with due regard to the requirements of the occupation and its attendant risks. For the various series of tests readers are referred to special publications.

The organisation of the service should prevent troubles that arise from monotonous and tiring work. The work hours, the rest intervals, the rapid reaction; calm disposition; smooth temper. medical attention, either for consultation or for emergencies.

If the patient requires prolonged treatment she is referred to her family physician, who may avail himself of X-ray or clinical laboratory examination of the blood, urine, sputum, etc., made in the company’s laboratories.

Accidents which do not necessitate the patient lying in bed are treated on the company’s premises. One of the largest American companies has in addition to a most elaborate X-ray department, an electro-cardiograph and a completely fitted emergency operating room.

There are also special services offered to employees, such as examination of the teeth by dentists, teeth cleaning by dental hygienists and examination of the feet by chiropodists.

Employees on duty are strictly supervised by the monitors who are on the watch, and as soon as a girl shows signs of fatigue and begins to make mistakes, she is temporarily taken off duty and sent to the rest room where a trained nurse looks after her.

Certain of the companies in addition maintain homes of rest in the country.

Recently instruction in domestic hygiene and care of the sick has been instituted and offered to women employees by the staff of the medical department. The doctors like all the employees to pass a medical examination each year; final physical examinations are made for disability, retirement and pensions.

The aim of medical service in the United States is especially directed towards the prevention of disease by means of propaganda work which endeavours to reach the employees in all sorts of ways: articles in the most widely read papers, posters, short talks, etc.

As regards other countries we may mention that in France the personnel of the P.T.T. is recruited by the Government, after an examination made by a medical committee who vigorously exclude tuberculous and suspected cases, also persons whose sight and hearing do not satisfy certain conditions. Weakly candidates and doubtful cases are adjourned for three months, six months or a year. On the other hand, no woman is passed for the town telephone service after the age of 30 years.

The fight against tuberculosis among the personnel of the postal services is to be waged chiefly by improvement of hygienic conditions in the workrooms, and the assistance measures provided for in the Finance Act of 1923 supplemented by the Decrees of 1923 and 1930. These questions come within the competence of a Superior Health Council attached to the Ministry of Posts, Telegraphs and Telephones (1929).

In Great Britain, according to a recent report (1923), certain English companies admit young girls of from 16 to 19 years to a first apprenticeship after a very strict medical examination. The apprenticeship lasts at least four weeks and is with pay. When a telephonist enters on duty she signs an agreement which provides for gratuitous treatment in hospital, dental treatment and, should necessity arise, a visit to a convalescent home. Telephonists enjoy an annual leave of fifteen days during the first five years and of 21 days after that. Spacious and airy dining rooms, rest rooms and playing fields, etc., are provided.

**Telegraph, Marine Cable, Field Telegraph, and Wireless Telegraph Services**

**Sources of Danger — Pathology**

The dangers which can be actually attributed to these occupations are not numerous. Among telegraph operators cramp of the hand is still occasionally reported — the cramp of telegraphists or users of morse instruments.

According to an enquiry made in 1922 by the International Labour Office in Germany, Austria, the United States, France, Italy, Holland and Switzerland, it seems that this neurosis of telegraphists is now a mild and a fairly rare disease, and that this is due to the disappearance of the morse apparatus, which has been replaced by more modern types (Hugues, Baudot). This disease is still seen in those countries where the apparatus in question is used.

In its report on telegraphists' cramp the Industrial Fatigue Research Board (1927) stresses the importance of the individual's constitution. Subjects who show psychoneurotic symptoms and insufficient muscular co-ordination tend to suffer from cramp. Contributory causes are the nature of the work, its monotony, speed, etc.
According to Lehmann, more than 5 per cent. of telegraphists become affected with weakness of memory, their occupation causing mental fatigue.

An enquiry made in 1907 by Rossoni and Zevi among the personnel of the telegraph service in Italy shows that a large number of troubles and diseases were associated with defective hygienic conditions of the offices. They drew attention to many infectious diseases, with tuberculosis and influenza at the top, and to diseases of rheumatic origin; to gastro-intestinal diseases; to diseases of the nervous system presenting the typical pathology for this category of workers, in the causation of which overstrain, fear of responsibility, dread of penalties, and night work are the principal factors; to nutritional diseases (anaemia, menstrual troubles among women and especially young girls); to affection of the eyes and ears due to bad lighting, noise, dust, etc.

Ssalt'ykovskij (1925) reported three cases of nervous exhaustion in telegraphists (Wheatstone apparatus).

The apprentices are moreover in poor condition of health, for they carry out all their work in very bad hygienic conditions. Work carried out in the interior offices by the apprentices, of whom the age varies from 12 to 16 years, is often the cause of anaemia, hernia, enlarged glands, cramps in the calves of the legs and synovitis in the joints, etc.

Telegraph and radio-telegraph messengers, who are often obliged to hurry, are particularly exposed to accidents such as falls from cycles, collisions with vehicles, etc., and also to diseases caused by exposure to cold, hernia, etc. Further, the men who erect the poles and put up the wires are similarly exposed to shocks or burns by contact with wires charged with high-tension currents.

Gilman Thompson quotes the case of a lineman who was electrocuted while repairing the line. But such accidents cannot be considered as peculiar to this branch of industry. The telegraph industry compared with others in reality only shows a slight number of dangers and no serious disease.

Telegrams for transmission by submarine cable are sent upon a ribbon moving at a rapid rate, similar to the tape machines used in the Stock Exchanges. The ribbon passes across the front of a typewriter so as to allow the operator to take down the messages as they arrive. This work requires very sustained attention, quick work, and is a cause of slight eyestrain. But it is easy to avoid these inconveniences by arranging a few moments of rest during the work and providing the operator with suitable illumination.

Field Telegraphy

Symptoms which can be attributed to eyestrain have been reported by Trombeta and Santa Maria (1908) among engineer soldiers employed in field telegraphy. The flashing light has a harmful effect on different parts of the eye and particularly on accommodation and the retinal adaptation. In the first stage are noticed symptoms of over-action of the accommodation, spasm of the ciliary muscle with myopia, caused by spasm of the accommodation; in the second stage are noticed symptoms of paralysis of the accommodation with asthenopia, etc. The subjective transitory symptoms are generally very slight and consist of conjunctival hyperaemia, lachrymation and photophobia. Symptoms arising from the accommodation or the retina are more serious: visual fatigue, slight distortion of colours, sometimes with a scintillating scotoma. The use of spectacles modifies the action of the flashing light upon the retina, but does not prevent the troubles of accommodation. Army signallers should not be employed at their work for too long a period, especially if there are neuro-pathic signs, and the white light used for the signals should be replaced by a coloured one.

Wireless Telegraphy

The crackling which is produced during the transmission of messages by wireless does not seem to be a source of trouble to the operator. On the contrary, operators employed on the receipt of messages are exposed to the same troubles as those which affect telephonists. The sounds received are short, piercing and strong, or very high and musical; these last are the only ones capable of being transcribed.

The speed of reception is proportionate to the speed of transmission, and fatigue makes itself felt all the sooner if the reception is very rapid. It is well known that wireless transmission is carried on better at night; but that causes more exacting work and serious strain among the operators. The messages from some countries are

---

1 In Great Britain some cases of mercurialism have been noticed among workmen employed in the construction of wireless apparatus owing to the use of a salt of mercury.
sent without interruption, those from other countries on the other hand are interrupted by regular interpolated pauses in the transmission.

The operators consider that the formation of ozone in their office makes breathing difficult, which is also accentuated by the action of a particular dust which forms during transmission and is scattered in the surrounding air. Certain conditions favour the formation of ozone, e.g., stormy weather, strong evaporation, and special types of sending apparatus. Nevertheless it is opportune to bear in mind that operators complain of troubles, such as vertigo and fainting, which cannot be attributed to the action of ozone.

It is probable that the cause is another substance which according to certain authors is an oxide of copper, formed in the interior of the apparatus and deposited on the surface in the form of a dust. But it is necessary to remember that symptoms of copper poisoning have never been found among operators. Others consider that in certain conditions of work oxides of nitrogen are formed, without being able to determine exactly their rôle in the pathogenesis of the troubles which have been noticed.

It is much more probable that the cause of the trouble is simply due to the injurious action of confined air. That is especially the case with ship operators. Conjunctivitis, keratitis, and recurrent eczemas have also been noticed, and among army wireless operators palpitations so serious as to necessitate discharge.

Out of 23 wireless operators examined in Russia by Kachkadamow (1923) from a medical standpoint, only two made no complaint regarding the state of their health; 18 complained of a feeling of heaviness in the head, faintness, apathy, somnolence, and inattention; 7 complained of troubles of hearing. The greater part of the operators were from 20 to 30 years of age (87 per cent. of those examined) of whom 15 had from 3 to 7 years' service.

Voss recalls that a German sailor developed a lesion of the cochlea, the origin of which has not yet been thoroughly elucidated.

Axmann reported (in 1924) some cases of falling of the hair, localised to the side which was exposed for some months to the light from the wireless valves. He considers that the valve acts as a Roentgen tube of small power.

Jellinek has recently (1925) drawn the attention of scientists and the public to the dangers of wireless receiving apparatus. He gives quite a series of measures which should be adopted to prevent as far as possible accidents which without any doubt are fairly serious.

The percentage ratio of days of sickness to days of work has been calculated to be 2.6-6.4 for medium-grade officials, 3.3-8.5 for subordinate employees, and 4.5-0.3 for women employees.

Prophylaxis

Merschetzky suggests the following measures: exclusion of persons of less than 18 years of age; medical examination on admission and periodically, at least every six months; both ears to be used at work; special supervision of operatives troubled with anaemia or nerve conditions; exclusion of every individual suffering from, or who has suffered from, middle ear disease, even if the other ear is normal; careful supervision of unhealthy conditions of the nose and throat; a maximum of 4 hours' work by day and 3 hours' by night; pauses of half an hour every two hours during day work and every hour and a half during night work; annual leave of 50 days taken if possible in several periods.

The application of ordinary rules of hygiene such as have been already mentioned, in connection with the telephone industry is essential for this group of employees, equally for those employed in inside work as for those employed on outside work.

The medical officer should closely follow the proportion of employees away from duty on account of accidents and take steps to find out the cause in each particular case. He should test the visual and aural acuity as well as the response to tests of the eye and ear, which have a direct connection with the state of the general health.

In telegraph stations situated in the southern and tropical regions, very particular attention should be given not only to the housing, workrooms and the feeding of the staff, but also to protection against infectious diseases and parasites. Thus for example, the All America Cables, Inc., require a very thorough medical examination as well as vaccination against smallpox, typhoid paratyphoid and typhus.

By means of these methods of prophylaxis "although this system extends to regions considered at present very unhealthy, the standard of health has been maintained at a very high level".
LEGISLATION

As regards compensation for telegraphists suffering from cramp, in the majority of cases they are transferred to work on different apparatus or are given other duties in the same department. That is so in Germany where, in addition to the telegraph department, affected persons who become affected with cramp are discharged directly they show symptoms of cramp; in Austria where the personnel is changed on the first signs of the affection; in France where it is still maintained that the affection is so mild that no difficulty has ever arisen from it; in Italy, and Holland where by agreement with the directorate of the telegraph department it is possible for certain cases so affected to be transferred to other duties; in Switzerland they are employed in administrative duties in the postal and telegraph departments as well as on the railways.

Compensation

Telegraphists' cramp is compensated by the state as an industrial disease in the following countries:

Austria. — It may entitle the victim to a pension in accordance with the operation of section 62 of the Labour Charter (Dienstpragmatik of 25 January 1914) and the regulations which lay down the manner of calculating the pension.

Italy. — By virtue of section 2 of the Code of Pensions Law which are peculiar to Italy (21 February 1896, No. 70), it is laid down that a person unfit for duty on account of injuries or disease contracted in the performance of duties has the right to retire on pension whatever may be his age and length of service. Nevertheless, according to information issued by the Ministry of the Postal and Telegraph Services, during the last five years none of the employees have been put on the retired list on account of telegraphists' cramp.

Switzerland. — Employees transferred into the railway services continue if possible to draw corresponding wages in their new employment; but in case of wage reduction every facility is allowed to ensure the deficiency being made up by the Pension Office, unless the employees should prefer to be given a partial pension calculated according to the part of the wages they have lost and the years of service at the time of their transfer. Where it is not possible to transfer these persons to different duties, they are treated in the same manner as a totally incapacitated person.

In the above-mentioned countries telegraphists' cramp is not regarded as an occupational disease.

It must, however, be notified compulsorily in Holland; and is a ground for compensation in Great Britain, Western Australia, Russia, and Japan.

In the United States telegraphists' cramp is not compensated in the following States: New York, Ohio, Illinois, Minne- sota, and no compensation is provided for by the laws at present in force. The laws of eight States including California, Connecticut, Hawaii, Massachusetts, Minnesota, Dakota, Porto Rico, and the Federal Government, as regards its employees, cover industrial diseases generally, either by naming them specifically or by defining the term, and telegraphists' cramp can be compensated by virtue of these laws.

The laws of 34 other States of the Confederation compensate only industrial accidents, and telegraphists' cramp is therefore not theoretically covered by these laws. Yet the interpretation of the word "accident" as an occurrence that could not be foreseen, dating back to a definite point in time and place, has caused some cases of industrial disease to be compensated as accidents when the date of onset of the disease can be attributed to a definite point in time and place. It is a matter of law and interpretation of the law.

On the other hand the constitution of the United States provides that matters affecting trade between States are not under the jurisdiction of those particular States but that of the Federal Government. Telegraphists certainly fall into the class of workers called "inter-State." Although there is not a Federal law of compensation, except for Government employees, there is a Federal Employers' Liability Act covering transport workers on railways between the States when employed on trade between States. The only step required to be undertaken by telegraphists who are employed on railways between States is to bring an action against their employers by virtue of the Federal Employers' Liability Act, which gives them favourable modifications of the existing regulations.

As regards trade re-education, the Federal Government in 1920 passed a law allocating certain credits to the States which could make up the sums necessary to provide the re-education of those persons who have been invalided either in trade or otherwise. Twenty-six States have accepted this offer, and it can be asserted that in those States a person suffering from telegraphists' cramp will receive the necessary re-education if he requests it in accordance with the regulations laid down. The question of the residence of the telegraphist and not the question of the "inter-State" nature of his work would be important at the time of his request.

Postal Service

The postal service does not involve a type of occupational disease different from that met with in analogous occupations.

The eyesight suffers a severe strain during the sorting of letters, particularly where this is done on the rail-
ways where the illumination is subject to frequent changes and where the jolting is severe.

The rural delivery service in remote regions is carried on under trying conditions, due chiefly to climate, with exposure to extreme degrees of heat, cold, and to falls of snow.

During work in the offices a considerable quantity of dust rises from handling large mail sacks especially after a long railway journey. Tuberculosis especially is very prevalent among office employees who work in bad hygienic conditions. Gilman Thompson has noted one or two cases of slight curvature of the spine produced by carrying, through periods of many years, heavy post sacks suspended by straps from one or other of the shoulders. Flat feet are also quite common among mail carriers. Postmen who have long journeys to make on foot in all weathers suffer the consequences of excess of fatigue and continual exposure to inclement weather. Neuritis of the hand has been noticed following on stamping letters. Men employed in the recently organised aerial post are subject to accidents common to all aviators but otherwise there is no specific hazard for them in connection with thus transporting mail.

Eisenstadt has reported that the most prevalent diseases among postal employees are those of the nervous system, the heart, and tuberculosis. Alcohol and venereal diseases in addition increase the risks of this occupation. Fatigue caused by sorting and the hunting out of addresses, bad hygienic conditions in the sorting rooms, irregular meal times, etc., evidently present conditions prejudicial to health, which cannot be overlooked.

Prophylaxis

In 1922 the employees of the postal service of the United States numbered 325,000. Medical examination on admission to the service is conducted by the Civil Service Commission. These examinations vary according to the class of employee; they are more severe for rural postmen and those employed in aerial services; for these last the medical examination requires physical fitness equal to that of military aviators. For admission to the postal services as mail carriers, the height should not be less than 5 feet 4 inches and the applicant should weigh no less than 135 lbs. with bare feet and ordinary clothes.

Medical examination has up to the present only been carried out upon selected groups; it is done gratuitously. Among the employees the most frequently observed causes of disability are flat feet, varicose veins, spinal curvature, hernia, glaucoma, tuberculosis, digestive troubles, etc. Medical examinations affecting discharges on account of disability, or for the assessment of pensions, are conducted by the United States Public Health Service.

In the United States Post Office a report was issued in 1922 of a careful study of the eye conditions of 4,785 postal employees in relation to the lighting of post offices, and many interesting facts were observed. It was found that the percentage of eye defects among workers was considerable, and that it bore quite a definite relation to such factors as glare, shadows, poor spacing and irregularity of lights, etc. As the work of the employees involves reading addresses, hunting for insufficient addresses in directories, puzzling out obscure handwritings, keeping accounts, etc., it is most important that this work should be done under the best conditions of lighting and as far as possible by daylight.

It was found that variations in the colours of the envelopes and inks add considerably to the visual difficulties, often straining the eyes and handicapping the worker. In the money order and registry departments, blue and red cards and blanks are used, which were found tiring to the eyes. The so-called "window envelope" (transparent envelopes) and glazed surfaced envelopes add to the difficulties of quick reading, requiring great concentration of vision. Gilman Thompson is acquainted with a postal clerk, a coloured woman, who recently in a speed contest sorted 30,000 letters in eight hours. While this of course was a maximum rate, it nevertheless gives some idea of the possibilities of eye strain among letter sorters, especially when speeding up in the holiday season, or on account of a delayed mail.

A later enquiry (1928) has shown that the improvement in lighting resulted in an increase in efficiency (especially in speed of sorting).

The following are the more important recommendations made by the Post Office Department as a result of this intensive study:

(1) There should be installed in the general workrooms and offices systems of totally enclosed units of the diffusing or light-directing type, giving a general intensity, when first installed,
of ten foot-candles approximately on a horizontal working plane 45 inches above the floor.

(2) All local lighting should be done away with.

(3) Wire screening at the backs of sorting cases should not be used on account of its effect upon the eyes, but should be replaced by two-inch wide wooden strips.

(4) New, post offices should be so constructed that during the daytime hours the maximum amount of work possible may be done under natural illumination.

(5) Post office blanks should be of a mat surface and light buff colour with characters printed in black.

(6) The eyes of employees should be examined once a year and any visual defects corrected.

(7) The relation of the separation cases, tables and desks to the lights should be such that no shadows fall on the working plane.

(8) To obtain the recommended intensity of illumination of ten foot-candles on the working planes, it would be necessary to use about two watts per square foot of floor area in the general workroom of the post office, the best spacing and mounting of these lamps depending upon the height of the ceiling and of the working plane.

(9) Care of the lighting should be placed in the hands of one man who should be responsible for the upkeep and care of units, cleaning them at least once a week and making measurements once a month with a foot-candle meter in order to see that the uniformity and constancy of illumination are maintained.

(New York).

Potassium

Potassium (symbol K) is very abundant in nature, its salts being found in vegetables, in sea-water, in rivers, etc. Potassium in a free state was obtained by Davy in 1807 by decomposing caustic potash by means of a powerful electric current. Industrially, it is obtained by methods similar to those utilised for the production of sodium (see article "Sodium and its Compounds").

It is sometimes manufactured from the tartrate which is brought to white heat in an iron retort. The potassium fumes are condensed in receptacles containing petrol which preserves the potassium from oxidation by contact with air. During the reaction there is also formed oxycarbide of potassium, which is explosive.

At the present time potassium is prepared industrially by an electrolytic method starting with the chloride.

Potassium is a metal which melts when not in contact with air. It has a silver aspect, is soft at an ordinary temperature, melts at 580° C. and evaporates at 720° C. with the production of greenish fumes. Potassium combines very readily with oxygen, resulting in the production of the oxide which together with water forms a hydrate. It is well known that a piece of potassium placed in water decomposes immediately, giving off hydrogen and great heat, with the result that the potassium at the surface of the water melts and burns simultaneously with the hydrogen.
Most of the salts of potassium are at present prepared with crude salts from the saline deposits of Alsace (Stassfurt salts), Spain, Chile, etc. A small quantity is also extracted from the washing water after washing dirty wool, from the residues of alcoholic fermentation of beetroot molasses and from marine algae, etc.

In the Stassfurt deposits below the bed of rock salt there are found beds of carnallite, which is a double chloride of magnesium and potassium, of sylvite, schonite, etc.

From the point of view of hygiene it is of interest to recall that one of the most serious problems in the Stassfurt district arises from the evacuation of waste waters rich in Mg.Cl., which, when discharged into streams, ditches, etc., have finally filtered through the soil, to a great distance, contaminating well-water sources of drinking water, spoiling fishing and interfering with the watering of cattle.

Rosenthal (1910) and later Wigand have studied the influence of climate in potassium mines on the health of workers.

Amongst other compounds of potassium may be recalled:

- The hydrate or caustic potash (KOH) prepared by adding to a boiling dilute solution of carbonate of potassium hydrate of calcium, or electrolytically, starting with potassium chloride. Combining readily with water, deliquescent on exposure to air, it has, in aqueous solution, a strongly alkaline reaction and easily causes saponification. It is employed in soap making, in glassworks and in the dyeing and washing of wools, etc.

- The chloride (KCl.) is found in abundance in the Stassfurt deposits (sylvite) or in the carnallite, together with magnesium chloride. It is used as a manure, for the preparation of other salts, in the electrolytic manufacture of caustic potash and potassium nitrate (conversion method), etc.

- Iodide (see article “Iodine”).

- The chlorate (KClO₃) is at the present time prepared electrolytically, starting with the chloride or directly from the carnallite (in Germany). The chlorate is an oxidising agent utilised in the following branches of manufacture: black gunpowder, Swedish matches, fireworks, etc. in dyeworks, for oxidising certain substances in the production of aniline black. It is currently replaced by sodium chlorate, which is less expensive (see article “Chlorates”).

The nitrate (KNO₃), or nitre, comes from the East Indies and especially from Ceylon. It is utilised in the manufacture of explosives because it does not contain perchlorates. It is likewise used as a manure.

In India the soil containing the nitrate is washed with water and then left to evaporate in vats which are heated in large boilers. The crystals of crystals which form on the surface of the liquid are then separated. These crystals, consisting of potassium nitrates, magnesium, sodium chlorides, potassium, potassium sulphate, are treated in special factories with hot saturated solutions of sodium chloride and sulphate. In this manner the potassium nitrate only passes into solution and is separated almost in a pure state simply by cooling. It is refined with nitre by boiling it with the mother liquors and filtered in a hot state under pressure. The filtered liquid is then left to cool and the nitrate becomes separated out in fine crystals. It is centrifuged and the mother liquors are re-utilised.

The sulphate (K₂SO₄) is used as manure, in the manufacture of alum, of glass, and of carbonate of potassium, etc.

- The carbonate (K₂CO₃), or potash, is obtained in large quantities from wood ash, ash of plants and residue from manipulation of beetroot, or by the Leblanc method starting with the chloride or sulphate of potassium. It is used in soap making, in glassworks and in the dyeing and washing of wools, etc.

- See also articles “Alkalis”, “Chromium and Chromates”, “Cyanogen and its Compounds” and “Sodium and its Compounds”.

**Sources of Risk**

In addition to the injuries common to all underground work, mining is a source of cutaneous lesions (dermatitis), liver troubles and, if the gangue contains silica, respiratory lesions (silicosis).

If the work is dusty the presence of more than 1 per cent. of potassium nitrate in the ore leads to anaemia, headaches and in the long run organic debility and nephritis. If the workers absorb the nitrate they show a heavy loss of chlorides (examination of urine).

Medical literature contains particulars of several cases of explosion which have been caused—chiefly in chemical
laboratories — by potassium. In one case explosion was due to a potassium-bromoform mixture. The explosion occurred during distillation owing to ignorance of the fact that organic chlorides in contact with alkaline metals give rise to explosion. In another instance the explosion was due to a molten potassium-sodium alloy. In this instance, also, the explosion was a very serious one. Storing of this mixture calls for precautions similar to those to be taken in the case of phosphorus. In a third instance, potassium had been mixed with pentachlorethane. Slight percussion is necessary to cause an explosion. Violent percussion, on the contrary, merely provokes slight explosion, or even no explosion at all. In other cases, mixtures of potassium and oxalylchloride or potassium and benzene (explosion in this case being due to the formation of peroxide by auto-oxidation) were to blame.

Potassium has a caustic action on the skin.

Electrolytic production of potassium compounds causes dermatitis: Oppenheim has observed twenty-six cases in the electrolytic manufacture of potassium chlorate.

Antimonide of potassium has given rise to explosion merely by the simple action of breathing on the part of the person examining it. The explosion resulted in burns of the eyes and face (Regnault).

The hydrate of potassium causes chemical burning of the skin and mucous membranes. Its solvent action on albumin, its capacity for saponification when mixed with fat substances and its ready combination with the water in the tissues explain its action being more caustic and deep-seated than that of the acids and also constitutes the reason why ulcers caused by it heal with difficulty and leave extensive scars. Dermatitis is localised chiefly on the backs of the hands, the forearms, the face and ears. When clothing is soaked in the lye the injury may, however, attack any part of the body.

The carbonate possesses a slighter irritant action than the hydrate, but it aggravates injuries caused by other substances. There are records of injuries due to solutions of carbonate of potash and soda in the wool industry (washing) during mordanting, in woodworking (polishing with carbonates and bichromate), etc. These injuries were generally forms of dermatitis.

The preparation of permanganate of potassium by starting with pyrolusite is said to have been the cause of a clinical picture recalling that of encephalitis lethargica (von Jaksch), which Strumpell describes as "an amyostatic complex". Ocular injuries, sometimes with serious sequelae, have been described by Cords, Kassner, etc. Potassium chloride is, to be regarded as a cause of anaphylactic shock rather than of occupational poisoning. From the toxicological point of view, it constitutes a blood poison. It forms methaemoglobin and sets up very serious forms of jaundice followed by anuria and coma.

For chlorates see that article. The salts of potassium possess a real but not very violent toxic action; even when they are not combined with a toxic acid (cyanides, arsenates, etc.). They are more especially muscular poisons. This toxic property must not however be exaggerated (Kohn-Abres). Frouin and Monté (1907) have studied the action of salts of potassium experimentally. They found that they caused renal sclerosis, hepatic cirrhosis with ascites, etc.

For hygiene, see articles "Alkalis", "Chlorates", etc. As regards legislation, under Argentine and French law women are excluded from the manufacture of potassium and salts of potassium. French legislation also prescribes their exclusion from the manufacture of potassium hypochlorite. In Belgium, young persons under sixteen years of age may not be employed in the manufacture of javel water. In Italy, boys under fifteen and women under twenty-one are excluded from employment in the manufacture of potash and salts of potassium.

Compensation for injuries due to potassium compounds is provided in Bulgaria (alkalis); Switzerland (alkalis, potassium chlorate); Japan under a general formula "harmful or toxic substances"; and likewise in countries which provide compensation for forms of dermatitis due to dusts and liquids. See the various articles, "Alkalis", "Chlorates", "Sodium and its Compounds", etc.; also "Occupational Diseases: Definition and Compensation".

BIBLIOGRAPHY

•••
Pottery Industry

"Pottery" is a wide term, including any article made of clay (or a mixture of clay and other substances) and hardened by fire, glazed or otherwise. All common articles, such as tiles, drain pipes, bricks, crockery, etc., are thus included.

In the manufacture of pottery there are two component parts: (1) a porous substance known as the "body", which may be made either of clay unmixcd with other ingredients, or composed of several, such as Cornish stone, china clay, combined, in the case of British china, with calcined felspar, generally containing some foreign matter. These distinct kinds of clay exist, primary and secondary — the former being derived from pure felspar, called kaolin or china clay, and the latter, if derived from pure felspar, generally containing some foreign matter. In the secondary clay, the sharp edges have been worn off and it has acquired the property of plasticity. These secondary clays are called "ball clays".

Manufacture of Earthenware and China

Technical Data

After the clays have been weathered, the raw materials of the "body" are ground up, mixed in a wet state and afterwards put through a filter press, from which they emerge in cakes or lumps. Water is, as a rule, added prior to grinding, so that the process is a wet one.

The lumps of clay must be freed from air bubbles, and this is effected by mechanical treatment in a pug-mill and by a manual process known as "wedging" when which is necessary. The clays are next carried to the benches in the potters' shops, where it is moulded. Various processes incidental to this are carried on, such as "throwing", that is, shaping the clay by hand while it revolves on the potters' wheel; "turning", that is, finishing the newly moulded article by turning on a lathe, and "pressing", as, for instance, hollow-ware pressing — articles such as jugs, ewers, etc. — by pressing into moulds, or flat pressing, shaping similarly dishes, plates, saucers, etc.

After being shaped, the clay articles, with their appropriate moulds, are set aside to dry, either on racks in the general workroom, or in chambers artificially heated by a coal stove, or by a battery of steam pipes, known as "drying" stoves. When the articles are sufficiently dry, they are detached from the moulds and placed on long boards which are carried on the shoulder to the next department. After moulding, the clay article is "fettled", that is, trimmed and finished.

"Towing of earthenware" is a special process of fettling applied to earthenware, each article being placed on a mechanically driven jigger (i.e. a vertical spindle, driven by mechanical power, on the end of which is fixed a mould, revolving rapidly in a horizontal plane), while a piece of material, such as tow, placed against the article, smooths it; much dust is haled in this operation, were there no locally applied exhaust ventilation.

"Biscuit placing" is the next process, i.e. placing the moulded and fettled articles in fire clay boxes or "saggers". In order to prevent the articles buckling, they are embedded in sand, and, in the case of china, in powdered flint. Exposure to the dust from powdered flint will set up silicosis, and this embedding in flint of flat china ware is the most dangerous dusty process in the industry. After setting and firing, the biscuit oven is drawn, during which there may be exposure to excessive heat. After withdrawal, the sand and dried flint adhering to the articles have to be removed. This can be done crudely by knocking or brushing, in which processes a certain amount of flinty dust will be given off, for which locally applied exhaust ventilation is essential. Nowadays
the danger from this source has been minimised in the case of china by placing the articles to be cleaned or scoured in racks inside a drum, together with a small quantity of bits of broken ware which, when they move as the drum revolves, clean the articles by friction. The axle of the runner is connected with an exhaust fan.

For manufacture of tiles, see page 716.

Glaze process. — The glaze is sometimes ready prepared or stored for pottery in casks. When a "charge" of glaze is required, a quantity of the lead compound is weighed out and mixed with the necessary silicates and silico-borates. When a raw lead glaze is used, the operation is carried out in the lead house, where the mixed materials are ground in a wet state. The articles are then dipped into the creamy mixture. Any ingredients soluble in water, e.g., borax, must be "fritted," i.e. fused with some of the siliceous matter, to form a crude glass, before they are ground and added to the other materials. In many cases, the lead compound is introduced into the frit; if the proportion of silica to lead in such a frit is high enough, a lead silicate is formed which is sparingly soluble in dilute acids and is very much less dangerous to health than the raw lead compounds used in glazes in which the borax and similar ingredients only are fritted.

Biscuit ware is almost invariably dipped by hand, and, after removing it, the worker gives his wrist a turn to get rid of excessive glaze. Each dipper has one or more assistants — those handing the ware to him being called the "putters up" and those taking the ware from him the "takers off." After dipping, the pieces of pottery are placed on boards to dry; the cleanliness of these boards is important. In large factories the dipped ware is placed on the shelves of an apparatus known as a "mangle" — a series of shelves attached to an endless chain which moves slowly through a heated chamber. Many articles as soon as they are dipped are ready for the glost oven, where the glaze is converted into a glassy coating, but, before they are fired, they are "ware cleaned," i.e., inequalities in a layer of glaze are removed, superfluous "glaze" is removed from the bases, etc., and the risk run by the workers so engaged, most of whom are women, would be considerable in the absence of local exhaust, except where the whole of the ware cleaning is done by such moist methods as will entirely prevent the evolution of dust.

"Glost placing," i.e., placing the ware in saggers and removing it into the glost oven, is usually done by men. Subsidiary operations are the arrangement of the thimbles, stilts and spurs, which have to be inserted and removed to prevent one piece of ware becoming attached to another. From the glost oven the ware goes to the glost warehouse, where the articles are sorted or polished.

Of the decorative processes, those carried out on the clay or biscuit involve, as a rule, no use of lead whatever. By far the most important of these is the printing process on biscuit earthenware; the design is engraved on a copper plate or roller and the desired colour, mixed in an oily medium, is worked into the engraving, from which a print is then taken on tissue paper; this is applied to the ware and rubbed on; the paper is then washed off leaving the colour behind adhering to the biscuit ware, which is then generally fired in a muffle-kiln (called hardening-on kiln) to drive out the oil, etc.

Glazes in which the pigments are mixed are known as majolica glazes; these generally contain a high proportion of raw lead and should therefore be handled with special care.

On-glaze decoration involves the use of enamel colours which usually contain a freely soluble lead flux. Ordinary painting with enamel colours, in an oily medium, involves no special risk; but where these enamels are blown on to the ware (aerographing) or applied in powder form to a previously oiled surface (ground laying, colour dusting), the use of local exhaust and other precautions are necessary. One means of applying coloured designs on glazed ware is by means of lithographic transfers, and although the manufacture of the transfers is not necessarily a pottery process, it is so closely allied to it that it is included generally in regulations applying to the pottery industry. After the design has been engraved on stone and the pattern printed in an oily medium on duplex paper, the required colours are dusted on dry; each colour in the design requires a separate passage through a lithographic printing machine followed by dusting with the appropriate colour and subsequent cleaning off of superfluous colour; efficient local exhaust is required at each dusting and cleaning operation. The finished sheets, known as ceramic transfers, go to the "lithographing shop" of the pottery where they are cut up; the thin tissue with the colour
on it is separated from the stiff backing on the duplex paper and applied to the ware, the paper being ultimately washed off leaving the colour design on the ware, just as in the simpler printing process described above.

**Dangers**

The pottery industry is one causing a high rate of morbidity and mortality, both in the processes giving rise to dust, and lead poisoning. Incidentally, too, the variations in temperature to which some of the workers are exposed give rise to rheumatism and diseases of the chest. A further danger to young persons arises from the lifting and carrying of heavy weights, notably in warehouses and packing departments. The degree of sickness, however, is very much modified, according to the manner in which the industry is practised — whether in a factory or as an uncontrolled home industry, as described by Chyzer in Hungary in his brochure *Des Intoxications par le Plomb*, the conditions noted were shocking, in respect of the frequency with which he observed paralysis, epilepsy — even among children — and pernicious effect on childbirth. And in the case of factories, conditions existing ten, twenty and thirty years ago were no doubt very different from what they are to-day. This is shown by figures in the statistics given later. In the same way, therefore, in which a malady may be said to be severe, moderate, or slight, so the evolution of an industry such as the pottery industry in regard to illness may also be referred to as being severe, moderate, or slight. The pottery industry is a large one, and close study of the cases that have occurred has been of the greatest help in elucidating the causation, e.g. of lead poisoning, from inhalation of dust and not from absorption through the skin.

**Dust**

The dust danger is incidental to all processes in the making of the body — in compounding and mixing native clays with Cornish stone, china clay, and calcined flint. The early process of grinding and mixing the raw materials of the body is generally done wet. In the work carried on in the potters’ shops, dust arises from the scraps of clay, which dry upon the floor; this is, however, much more marked after the clay articles have been dried. After moulding, the article is trimmed and finished — the process known as “fettling” — and if the articles are what is known as “white hard” dust is given off in the process. Quantities of dust are given off in the towing of earthenware and certain other fettling processes.

For the first firing, from which the ware emerges in the state known as “biscuit”, many articles are embedded in siliceous material, some of which adheres to the ware and has to be brushed off. For earthenware, sand is commonly used as a bedding material and the subsequent earthenware biscuit brushing gives rise to some dust. In connection with china and other ware for which powdered flint replaces sand as a bedding material, there may be a number of processes in which dust is evolved; these include the placing prior to firing, and subsequently: (1) emptying the ware from saggers, (2) knocking off the flint therefrom, (3) flat knocking, (4) fired flint sifting, (5) emptying baskets of ware for scouring, (6) scouring, (7) fine brushing, (8) bat. In all of these processes dust is evolved.

**Lead**

Apart from the risk of dust arising from uneven floors or benches and from cleaning or brushing these down with insufficient moisture, the following special dangers require mention.

In dipping the ware the glaze is splashed on to the face and overalls of the dipper and his assistants, and the ware cleaners. These splashes soon dry, and the overalls may become so stiff with the glaze that every movement — as in carrying boards — causes it to crumble off as dust, and so become inhaled from the air. Ware cleaning may have to be done so rapidly as to prevent all the dust being carried away by the exhaust.

Dipping boards, unless thoroughly washed after use, create dust when wet. Dipping the ware is placed on them or removed from them when they are handled and placed on, or taken off, the stillage bars, and when they are stacked. Danger arises at the mangle owing to dust, and the glaze placed makes dust when removing the ware from the board and placing it in the sagger. The very dangerous practice — formerly almost universal — of rubbing the bottoms of cups and other articles together, or rubbing them on a piece of leather fixed round the chest, is now replaced by removing the glaze with a moist piece of flannel.

In the decorative processes — ground...
lathing and colour dusting — the danger is from dust containing a high percentage of lead from the enamels used (30-50 per cent.) and in colour blowing from the spray, holding in suspension, as it does, the same enamel colours. A further danger in some of the decorative processes where turpentine or turpentine substitutes are used is the occurrence of dermatitis.

Results of Examination of the Air

Dusty processes. — Aspirating a known volume of air at breathing level through a filter filled with cotton wool, separating the dust from the air, and subsequently (with the usual precautions) weighing the dust, the following are some of the results obtained by G. Elmhurst Duckering:

<table>

American authorities summarise as follows the risks met with in the pottery industry: (a) Mixing of materials for preparation of the fritted glaze; grinding of the fritted glaze; mixing the latter with lead or other
substances; sieving; suspension in water of the product obtained. Risks: shovelling; weighing; transport of the glaze; grinding; sieving of the glaze. The risks are diminished when proper precautions are taken.

(b) Dipping of the piece in liquid glaze; drying; transporting to the ovens. Risks: splashes of glaze on the arms of the worker, on his clothes, and on the floor of the workroom. The splashes, once dried, are transformed into powder, which contaminates the surrounding atmosphere. Shelves should be made of cement and damped. The assistant dippers, who clean the pieces of ware after dipping, and place them on the shelves for transport to the ovens, are exposed to dust from these shelves and from the dried ware.

c) Firing. Workers are sometimes engaged wholly in placing the ware in saggars; sometimes they are also obliged to remove the excess of glazing material (a very dirty operation). Risks: lead dust. This work should be done while the pieces of ware are still wet.

(d) Decoration; preparation of the colours; application of the first coating of colour with a pad or by the spray method. This process should be carried out under a hood furnished with a ventilating apparatus for removal of dust and fumes. Where such apparatus is provided and functions adequately, the danger is very slight. Risks: this work is extremely dangerous unless the decorating processes are effected in the manner just referred to.

e) The manufacture of household articles, etc., in yellow earthenware, containing from 40 to 50 per cent. of a mixture of white lead and minium, as well as articles containing 10 to 50 per cent. of lead, work in the course of which workers are exposed to the risk of lead poisoning (dust).

As regards glazing with a fritted lead glaze, American authorities are of the opinion that when carefully prepared these glazes are practically insoluble in almost all the diluted chemical reagents. In this manner the workers would appear to be safe from the possibility of lead poisoning. The use, therefore, of fritted glazes reduces the danger of lead poisoning, which becomes confined merely to the operations involved in the preparation of the fritted compounds. Fritted lead glaze can be used by itself or in combination with various other materials. The quantity of soluble lead present in the glaze is then diminished and the danger from lead poisoning reduced.

STATISTICS

In Belgium Schoofs (1913) made a study of pottery processes in which cases of lead poisoning occurred, but no statistics are available in regard thereto. The improvements introduced in regard to methods of work, the elimination of lead from certain enamels used, together with attention to personal cleanliness, have certainly contributed to the reduction of the frequency of lead poisoning in the industry.

In France the notification of lead poisoning, rendered compulsory by the Act of 1919, has resulted in the return of 23 cases in 1923, 23 in 1924, 21 in 1925, 45 in 1926, 25 in 1927, 29 in 1928, 33 in 1929, 16 in 1930, 14 in 1931.

An enquiry made by Heim de Balsac, Agasse-Lafont and Feil (1924) into the lead risk amongst workers in pottery and porcelain factories, has revealed the existence of the lead line amongst 50 per cent. of the workers, who had all red corpuscles with punctate-basophilia. No worker, however, had suffered from colic, though certain of them had been in the factory for 37 years. In the departments of the factory other than the enamelling department, the presence of the blue line and punctate basophilia was not so frequent, though far from being negligible.

In Germany several enquiries made over some time have served to draw attention to health conditions in the pottery industry.

An official report for the period 1900-1903 dealt with 13,968 establishments and covered 312,570 workers. 42,664 of whom were women, and 4,931 young girls. 10,362 workers (3.3 per cent.) in 1,672 establishments were using lead glazes. The average figures for the period 1900-1903 are as follows:

<table>
<thead>
<tr>
<th>Nature of manufacture</th>
<th>Number of firms</th>

The same occupational categories: Local Sickness Fund, Leipzig
According to the Leipzig Sickness Fund, the pottery workers showed a rate of days of sickness which exceeded by about 10 per cent. the average rate. The morbidity among the workers was higher than for all the members of the Fund together; about 40 per cent. higher for respiratory diseases; 20 per cent. for diseases of the digestive system and about 5 per cent. for diseases of the skin. Forms of rheumatism were equally more frequent, as well as external lesions which were about 20 per cent. below the average (Leymann).

The Federation of Workers in the Porcelain Industry have supplied "morbidity" figures covering the period 1907-1913. Cases of sickness amounted to 29.7 per 100 members, with 700 days of sickness. Amongst cases of sickness were found diseases of the throat (0.54 per cent.), catarrh of the upper respiratory passages (0.86 per cent.), lower (0.025 per cent.), diseases of the lungs (2.58 per cent.), tuberculosis (0.59 per cent.), diseases of the nervous system (1.147 per cent.), of the senses (0.774 per cent.), influenza (4.31 per cent.), rheumatism (4.4 per cent.), lead poisoning (0.112 per cent.), diseases of the digestive system (2.67 per cent.), of the kidneys (0.43 per cent.), wounds (2.51 per cent.), etc.

In the royal china factory at Meissen, employing an average of 550 workers, there were during the period 1904-1915, 27 cases of sickness per 100 workers, with 914.1 days of sickness. Amongst the cases of sickness, affections of the respiratory passages amounted to 3.6, 1.6 of these being tubercular. Koelsch found that in the Bavarian potteries high temperatures and humidity might furnish an explanation of the high incidence of respiratory diseases and disease forms due to cold. He also found out that the suspension of dust in the atmosphere of the workrooms in the potteries contained 20 per cent. and over of the dust in the air.

Amongst the porcelain workers Koelsch frequently met with conjunctival catarrh, catarrh of the pharynx, and respiratory diseases, though complaints as to serious ill health of this kind were rare. 9 in 500 male workers (1.8 per cent.) and still fewer amongst 500 women workers. These troubles consisted in obstructive forms of catarrh of the respiratory passages and asthmatic affections. Medical examination showed the existence of three distinct types; acute chronic irritation of the respiratory passages, subacute forms and tuberculosis. Men were found to be more frequently attacked than women, and the workers most frequently affected were the turners. Tuberculosis affected 3 per cent. of the men and 10 per cent. of the women. It is obvious that the incidence of this lesion is in strict relation to the quality of the dust encountered (Koelsch, loc. cit.). In cases evolving slowly, however, the disease followed a benign form. Whilst the number of cases of respiratory diseases due to dusts was very high, and even after five years of work reached 30 per cent. amongst the men and 30 per cent. among the women of ages averaging from thirty to thirty-five, clinical examination revealed no characteristic results, and the differential diagnosis between pneumoconiosis and tuberculosis is extremely difficult. Thiele has also studied this question and, on the basis of 668 examinations made under fairly difficult conditions and without the aid of X-rays, was only able to find 6 cases of tuberculosis amongst 100 workmen and 5 amongst 100 women workers. Lead poisoning was very rare.

Lehmann likewise does not believe that a high incidence of tubercular infection exists amongst the workers in this industry.

Harms, with the aid of X-rays, found amongst 41 women workers in the porcelain industry 31 cases of pneumoconiosis (75.7 per cent.) and Roessle found 29 cases amongst 45 women workers examined (44.4 per cent.).

The Jena school are of the opinion that porcelain dust may in the long run exert an irritating action, with formation in the pulmonary tissue of a reactive tissue, which may easily be confused with tuberculosis. It also lays stress on the concomitant action of other factors, such as social conditions, general conditions of hygiene, as well as personal circumstances.

Holtzmann and Harms have studied the question of inhalation of dusts amongst workers in the porcelain industry (1933). Their enquiry led them to the conclusion that subjective symptoms are in general very slight, not only at the beginning of the career (ten years), but even later, and that there is no evident relation between the duration of inhalation of dust and the outbreak of bronchial symptoms. In the majority of the cases physical symptoms are almost negative. Under the X-rays these are existent only in advanced cases, which, however, cannot be said to present a characteristic peculiarity. The authors in question formed the conclusions of De la Camp, and admit that symptoms of pneumoconiosis without complications are most usually very slight and even negative. Amongst the complications found were chronic bronchitis and acute or chronic broncho-pneumonia. Tuberculosis is very rare in the Baden factories, and therefore of slight importance amongst these workers. Where it occurred, it followed a benign course.

Meyer (1924) recalls that in the small potteries of Hesse there is used as a glaze no oxide of lead (litharge) but lead sulphite (galena), probably because the latter has a lower point of fusion. Since 1917 and up to 1924 these workshops only used minium for glazing. The danger exists in the fact that with this composition a greater quantity of lead in the form of oxide remains in the receptacle than is the case with other glazing materials.

In 1925 Gerbis examined 128 workers in a pottery factory who had come in contact with glazing products; 23 were not twenty years of age; 42 were under thirty; 54 under sixty, and over that age. Gerbis found that the best conditions from a
Health point of view were met with in the workshops where fritted glaze was handled, and in those workshops where crude glaze was manipulated when the work was done in a wet state. He also was impressed by the importance of personal cleanliness as a means of prevention.

Of 85 workers 19 had already suffered from symptoms of lead poisoning; colic, 8 cases; lead line, 12; punctate basophilia, 5; digestive derangements, 4; nervous derangements, 1. Out of 43 women workers 4 were found to have suffered from lead colic; 18 had lead line; 17 punctate basophilia; while 6 suffered from digestive derangements and 7 from nervous troubles.

The total number of persons, in Great Britain, employed in the china and earthenware industry, is estimated at about 65,000, of whom about 25,000 are employed in processes involving exposure in some degree to dust of clay and flint, and about 7,000 in processes involving risk of lead poisoning.

Dr. Middleton has furnished the following account of the results of an investigation undertaken by the Home Office in 1925 into the incidence of silicosis in the pottery industry in North Staffordshire:

"The work was carried out by two medical men with special knowledge of silicosis, with the assistance of a medical radiologist. A number of workers were selected from some thirty occupations in which the workers are exposed to inhalation of dust. In all, 532 persons were examined clinically, and 230 were X-rayed.

Evidence of silicosis was found in those employed in china placing, where dry flint is used, and in the subsequent incidental processes; in the use of sand as a placing material; in the milling of flint and in the sliphouse; in processes of manipulation of the body in the clay state; and, in addition, in saggar making and in ware polishing; in which exposure to flint dust is only incidental. The following table shows the incidence of fibrosis of the lungs as found by clinical examinations in certain of the groups of workers; the numbers examined radiologically, and those in whom evidence of silicosis was found, in the same groups:

* An interesting result of the investigation is the evidence of the incidence of silicosis amongst workers whose occupations expose them to the inhalation of dust consisting of the mixed ingredients of the composite body of the ware in which flint occurs. The evidence tends to indicate that free silica, in the form of flint or quartz, is the most important factor in the causation of serious respiratory disease in the industries. It is obvious, when the occupations are considered in which silicosis was found, that the degrees of risk vary within very wide limits; thus, the group of occupations in which dry flint is used in china placing, scouring, etc., show a high incidence of silicosis amongst those examined. In the case of the female workers the proportion of persons employed for more than twenty years tends to fall, consequently the incidence of silicosis amongst them, while continuing at work in the industry, is lower than amongst the male workers. It is significant that in the occupations where the incidence of silicosis is high,
it becomes evident at an early stage in the occupational history of the workers. This feature may be regarded as a true measure of the severity with which silicosis is likely to occur under given conditions.

An investigation was made into the atmospheric dust in certain branches of the pottery industry, to provide a connecting link between the state of health found by examinations of the workers and the hygienic conditions under which their work is carried on.

From the point of view of the dust hazards the occupations in the industry fall into four groups: (1) those in which the raw materials are handled; (2) the manipulation of the composite body of the ware; (3) the use of flint or sand for embedding the ware in firing, and its subsequent removal from the ware; (4) occupations involving exposure to other dusts, as in mould- and squeaker-making.

The dust samples were taken with Owens' dust-counter at the breathing level of the worker.

"In the milling of flints, for use in pottery manufacture, the most dangerous process is that of crushing the flints in a machine crush roller. A sample taken to the ward of such a machine gave 4,314 particles in 1 c.c.; 8 were over 1,000; 11 were over 500, and 4 were under 500 particles. Of these, 6 gave counts of over 2,000 particles in 1 c.c.; 8 were over 1,000; 11 were over 500, and 4 were under 500 particles. The proportion of mineral (flint) particles in the counts varied from 15 to 50 per cent.

In the process of placing china ware in flint for firing 29 samples were taken. Of these, 6 gave counts of over 2,000 particles in 1 c.c.; 8 were over 1,000; 11 were over 500, and 4 were under 500 particles. The proportion of mineral (flint) particles in the counts varied from 15 to 50 per cent.

"In china potters' shops 8 samples gave counts from over 3,000 to over 7,000 particles in 1 c.c., the proportion of mineral (composite body) varying from 15 to 80 per cent. This series of dust counts is sufficient to indicate that a source of danger exists in workrooms in which the china body is in the damp, or even wet, state. The processes of taking the fired china ware from the saggers and removing adherent flint dust from it produce much dust. The counts of 13 samples taken at these processes range from over 5,000 to over 11,000 particles in 1 c.c., the proportion of mineral (flint) being from 20 to 80 per cent.

"In the manufacture of earthenware, dust is produced in fashioning the ware from the body in the potters' shops, and in toning. In 18 samples in this series the counts range from over 300 to over 2,000 particles in 1 c.c. Some of these represent what appear to be definitely dangerous atmospheres. The processes in the manufacture of tiles, sanitary earthenware and electrical fittings are similar and gave similar results to those found in the manufacture of earthenware."

In Great Britain mortality statistics, have been carefully prepared by the Registrar-General, who, every ten years, has surveyed the mortality of men in a large number of occupations, and he has adopted a comparative mortality figure in regard to twenty-two different causes of death in all the industries.

The following is the comparative mortality figure of males aged twenty-five to sixty-five years in 1910-1912 from: (1) all causes; (2) phthisis; (3) gout; (4) lead poisoning; (5) diseases of the nervous system; (6) bronchitis; (7) pneumonia; (8) other diseases of the respiratory system; and (9) Bright's disease, among (a) all occupied and retired males, (b) coal miners, (c) printers, (d) potters, (e) dock labourers, and (f) cutlers:

From these it will be seen how much in excess is the mortality from phthisis, respiratory diseases, and lead poisoning. Dr. Tatham, the Superintendent of Statistics, wrote as follows of the potter in the decennium 1900-1902:

"Pottery, earthenware, etc., manufacture. — Between the ages of twenty and thirty-five years the mortality of potters falls below that of occupied and retired males generally; at every other age, however, it shows an excess which amounts to no less than 74 per cent., between ages 30-50."

1 The comparative mortality figure represents the number of deaths that would have occurred if the occupational death rates from the several causes and at the several age-groups had been operating upon a sample of the general male population enumerated at the census of 1911, which at that time (1900-1909) produced 1,000 deaths. This standard population is 71,065.
POTTERY INDUSTRY

forty-five and fifty-five years, and to 66 per cent. between ages fifty-five and sixty-five years. In the main working time of life the comparative mortality figure is 49 per cent. above the standard. The principal excess falls under the head of respiratory diseases, for which the mortality figure is nearly thrice the standard. There is also a considerable excess in the mortality from phthisis, from nervous and circulatory diseases, and from suicide. These workers are also specially liable to lead poisoning.

Lead. — In Great Britain, fortunately, excellent statistics as to morbidity from lead poisoning in the potteries are available for more than a quarter of a century, owing to the obligatory notification of lead poisoning (and certain other forms of poisoning) required, first, under the Factory and Workshop Act of 1895. These statistics have been kept on a uniform plan for many years past, and from time to time (when incidence of poisoning had to be closely watched) a census of persons employed in the different processes was taken, so that an attack rate per thousand employed in the different processes could be obtained. The pottery industry in Great Britain comprises seven main classes: china, earthenware, tiles, majolica, Jet and Rockingham, china furniture and electrical fittings, and sanitary ware. These can all be separately dealt with. First, however, figures may be given from 1901 onwards of the actual number of cases reported:

Years | All causes | Tuberculosis | Bronchitis | Pneumonia | Chronic nephritis
--- | --- | --- | --- | --- | ---
1901-1911 (average) | 777 | | | | 
1912-1914 | 571 | 49 | 474 | 146 | 221
1915 | 472 | | | | 
1916 | 471 | | | | 
1917 | 146 | | | | 
1918 | 221 | | | | 
1919 | 141 | | | | 
1920 | 230 | | | | 
1921 | 97 | | | | 
1922 | 87 | | | | 
The raised figures relate to deaths.

The table at the top of page 707 gives the number of reported cases and the proportion of cases to persons employed, in the several classes of earthenware and china works, and in the various processes, from 1901 to 1911.

The figures in this table show that the greatest risk incurred is in the earliest processes to dippers, and to their assistants, the ware cleaners, and also how, by successful application of preventive measures in the shape of exhaust ventilation, periodical medical examination, and, finally, substitution of leadless or low solubility glazes for the raw lead glazes formerly used, the danger from lead poisoning has been greatly reduced. In 1925 it was stated that practically no cases of acute plum-bism were occurring, but that such cases as were reported were due to the sequelae of lead poisoning — e.g. chronic Bright’s disease, cerebral haemorrhage — contracted under the unsatisfactory conditions that prevailed many years ago.

It will be seen that the pottery figures show a marked diminution in morbidity without a corresponding diminution in mortality. This is partly due to the fact that cases such as those just mentioned sometimes do not become included in the statistics until after death, when as a result of official enquiry into the cause of death the fact that it was ultimately due to or hastened by lead poisoning is brought to light.

In Hungary, B. Chyzer studied (in 1908) the incidence of lead poisoning amongst pottery workers, and he has drawn attention to the incidence of cases of tetanus, several of which were met with amongst the children of pottery workers. The incidence of tuberculosis was connected by this expert with the action of quartz dust. He found lead poisoning to have occurred very frequently, and with very serious consequences.

In Italy, Guidelli effected an enquiry into the pottery industry at Laveno, where he met with 8 cases of lead poisoning per 100 workers. The enquiry dealt with 500 workers. In 1908 R. Marcello studied the same industry in Sardinia, and in 1907 Pieraccini published the results of a very thorough enquiry carried out in Tuscany. He examined conditions in all branches of
the pottery industry, and studied not only the hygienic and sanitary conditions of the workers, but also several improvements made in industrial technique in a large factory in the district, and he was thus able to bring to light the favourable result is that tuberculosis in all forms has the protection of the workers' health. The industry.

According to Levitzky, 50.7 per cent. of the turners suffered from some form of respiratory diseases. As the result of experience in Russia, the use of a wet sponge in the polishing of ware is said to be productive of good results.

An enquiry made in 1925 amongst the pottery workers in four villages of the district of Jegorjewitz (Government of Moscow), who were engaged on home work, and 24 of whom were submitted to medical examination (17 had worked over periods varying from eleven to fifteen years) showed that 4 only were free from symptoms of lead poisoning.

In Sweden an enquiry carried out in 1928 by the Department for Social Affairs covered 6 factories; 71 persons were examined, 39 men and 30 women over eighteen years of age, and 2 women under eighteen. Amongst these, 29 were engaged in finishing and dusting off, 6 in warehouse work and in grinding, and 6 in fritting. In 4 factories only lead glazes were used, and in 1 only leadless glaze.

The enquiry revealed a single case of lead poisoning, affecting a dipper who had been working for fifteen years. Another worker had been treated thirty-eight years previously for a form of lead poisoning, but at the moment of the enquiry he showed no symptom of poisoning. Further, amongst 42 per cent. of the individuals examined, slight symptoms only, due to the chronic absorption of lead, were met with: pain in the joints (7); colic (5); constipation (2); headache (5); blue line (6); trembling of the hands (1); radial-paralysis (1); anaemia (5); blood-pressure above 150 mm. (8); red corpuscles with punctate-basophilia (up to 300 and over per million) (23); albumen in the urine (2).

The state of health of the workers was recognised to be better in those factories which used only fritted lead. The workers most exposed to risk seemed to be those engaged on fritting and dippers.

In the United States enquiries into the pottery industry have been carried out by Hamilton (1910-1911), Hayhurst (1914), and the majority of them contain high proportions of soluble lead. Out of 107 samples 73 per cent. contain over 10 per cent. of soluble lead, and 11 more 20 to 50 per cent. Similarly, the cleaning of enamelled ware is often executed in America after a day spent in dipping, and in this way the operation is an extremely dangerous one.

In 1911 the conditions in potteries were very bad, especially in the glazing and decorating departments: lack of cleanliness, dry-cleaning of the shelves, etc. Hamilton found that amongst the 1,100 male workers in the potteries of New Jersey and Ohio in 1911, there were 87 cases of lead poisoning, and amongst 400 women workers, 57 cases.

The enquiry made by Hayhurst in 1914 affected 47 factories of the State of Ohio, giving employment to 8,146 workers, 2,555 of whom were exposed to the risk of lead poisoning, and 109 of whom showed symptoms of poisoning.

The enquiry made by the Public Health Service in 1919-1920 covered 92 factories in New Jersey, Ohio, Western Virginia, Kentucky, Tennessee, Indiana, Illinois, Wisconsin and Pennsylvania. Dr. Hamilton, from reports made by medical men furnished by hospitals as well as from her own experience, was able to collect a total of 217 cases of lead poisoning, distributed amongst 1,912 workers. The majority of the cases affected workers engaged in enamelling, who numbered in all 900.

The type of poisoning is often very serious; thus, in four potteries in the neighbourhood of Pittsburg, there were found amongst 365 workers 165 cases of lead poisoning, with 11 deaths, 25 cases of paralysis and 8 cases of encephalopathy.

It should be remarked that in the American pottery industry the lead compound is mostly added after the fritting of the glazing material, so that its solubility is not in the least diminished. All the American glazes are lead glazes, and the majority of them contain high proportions of soluble lead. Out of 107 samples 73 per cent. contain over 10 per cent. of soluble lead, and 11 more 20 to 50 per cent. Similarly, the cleaning of enamelled ware is often executed in America after a day spent in dipping, and in this way the operation is an extremely dangerous one.

Cases of lead poisoning (positive, probable and doubtful) amounted to 333 amongst 1,436 workers examined; 8.8 per cent. positive and 14.2 per cent. probable. The positive cases were returned as follows: 13.1 per cent. of workers aged forty years and over; 6 per cent. of those aged twenty-five to thirty-nine years. Amongst the women, cases of lead poisoning affected 80 out of 373 examined, and positive cases were met with chiefly amongst those aged from twenty-five to forty and upwards.

According to the statistics of Hoffmann, 32.2 per cent. of the workers in the pottery industry die of tuberculosis. In a summary of the results of the Ohio enquiry, R. F. Albaugh draws attention to the fact that 5.1 per cent. only, out of 2,882 workers exposed to the risk were over forty-five years of age, which points to the fact that for some reason or other the workers leave the industry before middle age. Of the workers aged over forty-five about 15 per cent. were victims of lead poisoning.

**PATHOLOGY**

Arlidge, who was certifying factory surgeon for Stoke and physician to the North Stafford Infirmary, had great experience of the effects on the workers of the dust and lead in pottery manufacture. In his book, *Hygiene, Diseases and Mortality of Occupations* (1892), he states:

The siliceous constitution of potters' clay is accountable for the mischief it causes
to the lungs; and, as a general rule, the injury caused is greater in proportion to the amount of dust given off in the particular process carried on; with this qualification, that the effects produced are somewhat varied by the proportion in which silex is present. The fictile compound forming the body of china articles is more prejudicial than an earthenware body; and is rendered still more so by the employment of fine flint and sand for placing, and by the necessity subsequently of cleansing the ware from the adherent dust. One branch of the trade suffers more than another according to the quality and quantity of the dust evolved.

Arlidge noticed greater frequency of lung lesions among turners and pressers than among throwers. Injury to health, however, was greatest in the case of china scoters, who, at the time he has been brushed and beat off the dust from the china ware — a proceeding accompanied by the production of clouds of flint dust. This process, however, has been metamorphosed in recent years by carrying out the process in revolving drums, as previously described.

Arlidge says:

When uncomplicated by tubercle, the potters' disease advances imperceptibly, and without constitutional disturbances. One of its first symptoms is a clearing cough on first rising, but soon to become met with on any change of temperature, and accompanied by shortness of breath. Haemoptysis does not usher in the malady, and more frequently than not never makes its appearance. The appetite and the general bodily functions remain long intact; there is no febrile action, no accelerated pulse, no hectic and no rapid emaciation. Anaemia is no necessary adjunct. The sputa remain for long white and frothy, with specks or streaks of black matter, which is inhaled dust. Later on this mucus expectoration gets purulent, heavy, and forms pellets, but is not green. The cough is more paroxysmal and violent than that of phthisis, and the urgency of the dyspnoea greater, and out of proportion to the ascertained extent of consolidated lung. The signs of consolidation are not so specially limited to the infra-clavicular spaces as in tubercular lesion, and hence the sinking below the clavicles is not marked. Areas of dullness on percussion are often found distributed at different parts, particularly in the scapular region, and near the base of the lungs. There is not an equal shrinking and contraction of the thoracic cavity at large. Between these an emphysematous condition is discoverable; a phenomenon more common along the anterior margin of the lungs. There is not an equal shrivelling and contraction of the thoracic cavity at large.

As might be foreseen from the increased strain on the pulmonary circulation, the heart gets frequently involved, the right side becomes dilated, and the valves inefficient; hence anasarca in prolonged cases is no infrequent occurrence before the scene closes. I would add that the general aspect and physiognomy differ from that of tubercular phthisis. The features are rather those of anemic anaemia; subject to a frequent occurrence of the lustrous eye, the often pink and transparent skin of phthisis, the clubbed finger-ends, and the incurved nails are wanting.

But in looking for these distinctive signs, we must never forget how frequently tubercular deposit modifies the picture of fibrosis I have endeavoured to present.

In 1922, H. Zuber, of Geneva, described three fatal cases (with autopsy) of pulmonary lesions without tuberculosis, amongst workers engaged in china manufacture. The lesions were symmetrical, and were located specially in the upper lobes of the lungs. In spite of the fact that the lesions were very serious, there was no tendency to the formation of cavities. Vascular lesions sometimes showed in the form of obliterating arteritis.

Lead poisoning in pottery manufacture does not differ from lead poisoning generally.

In the early period, when little but raw lead glazes were used, with locally applied exhaust ventilation indifferently carried out in several of the processes, inhalation of dust of lead compounds was general, and where inhalation of dust is pronounced there is much greater risk of the more severe symptoms of lead poisoning — encephalopathy (convulsions and blindness) showing themselves. The proportion of cases of this severest form of lead poisoning were noticeably more frequent in the early period.

The Austrian enquiry of 1913 revealed the fact that in glazing factories almost half the workers (45 per cent.) in average-sized earthenware factories and in those of lesser importance, more than one-third (36 per cent.), in workrooms for the decoration of china about one-seventh (14 per cent.), and finally, over one-seventeenth (6 per cent.) in the large pottery factories, might be considered as exposed to the lead risk.

Lead poisoning symptoms amongst workers exposed to the risk of poisoning were found to be present to the following extent:

<table>

Deformations of the lower limbs met with amongst pottery workers working on a lathe have been described in detail.
by Pieraccini. A sufficient explanation thereof is provided by studying the manner in which the worker effects his work. He is seated on a board in front of the setting bench, and rests his left foot on a low plank placed parallel to the seat, so that he may exert the maximum pressure on it. The other foot exerts strong pressure on a wooden disc turning on a central pivot. A vertical axis runs from the centre of this disc, and carries at the top a small disc on which the clay is worked. The circular movement of the lower disc is produced by the left foot, and more rarely by both feet which push it forward in the direction in which the feet move. This kind of dance is executed with bare feet, to economise shoe leather. It is not surprising that in the long run the foot, and especially the left foot, develop a deformity consisting of flat foot and especially of a deviation towards the central axis or towards the outer edge of the foot from the first and partly from the second, third and fourth toes. There is fairly often met with, also a tuberous form of osteoperiostitis, situated on the first metatarsal-phalangeal joint. The left foot is more affected than the right, since it is placed nearer the centre of the disc, where the movement is naturally much more rapid than at the periphery.

Barretoni described in 1923 stigmata (callosities) noted amongst pottery workers. These were processes of epithelial formation on the hands of the workers engaged in finishing plates, saucers, and in general the workers using lathes. Rubbing of the hand against the ware turning at high speed, which is never perfectly smooth, caused on the left hand (thumb, first finger, small finger, thenar and hypothenar regions) and on the right hand (first and middle finger) a lesion which is not serious in itself, but which may provide a path of entry for pathogenic germs.

Russian contributions in the last few years have become very numerous; Atabekian, of Moscow, in studying (1926) the influence of heat on workers engaged in removing ware from the ovens, has remarked an increase of the body temperature, a higher pulse rate, etc. The workers complained of varying symptoms: palpitation, vertigo, etc. The same question was studied by Efremova in 1927.

Kawaleroff and Kagan in 1926 carried out an enquiry into the extent of lead poisoning amongst pottery workers, and studied lesions of the skin and nails amongst workers manipulating glazing products and workers in the decorating departments. The skin of the hands and the forearms was found to be dry, ridged, and sometimes swollen and pale pink in colour, almost as if it had been powdered. The lesions healed with difficulty, for eczema was frequently present.

The nails were thin, furrowed, brittle and painful, cut and eroded at the edges. Amongst women workers engaged in decorating, the use of colouring mediums and of spirit of resins incaused dermatitis, rhagades, and even painful ulcers. They complained of headache, cough and vertigo.

Rostowzwo in 1926 also drew attention to this incidence of skin diseases amongst Russian pottery workers. The lesions were situated at the base of the finger, more rarely on the palm of the hand; they affected especially workers engaged in shaping the clay and sorters. Amongst dippers the lesions (eruptions, drying of the skin, increased sensitiveness) are favoured in development by the irritating action of the liquid into which the ware is dipped.

In 1925 Kalf Kalif, of Kharkov, studied cardiovascular troubles and anaemia amongst workers in the pottery industry; Gertschik in 1927 studied the effects of working by wet methods during polishing, which he found, however, did not give good results except when subdivision of work was adopted in the factory. In fact if the same worker is called upon to perform all the operations of shaping and polishing, he is obliged to handle dry products giving off large quantities of dust. It is therefore essential that the work should be done whilst the materials handled are still slightly damp.

The pathology attaching to this class of workers comprises other lesions, such as: varicose veins in the lower limbs; wounds; rhagades; ulcers either on the hands or on the feet (where workers did not wear shoes); painful arthralgia; neuralgia and neuritis (in one cases located on the cubital edge of the arm; Ceni, 1905); diseases arising from cold; derangements of the digestion; cardiovascular lesions; and in particular arteriosclerosis amongst workers at the ovens (dry heat, high temperature); the risk of lead poisoning during application of the glaze (removal of excess by the cubital edge of the left hand: in certain glazes the lead contained amounts to 75 per cent.); during firing (lead fumes in the workshops where the kilns are not well constructed or are cracked); danger of inhaling silicious dust at all stages of manufacture, but chiefly during the
cleaning of biscuit after withdrawal from the oven by means of brushing in an enclosed space.

HYGIENE

Meticulous attention to detail, not only in the provision, but also in the maintenance, of the locally applied exhaust ventilation alone can allay the danger in the processes in which dust is incidental, whether in body making or in the application of glaze. In manipulating the raw materials of the body in the slip house, wet grinding is the common practice, so that no dust arises. Potters' shops require to be cleaned daily by a moist method, and provided with means for effective ventilation. Locally applied exhaust is required specially in the processes of dry fettling, towing of earthenware, biscuit placing in flint, in emptying the ware from the saggers and the scouring of biscuit ware, etc., unless these processes, e.g., china scouring, can be carried out in closed-in apparatus, preventing the escape of dust into the workroom; but, even then, the "rumbler" requires to be under a negative pressure. Similarly, in the lead processes, so long as they are wet, or removal of the glaze with a damp sponge or flannel is carried out in closed-in space. In the dipping house, impervious floors should be provided, to be washed down so as to prevent the risks from sweeping. The walls adjacent to the dipping tubs should be tiled or painted with washable paint, and cleaned daily.

To reduce risk or remove the danger of lead poisoning in the pottery industry, use of low solubility glazes or of leadless glazes are advocated. On this point the English Committee appointed in 1910, reported:

The effect of melting the lead with siliceous matter practically amounts to imprisoning it in such a manner as to render it less liable to the action of the acids which it meets in passing through the human body, and in consequence largely reduces the likelihood of its absorption into the blood. If the frit is properly compounded, all but a small fraction of the lead is rendered insoluble, and glazes so made are spoken of as low solubility glazes. The finished glaze generally contains from 12 to 22 per cent., or more, of lead oxide, but after the process of fritting with sufficient siliceous material only from 2 to 5 per cent. remains soluble. Raw lead comprises red lead, white lead, and litharge. If introduced in this form as a constituent of glaze it is soluble in dilute acids. If, however, the raw lead is fluxed by heating with a part or the whole of the silica, it is converted into "frited lead". The solubility of the frit depends upon the relative proportions of material taken. Thorpe, as a result of numerous analyses of lead silicates (after determining their solubility as regards lead) both simple and complex, in the use in the potteries and on the Continent, found that the quantity of lead dissolved had no necessary relation to the quantity of lead in the silicate. Primarily and in the main the insolubility of the lead depends not upon any one oxide or group of oxides, but upon the maintenance of a certain proportion between the whole of the basic oxides on the one hand and the whole of the acidic oxides on the other.

If the value of ratio —— higher than 

*acids* bases

or approximately equal to, 2, the amount of the lead extracted is small, but if it falls much below 2, the quantity of lead dissolved begins rapidly to rise.

On the subject of the use of leadless glazes, the Committee conclude that in all classes of pottery ware a great many articles can be manufactured in a very high state of perfection, with reduction in the cost of production of certain classes of common ware, such as jampots and Persian painted ware; but that in certain other classes, owing to the excessive number of "seconds", their use would entail cost or sacrifice of quality, so much so as to involve loss of important markets; and finally, that certain kinds of ware, in consequence of difficulties relative to accuracy in reproducing old patterns, colour, or methods of decoration, cannot at present be made at all without use of lead.

LEGISLATION

Women are excluded from grinding in the pottery industry in Argentina. Young persons under eighteen from pottery workrooms and pipe factories in France where there is free liberation of dust; in Switzerland from manipulation of any non-frited lead glazes. Boys under sixteen years of age and women under twenty-one are excluded from grinding and dipping in Spain; boys under fifteen and women under twenty-one from workrooms in the pottery industry where dust is freely liberated, unless diffusion is effectively prevented, in Italy; from workrooms where there is abundant liberation of clay dust in Japan; young persons under fourteen are excluded from places where dust from grinding and bolting is freely liberated in Belgium; women and children under fifteen are excluded in Estonia (except from shaping of earthenware and porcelain).

Adult women are excluded in the States of New Jersey and Pennsylvania from operations during which all substances or compounds or colours containing more than 2 per cent. of lead are handled, and
in Great Britain from the manufacture and decoration of pottery, mending of bisque with lead glazes, and sealing with lead compounds containing more than 0.5 per cent. of lead (soluble compound), from weighing, shovelling and mixing of non-fritted lead, etc. In France they are excluded from dry-dusting, colour-dusting in chromo-lithography for pottery, where exposure to dust is involved; in Japan from every process where there is production of dust; in Austria to 20 per cent.; in Switzerland women are excluded from manipulation of unfritted lead glazes, etc. (See also in the article "Lead" the Draft Convention adopted by the International Labour Conference at Washington in 1919.) Special legislation has been issued in Germany (Regulations for Pottery Factories in regard to Chromo-lithography, 1 January 1923). Special regulations exist also in the United States: States of New York (General Factory Law: removal of dust by exhaust apparatus in the pottery industry), New Jersey (prevention of lead poisoning in pottery factories, etc.: Standard Regulations for removing dust generally in the Manufacture of Pottery, 15 September 1919), Ohio (prevention of occupational diseases, October 1919; Pennsylvania (prevention of occupational diseases, July 1913); in Finland (Regulations of 30 December 1925); in France, Regulations relating to white lead (1 October 1911) were also applicable to workrooms for pottery decoration. In Great Britain the Pottery Regulations of January 1913 made under the Factory and Workshop Act, 1901, deal drastically with the prevention of dust, lead poisoning, and excessive weight carrying. As regards dust and lead poisoning, all known methods of prevention are utilised, e.g.: (1) substitution of innocuous for noxious materials — allowing dust-exposure from onerous and costly requirements as, for example, examination by the certifying factory surgeon, where leadless or low solubility glazes are used; (2) limitation of age; (3) monthly examination of lead workers, and (a) six-monthly examination of young persons and children engaged in carrying or lifting work, and (b) of china biscuit emptiers and scourers, and of females employed as wheel turners; (4) dust prevention either by locally applied exhaust ventilation or by use of damp methods; and (5) ordinary welfare requirements.

Definitions are given of (1) leadless glaze, and (2) low solubility glaze, as follows:

* Leadless glaze * means a glaze which does not contain more than 1 per cent. of its dry weight of a lead compound calculated as lead monoxide.

* Low solubility glaze * means: (1) a glaze which does not yield to dilute hydrochloric acid more than 5 per cent. of its dry weight of a soluble lead compound calculated as lead monoxide when determined in the manner described below; or (2) a glaze containing no lead or lead compound other than galena.

A weighed quantity of dried material is to be continuously shaken for one hour, at the common temperature, with one thousand times its weight of an aqueous solution of hydrochloric acid containing 0.25 per cent. of HC1. This solution is thereafter to be allowed to stand for one hour, and to be passed through a filter. The lead salt contained in an aliquot portion of the clear filtrate is then to be precipitated as lead sulphide, and weighed as lead sulphate.

The schedule of lead processes is as follows:

(a) Making or mixing of frits, glazes, or colours, containing lead.

(b) Dipping or other process carried out in the dipping house.

(c) Application of majolica, or other glaze, by blowing, painting, or any other process except dipping.

(d) Drying after the application of glaze by dipping, blowing, painting, or other process.

(e) Ware cleaning after the application of glaze by dipping, blowing, painting, or other process.

(f) Placing of ware on racks or similar articles prior to their transfer to saggars or kilns for the glost firing.

(g) Glost placing.

(h) Washing of saggars with a wash which yields to dilute hydrochloric acid more than 5 per cent. of its dry weight of a soluble lead compound calculated as lead monoxide when determined in the manner described in the definition of low solubility glaze.

(k) Preparation, or weighing-out, of flow material.

(l) Ground laying, including the wiping off of colour after this process.

(m) Colour laying, including the wiping off of colour after this process.

(n) Colour blowing whether on-glaze or under-glaze, including the wiping off of colour after either of these processes.

(o) Colour grinding for colour blowers.

(p) Lithographic transfer making.

(q) Any other process in which materials containing lead are used or handled in the dry state, or in the form of spray, or in suspension in liquid other than oil or similar medium; provided that the stopping of biscuit ware with a material containing lead shall not be deemed to be a process included in this schedule.

(r) Scouring of biscuit ware which has been fired in powdered flint.

(s) Emptying of biscuit ware which has been fired in powdered flint from
the baskets or other receptacles in which it has been conveyed to the biscuit warehouse or scouring shop.

Both leadless glaze and low solubility glaze factories are exempted from the requirement of periodic medical examination of lead workers. This is a considerable indulgence to manufacturers to adopt either the one or the other.

Where raw lead glaze is used, women and young persons are debarred from certain named processes. In all potteries no young person other than a male young person who wedges clay only for his own use is allowed to be employed in the wedging of clay, and no women without a certificate of permission to work. Similarly, no young person is allowed to be employed in carrying work without a certificate from the certifying factory surgeon specifying the maximum amount, and, with certain exceptions, no certificate can allow the carrying of more than 30 lbs. by anyone under sixteen years of age. No girl under sixteen is allowed to be employed as a lathe treater, and no young person as a dipper, and no girl under seventeen or boy under sixteen as a dippers' assistant or ware cleaner.

Somewhat similar restrictions are placed on women and young persons in glaze placing. Women are prohibited from carrying saggars full of ware.

Periodic medical examination. — In addition to the monthly examination of workers in lead processes, young persons engaged in carrying or lifting work have to be re-examined by the surgeon twice in the first period of six months, and once in each period of six months afterwards until they reach eighteen years of age. China biscuit emptiers and scourers also undergo a six-monthly examination. Results of examinations and permission to work is entered by the surgeon in a special health register.

Suppression of dust. — The following processes must be carried on under an efficient exhaust draught: fettling, sifting in powdered flint (unless done in effectively enclosed machines); batching of biscuit ware; glaze blowing; ware cleaning (unless done on entirely with the use of wet materials, or if the ware cleaning be done within fifteen minutes after the moment when the glaze is applied — the glaze scraped off, if not removed by exhaust draught, to fall into water); ground laying; colour dusting; colour blowing; making of litho transfers; removal from the saggers of biscuit flat ware bedded in flat; flat knocking and fired flat sifting to be done in effectively enclosed receptacles connected with efficient exhaust draught (unless so contrived as to prevent the escape of dust). Respirators are only required in emptying ovens, 125° F. is the maximum laid down for general purposes.

Where raw lead glaze is used, women and young persons are debarred from certain named processes. In all potteries no young person other than a male young person who wedges clay only for his own use is allowed to be employed in the wedging of clay, and no women without a certificate of permission to work. Similarly, no young person is allowed to be employed in carrying work without a certificate from the certifying factory surgeon specifying the maximum amount, and, with certain exceptions, no certificate can allow the carrying of more than 30 lbs. by anyone under sixteen years of age. No girl under sixteen is allowed to be employed as a lathe treater, and no young person as a dipper, and no girl under seventeen or boy under sixteen as a dippers' assistant or ware cleaner.

Somewhat similar restrictions are placed on women and young persons in glaze placing. Women are prohibited from carrying saggars full of ware.

Periodic medical examination. — In addition to the monthly examination of workers in lead processes, young persons engaged in carrying or lifting work have to be re-examined by the surgeon twice in the first period of six months, and once in each period of six months afterwards until they reach eighteen years of age. China biscuit emptiers and scourers also undergo a six-monthly examination. Results of examinations and permission to work is entered by the surgeon in a special health register.

Suppression of dust. — The following processes must be carried on under an efficient exhaust draught: fettling, sifting in powdered flint (unless done in effectively enclosed machines); batching of biscuit ware; glaze blowing; ware cleaning (unless done on entirely with the use of wet materials, or if the ware cleaning be done within fifteen minutes after the moment when the glaze is applied — the glaze scraped off, if not removed by exhaust draught, to fall into water); ground laying; colour dusting; colour blowing; making of litho transfers; removal from the saggers of biscuit flat ware bedded in flat; flat knocking and fired flat sifting to be done in effectively enclosed receptacles connected with efficient exhaust draught (unless so contrived as to prevent the escape of dust). Respirators are only required in emptying ovens, 125° F. is the maximum laid down for general purposes.

Temperature. — A wet bulb thermometer is required in any workroom in which articles are allowed to dry, or in connection with which artificial heat is used, and the wet bulb must not exceed 70° F. except at such times as the reading of the wet bulb thermometer in the shade in the open air exceeds 60° F. In drawing ovens, 125° F. is the maximum laid down for general purposes.

The usual regulations apply in the case of overalls and head coverings, suitable accommodation for keeping and drying outdoor clothing, messroom accommodation for lead workers, washing accommodation and cleanliness of floors — daily cleansing by a moist method.

Special regulations apply to the lead house, dipping house, cleansing of boards on which dipped ware is placed (those used in lead processes to be painted red at the ends, etc.), majolica painting, aero-graphing (no short-sighted person to be employed unless wearing suitable glasses, as certified by the certifying surgeon).

Finally, a novel requirement is enjoined — self-inspection of the workrooms by a person appointed specially for the purpose, competent and fully conversant with the meaning and application of the Regulations. He is required to keep in the factory a book in which any breach of the Regulations or any failure of apparatus, and such steps as have been taken to remedy defects, are to be entered. Power is given to take samples for analysis.

The Pottery (Silicosis) Regulations of 24 May 1932 contain further preventive measures in regard to the protection of workers in certain processes from the risk of silicosis and include provisions concerning the wearing of overalls, ventilation, washing, the cleaning of workrooms, the avoidance of dusts, etc.

In the Netherlands, a Royal Order of 10 August 1929 contains regulations giving effect to the Labour Act of 1919, and contains, in paragraph 3 (sections 47 et seq.), provisions in regard to the work of women and young persons in the making of bricks, the preparation of clays, and the firing of bricks and tiles, the making of pavement slabs, and the covering of pipes in earthenware; paragraph 4 (sections 50 et seq.) contains provisions relative to factories and workshops where operations connected with the manufacture of articles are carried out (very detailed provisions).

In Norway the Royal Order of 30 October 1919 contains provisions in regard to hygiene in factories where lead compounds and other toxic substances are handled, and also provisions in regard to china, porcelain and earthenware factories.

In Russia the Compulsory Order of the Labour Commissariat, dated 15 July 1927, deals with the measures of protection to be taken in the pottery trade.

In Yugoslavia, Regulations of 25 October 1921 relative to hygiene and safety,
provide in sections 135 et seq., prescriptions relative to industries in which lead is used (section 142: "Pottery"); the operation of dipping with the bare hand in hot solutions of salts of lead, etc., is prohibited.

The International Association for Labour Legislation (Basle) for long studied this question, either in national committees or during its meetings. The Delegate Meeting held in 1910 (Lugano) decided to recommend to the Governments, by means of a petition lodged with the International Labour Office (Basle), the following recommendations relative to regulation of health conditions in the pottery industry:

I. The Governments should take steps towards the abolition of the use of lead in the pottery industry. To this end the following measures should be adopted:

1. In the manufacture of china and earthenware fired at a high temperature, the use of lead glaze should be prohibited.

2. As regards the manufacture of earthenware fired at a low temperature, a provisional list of articles should be drawn up which can, at the present time be manufactured without lead. This list, which would be subject to extension, should contain articles of common use such as pots, washing basins, dishes, mugs, bowls, etc., electrical insulators, etc.

3. As regards the manufacture of common pottery and plain stone tiles fired at a low temperature such as are manufactured on the Continent both in small workshops and in the workers' homes, litharge and red lead should be replaced by galena or any other less dangerous glaze. The preparation and use of unfritted glazes and the fritting process should be prohibited in such works.

The following measures would tend to encourage the gradual adoption of leadless glazes in the ceramic industry:

(a) The instruction and assistance of all occupiers in the industry wishing to make a practical trial of the use of leadless glazes;

(b) The strict enforcement of hygienic regulations in works using lead glazes.

II. Regulations for factories and workshops should only apply to establishments where leadless glazes are exclusively and permanently used. Factory inspectors should have power to take samples of analysis at all stages and at any time, samples of glaze and of the substances used in the preparation of the same.

1 Within the meaning of these provisions leadless non-poisonous glazes shall mean all compositions or frits used for glazing in the ceramic industry which contain not more than 1 per cent. of lead. Compositions containing no lead compound other than galena shall be held to be leadless. All other glazes shall be held to contain lead within the meaning of these provisions.

III. The following regulations should be adopted in the case of works using lead glazes:

1. The competent authorities shall have power to require, where necessary, the glazes used to be modified in order to prevent injury to the health of workmen employed in contact with the same.

2. The mixing, grinding and transportation of lead glazes as well as the lead used in their preparation shall be effected either in a thoroughly damp state or in apparatus which permits no dust to escape.

3. Frit-kilns must be so arranged that the molten frit can flow off into water, and frits must always be drawn off in such a manner.

4. Calcining shall be effected in a place separated from all the other workplaces, and exhaust ventilation in good working order shall be placed over the openings of the furnace.

5. Effective exhaust ventilation shall be applied in a suitable manner at all points where dust is generated such as the openings of grinding and mixing apparatus of transport apparatus, and of frit-kilns, and benches where glazes are applied in a dry state, where glazes of colours are applied by dusting, or where ware-cleaning is carried on.

All places where lead glazes or the lead used in their preparation are handled must be at least 3.5 metres in height, and 15 cubic metres of air space shall be allowed for each workman.

The floor must be impervious and washable, and the walls covered to a height of 2 metres, with a smooth and washable coating or paint.

6. No glazes shall be manufactured or used in living or sleeping rooms, and no lead glazes or lead used in their preparation or pottery covered with unfired glaze shall be brought into or stored in such rooms.

Where more than five persons are employed full time in an undertaking the said processes shall not be carried on in living or sleeping rooms or in rooms where other work is carried on, nor shall glazes, the lead used in their preparation, or pottery covered with unfired glaze be brought into or stored in such places.

7. On the conclusion of a suitable period of transition no female person shall in any circumstances be employed in any kind of work whatsoever which would bring her into contact with unfired lead glazes or compounds or with the lead used in their preparation. No male young persons under eighteen years of age shall be employed in such work except in so far as may be necessary for the purposes of learning the trade.

No young persons under eighteen or women shall be employed in any circumstances in the calcining process or in cleaning places where the above-mentioned substances or objects covered with
unfired lead glazes have been manipulated or stored.

(8) Hours of work shall be reduced for all persons employed in the processes mentioned in the preceding paragraphs in proportion to the dangers attendant upon the respective processes, and especially in the case of workmen in the calcining process, who shall not be so employed continuously.

(9) All workpeople employed in the manufacture of glazes containing lead as well as those who come into contact with raw glazes or the lead used in their preparation, shall wear special working clothes.

(10) The employer shall supply without charge a sufficient quantity of suitable working clothes, drinking and washing water, glasses, soap and towels. The employer shall provide for the washing of the said working clothes and towels.

(11) No person shall eat, drink or smoke in, or bring any food, drink or tobacco into, places where lead glazes or the lead used in their preparation are handled, or which are used for storing these substances or pottery covered with unfired lead glazes.

(12) The workpeople in question shall be examined every three months by a medical practitioner, appointed by the State authorities. The result of the examinations shall be entered in a register kept by the employer in the employment, which shall be open to inspection by the medical practitioner.

(13) No workman who is suffering from lead poisoning, or who has been found by the medical practitioner named in paragraph (12) to be unfit on medical examination by the medical practitioner appointed by the State authorities. The result of the examination shall be entered in a register kept for the purpose which shall be open to inspection by the inspecting authority.

(14) Two cloakrooms shall be provided, one for working and one for outdoor clothes, with a suitable lavatory and bathroom between the two. A mess-room shall also be provided.

(15) Employers shall give all workpeople contemplated in paragraph (9) on entering the employment, printed instructions as to the dangers of lead poisoning and its prevention, and shall affix such instructions in the workplaces.

(16) In the case of establishments using lead glazes so composed that the consequent risk to health is small, temporary exceptions from the preceding provisions may be allowed by the authority in exceptional circumstances.

In the Netherlands, diseases of the skin (eczema, dermatitis), as well as pulmonary diseases occurring amongst workers in the pottery trade, are subject to compulsory notification. Compensation for occupational diseases in this industry is usually confined to lead poisoning (France (decoration of china by the use of lead products in the pottery industry where lead enamels are used), Germany, Great Britain, Switzerland, U.S.S.R., in some states of the United States, etc. (see article "Occupational Diseases: Compensation ")) in Great Britain it also covers silicosis amongst workers in the refractory industries.

The problem of compensation for silicosis in the pottery industry was studied by a British Departmental Committee appointed in 1907 and reconstituted in 1957, as a result of which the Various Industries (Silicosis) Scheme was issued in 1928.

Manufacture of Bricks and Tiles

TECHNICAL DATA

In this section will be discussed the technology and pathology of the brick and tile industry, including ordinary and ornamental tiles made of terracotta and earthenware.

This industry is, even at the present time, found in certain districts to be
carried on under primitive conditions, whilst in other centres it has been modernised and is effected with highly perfected automatic machinery.

For the manufacture of bricks, tiles and tiled flooring, the clay used is of a slimy consistency, being more or less pure clay. When the clay is too fat, it is mixed with sand or coke dust. The chamois yellow or red colour depends essentially on the composition of the earth used.

Manufacture is effected by hand or mechanically. The clay shaped by hand is dried in the open, firing being done in temporary kilns, or in fixed ovens, but always in an intermittent fashion. This primitive method is becoming more and more entirely replaced by the mechanical process, which involves the use of perfected apparatus (moulding machines, drying stoves, continuous kilns).

The principal processes in this type of manufacture are moulding, drying and firing. Certain products require supplementary operations such as pressing of bricks, flattening and cutting of square tiles, rolling of piping and varnishing.

Brick-making establishments only work during the six summer months, winter being devoted to the extraction of the clay. The relatively high cost of the raw material and the existence of small local factories.

While the kneading of clay with water and hand moulding on a bench are very tiring, work on the hearth tamped for the drying of moulded bricks, the operation of turning these from time to time, and drying them, building them into stacks is done in order to ensure free circulation of air between the bricks, constant supervision to protect them against unduly strong sun or from frost and rain, etc., are equally tiring operations.

The conditions of these workers, who, in certain districts (north of France, for example), form shifts grouped in certain working centres where they live and work for the time being, require attention on the part of factory inspection services in order to assure the existence of adequate living conditions, sleeping quarters and suitable working conditions.

It is true that modern methods are being introduced into this industry at an increasing rate, more especially on account of the difficulty found in recruiting labour for an occupation which involves such trying and difficult conditions.

The simplest means of mixing consists in cutting up the clay and kneading it by means of a curved knife after having watered it. At times, however, a special machine is used, worked by the arm and known as a "mill". In larger establishments vertical mixers are used, especially where the clay worked is soft. In modern establishments mixing is more thorough and comprises the use of several kinds of apparatus (mixing and rolling, even repeatedly).

The paste, after preparation, is subjected to shaping or moulding. The bricks, pantiles and flooring tiles of ordinary quality are moulded by hand on the moulding bench, by the use of a mould which consists of a wooden frame formed of four small boards. The piece of clay is introduced into this by the worker, pressed and smoothed with a damp plane. Immediately removes the mould and takes out the contents to the hearth for drying.

In mechanical manufacture the clay is first of all submitted to mixing in grinding and kneading machines, where plates and knives are arranged in such a manner that their rotation cuts into small pieces and kneads the clay, and thereafter pushes it towards an orifice, the diameter of which is more or less that required for the finished brick. The clay falls on an iron plate provided with a cutting frame, which on being lowered cuts out a certain number of bricks each time. This kneading machine may also be combined with a press, which subjects the clay to considerable pressure, transforming it into a solid mass.

Sometimes an impact press is used, which enables bricks to be manufactured directly the clay is extracted, without any preliminary operations.

Tiles and flooring tiles are manufactured by means of special frames and by an analogous process.

In mechanical manufacture moulding is effected by drawing the clay, followed usually by pressure in a mould. By imparting the desired section to the clay emerging from the perforated plate, bricks with special mouldings or ridges are obtained. Likewise hollow or perforated bricks are made by the use of perforated plates constructed for the purpose. For tile-making the drawing machine furnishes a flat band of clay, which is cut up into small cakes. In certain cases pantiles emerge from the drawing machine complete, so that it is no longer necessary to subject them to hand-shaping. For flat tiles the cakes of clay are submitted to pressure in moulds. Removing of edges is done by hand.
and the clippings are conveyed to a grinder for mixing with fresh clay. Flooring tiles and drainpipes are also manufactured mechanically.

**Drying** prior to firing is a delicate operation effected at ordinary temperatures or by artificial heat.

Natural drying at ordinary temperatures is adopted not only for handmade tiles but also in mechanically conducted brickworks. For artificial drying there are used either hearths which disseminate heat or aerocondensers.

Bricks, tiles, etc., are sometimes covered with an ordinary glaze to impart a more pleasing aspect to them. For this purpose there is used lead sulphide diluted in clay and water. Where black and opaque varnish is required, manganese dioxide is added to the mixture.

**Firing** is done in clamps or in intermittent or continuous kilns. Firing in clamps is only followed in the country. The best results are obtained by the use of intermittent kilns, in which firing is effected either by stratification or by a long flame. When a reducing atmosphere is brought about in the kilns after termination of the firing, a blue colour is imparted to the products. For artificial drying there are used hearths which disseminate heat or aerocondensers.

Flooring tiles and drainpipes are also manufactured mechanically. The problem is therefore a very delicate work. The kiln is lit after the formation of a few layers of brick only. The work of building up and finishing becomes extremely trying, because the lower rows of bricks must be already dried in order to support the weight of the later rows without marking. All the work is therefore effected in a hot and smoky atmosphere, containing a heavy proportion of carbon monoxide and sulphurous fumes. In calm weather such an atmosphere is almost irrespirable.

Special apparatus, for example that of Dubar and Baert, has been proposed with a view to hastening the building of the kilns by means of mechanical manipulation, involving diminution of the number of men or compressed air. The health risks to which the workers are exposed are in this way reduced. This apparatus also enables the dismantling of the kiln with less liberation of dust than the former hand method. Cinders from combustion constitute considerable annoyance for the workers.

The worker entrusted with firing keeps up the most favourable temperature for this purpose by charging the kiln from time to time with small amounts of combustibles, fed at short intervals through a large number of apertures. If the draught is insufficient during hot weather the kiln backfires, and the worker in charge is highly inconvenienced by gas escaping from the charging apertures. Even at normal times he is exposed to the effects of heat and reflection when he looks to the fire after each addition of fuel.

**Continuous kilns** have the advantage of permitting the greatest possible recuperation of heat loss. They utilise the calories stored up in the combustion gas for the gradual heating of freshly introduced products before they are submitted to firing, and enable use to be made of heat given off by the cooling of the fired products for preliminary heating of the air intended for combustion. There are several types of continuous kilns, the original type of which (Hoffmann kiln) has been provided with several improvements and alterations of importance.

Modern technical methods utilise types of kilns with forced draught, capable of putting to effective use the lost heat (for drying tunnels). In order to assure regular and perfect distribution of the fuel, recourse is had to automatic charging apparatus with utilisation of ordinary fuel arranged on the platform of the kiln. Attempts have also been made to utilise gas generators which send combustible gases for burning into the kiln.

Fired bricks, at the moment of removal from the kiln, should be sufficiently cooled to prevent the work of their removal being in any way trying for the worker engaged thereon. In practice, in the majority of cases, it is not so. If a ventilator is situated before the kiln door used for removal of the bricks, in order to accelerate cooling, a cloud of dust is raised from the deposit of dust on each brick handled. The problem is therefore a very complicated one, and it is essential to limit efforts to accelerating the passage of air through the fired bricks rather than creating a draught at the point of removal from the kiln. It has therefore been proposed to blow this air in through apertures in the hearth of the kiln, or to arrange in the vault of the hearth a number of beams, which would descend and separate the rows of bricks, thus facilitating the passage of air through the bricks to be cooled. These solutions of the problem are
hardly more satisfactory and the question still requires thorough consideration.

Compact qualities of pottery also include stoneware, which, thanks to firing carried to about 1,250° C. and sometimes 1,500° C. begins to undergo vitrification. The glaze used thus becomes hard, resonant and impermeable. Confusion between stoneware of this kind and artificial stoneware must be avoided, the latter consisting of a mixture of sand and lime treated with steam after moulding. A silica of lime obtained provides an imitation of certain kinds of stone.

Vitrification. A silica of lime is mixed with sand and lime treated with steam after moulding. A silica of lime is thus formed, so that the product obtained provides an imitation of certain kinds of stone.

For certain industrial purposes the stoneware to be manufactured has to be sufficiently refractory.

Materials made of dull stoneware are used for flooring tiles and paving stones, and certain tiles for facing buildings. The clay is mixed with a certain quantity of brick debris or terra-cotta, or white sand, according to the product required. Certain clays may be fired into stoneware naturally without being melted, but for certain other products there has to be added, on the other hand, slag from blast furnaces, felspar, etc.

Manufacture comprises the operations of preparation (grinding, pulverising, mixing and kneading, drawing of the mixture and a second pulverisation before use), moulding, drying and firing.

Certain products require to be fired in small saggers made of fireclay. The fired products are removed from the kiln, cleaned and stored. Pottery consisting of ordinary dull or varnished stoneware is used for making apparatus for chemical products, drainpipes and accessories, and various objects of domestic use.

Fireclay bricks are used in the construction of furnaces and especially for the inner lining of blast furnaces, Bessemer furnaces, etc., for metallurgical work.

There must finally be recalled Schist bricks composed of débris of coal schists coming from coal mines, and which are only utilised in the making of embankments.

Schists are employed alone or with the addition of fine clay. Two methods of manufacture are followed: work with dry paste and work with semi-soft paste. It is, however, necessary to break up and pulverise the schist in the first place, and this is done by the use of grindstones.

The schist prepared in this way is mixed, moulded and on emerging from the press is fired without undergoing drying.

Statistics

In the United States, A. Hamilton, in an enquiry covering 68 factories (1911-1912), met with 501 cases of lead poisoning (7.2 to 13.2 per cent.). Hayhurst in 47 factories (1914) only found (4.2 per cent.), whilst the Public Health Service in 1919-1920, during its enquiry covering 92 factories, revealed 270 cases (15 per cent.). It is worthy of remark that amongst the 300 cases assembled by Hayhurst, the investigators acting on behalf of the Public Health Service found that 40 out of 50 were still suffering from lead poisoning; as regards the other 59, no information was available except in the case of 24, 5 of whom had died.

In 1911 about 1,000 persons occupied in the tile factories were in contact with glazes in which lead was present in proportions varying between 5 and 20 per cent. (in most cases over 15 per cent.). The product in question was usually white lead. In the United States lead is not fritted, but added in part at least subsequent to fritting. For tiles and certain types of flooring tiles very high proportions are reached (50 to 60 per cent.). Trimming these tiles is extremely dangerous, because it is done dry, while in Germany and Great Britain this operation is performed in a wet state. The incidence of lead poisoning (1911) amounted to 15.1 per cent. amongst the men and 11.5 per cent. amongst the women. A comparison with the incidence in Great Britain is very striking:

<table>

Comparative mortality statistics have been prepared by the British Census Office. In general the figures for brick and tile factories prove that there are few occupations with such a low mortality (J. Latham). For the years 1900-1902 and 1910-1912, they were as follows:

For 1921-1923, see note, p. 719.

Legge reported in 1900 on the mortality from phthisis or silicosis amongst workers making bricks and stoneware. He did not think it worth while to continue his enquiry until he had obtained accurate information as to the rôle played on the one hand by dust and on the other hand by the tubercular bacillus in the production of pulmonary diseases.

Microscopic examination of the lungs of the workers in the stoneware industry has revealed the close relation between tubercular phthisis and lesions caused by dust. Legge has insisted on the importance of determining the effect on mortality of lesions caused by dust apart from infection.

Sydney Smith and Collis have studied information as to the role played on the one hand by dust and on the other hand by the tubercular bacillus in the production of pulmonary diseases.

Microscopic examination of the lungs of the workers in the stoneware industry has revealed the close relation between tubercular phthisis and lesions caused by dust. Legge has insisted on the importance of determining the effect on mortality of lesions caused by dust apart from infection.

The pathology of the workers in brick and tile factories varies largely in accordance with the methods of work followed. In fact, the introduction of mechanical and automatic apparatus has rendered this work much less tiring than was the case formerly when hand-work only was done.

German morbidity statistics provided by Gottschalck (1908) point to the predominance of rheumatism, particularly of a muscular type (lumbago). Under the former method of hand-presses, where the workers often worked barefooted and without assistance, the bending of the body required for stacking the bricks after manufacture, exposure of the workers to hot sunshine while perspiring from effort without adequate protection, rendered the work extremely trying. Hands and feet were often the seat of bruises and rhagades, facilitating the entrance of ankylostomiasis larvae when these were present in the soil of the brick yards. The Italian and German brick yards, etc., were infected in this manner a few years ago. Those in hot climates in particular are still affected and the disease from which the workers suffer is known under the name of "brick-workers' anaemia".

Erythema caused by sunlight, heat-stroke and dermatites are not rare amongst these workers. The transport of the clay, the operation of diluting it with water, kneading and even moulding it in certain countries is carried out by women and even by children, and their health, needless to say, suffers serious injury in consequence.

In small factories the glazing material is prepared on a hearth, without
draught and too often without any means of protection. The glazing medium is applied by means of a rag, applied to the object to be glazed, which is then dried in the air.

The risk of lead poisoning is very great in brickworks where primitive methods are followed.

The use of silica during moulding for preventing the paste from adhering to the mould gives rise to the liberation of large quantities of dust.

An enquiry carried out in 1926 by Sutherland and Bryson, in an English pottery where vitrified brick and ornamental tiles were made, has proved silicosis to be fairly widespread in this industry. Radioscopic examination of the workers in the workshop where the clay underwent the preliminary processes of preparation has proved the existence of silicosis amongst them. A similar result was shown by the examination of 6 men and 19 women engaged in moulding by means of a press. Six women, had had cases of tuberculosis in their families, 10 complained of difficulty in breathing and 11 of suffering from cough. Their physical condition was, however, good. Clinical examination showed 2 cases of fibrosis and 3 of bronchitis amongst the men, and 2 cases of fibrosis and of bronchitis amongst the women; 3 men and 1 woman showed signs of silicosis on radiographic examination; 3 men engaged in trimming tiles were likewise submitted to radiographic examination. The operation in question consists in rendering the tiles even and smooth, first by means of a hand grindstone, ultimately on a mechanical grindstone. Fibrosis, noted on clinical examination as affecting 3 workers, was not confirmed as such by radiography. The risk from silicosis in the manufacture of tiles is therefore extremely pronounced (see above, for air analysis and quantitative determination of dust contents). It should also be remembered that certain German authorities refer to a "brickworkers' aluminosis".

Tuberculosis, however, does not in general show a very high incidence rate, though Hoffman gives a percentage of 15.6, and in the case of 527 deaths attributes these in 82 instances to tuberculosis.

Digestive diseases (forms of gastralgia, gastro-enteritis, etc.) are in strict relation to the objective conditions (heat, humidity, etc.).

In certain countries — hot climates — noxious and parasitical diseases are fairly frequent: typhoid fever, helminthias.

Israelsohn (1927) has reported the occurrence amongst brickworkers of acute tenosynovitis of the muscles of the forearm, and particularly of the flexor muscles.

G. Blagovidoff (1925) has reported crepitant tenosynovitis of the wrist amongst moulders.

According to Mory, moulders suffer on commencing work from oedema of the hand, as well as tenosynovitis localised at the upper part of the radius.

Amongst certain workers the fingers and the hand become so swollen that they cannot close the hand or lift an object with the fingers. Other authorities, however, have not met with this type of lesion.

Women suffer from varicose veins, lesions of the sexual organs, miscarriages, etc.

In 1913 Legge, in response to a complaint lodged relative to the inferior quality of petrol utilised in brick-moulding, visited several brick factories and found that not only the bricks but also the entire surroundings of the process were impregnated with petrol. The workers suffered from intense eczematous eruptions on the arms, thighs and legs each time that the skin came in contact with a product or that the clothing became saturated with petrol. These troubles disappeared with the introduction of a product of better quality.

Similar but less serious forms of eczema have been met with in other brick works, using for the same purpose creosote oil. In one case an old worker showed eczematous ulcerations of the forearm which developed an epitheliomatous form necessitating surgical intervention.

**Hygiene**

For all operations in which lead is used reference should be made to the preceding part of this article: "Manufacture of Earthenware and China ".

Reference has been made above to the main technical improvements which can be introduced in regard to the manufacture of bricks and tiles (use of mechanical and automatic apparatus). Hand work should be as far as possible abandoned, for it is increasingly difficult to find workers ready to engage in such trying and heavy work.

The seasonal work requires the construction of temporary settlements, which ought to comply with legislative requirements (see article "Agriculture Labourers ").
Welfare measures are particularly essential when there is taken into account the nature of the work, in the open air, subject to atmospheric conditions, rendering the workers liable to contract all types of diseases connected with cold. For this reason it is necessary to provide adequate protective clothing, including waterproof footwear or clogs.

Special accommodation should be provided for clothing during working hours and facilities for drying it when wet. There should also be at the disposal of the workers messrooms with chairs or benches with backs, as well as facilities for heating food and boiling water. It is equally essential that there should be available a first-aid box and that restroom should be provided (for use in stormy weather, etc.).

It is, of course, essential that good drinking water should be provided. The transport of heavy loads by women and young children should be prohibited.

LEGISLATION

Legislation in regard to brick works is often included under regulations covering china and earthenware factories. It should, however, be recalled that young girls under sixteen are excluded from work in brick and tile works in Great Britain, that young persons under sixteen are excluded in South Africa from the processes of grinding and sieving raw materials containing not less than 80 per cent. of silica (SiO₂). The general aim of refractory materials and other processes is to prevent the effects of dust, either by damping by means of steam jets, or by localised ventilation, or by the wearing of respirators. The application of such legislative provisions is extremely difficult, especially in regard to the wearing of respirators in kilns, etc., for instance. The Regulations in question are therefore at present undergoing reconsideration (1927).

In Great Britain, Regulations covering the manufacture and decoration of pottery, dated 7 January 1923, set forth very detailed measures relative to the industry in question. In virtue of section 66 of the Act of 1901-1911, no young persons may be employed even in a workshop specially indicated by the said Act, without furnishing a certificate of fitness signed by a certified surgeon.

The Regulations of 29 April 1919, covering the operations of grinding and sieving of refractory materials and other processes involving their manipulation, apply to raw materials containing not less than 80 per cent. of silica (SiO₂). The general aim is to prevent the effects of dust, either by damping by means of steam jets, or by localised ventilation, or by the wearing of respirators. The application of such legislative provisions is extremely difficult, especially in regard to the wearing of respirators in kilns, etc., for instance. The Regulations in question are therefore at present undergoing reconsideration (1927).

In Belgium, the Royal Order of 15 February 1926 deals with the firing of bricks, and the Royal Order of 4 July 1925 with the hygiene and sanitation of the living quarters of workers engaged in brick manufacture. For other provisions, see also the laws referred to above in connection with china and earthenware factories.

In the Netherlands, skin diseases (eczema and dermatitis), cancer of the skin, cancerous tumours, pulmonary troubles, conjunctivitis, inflammation of the aponoeuses and of the sub-cutaneous cellular tissue, as well as ulcers of the cornea and of the conjunctiva, occurring amongst brick workers, are subject to compulsory notification. (For compensation, see above.)

In Great Britain, compensation of silicosis amongst workers in the refractory industries was provided by the Silicosis Acts of 1918-1924. At the present time this provision is incorporated in section 47 of the Workmen's Compensation Act of 1925.

Partial or total incapacity for work due to silicosis complicated by tuberculosis, or death certified by the medical office specially set up in execution of the law, are subject to compensation. (For details see article "Tuberculosis and Silicosis").

Sir Thomas Legge (London.)

Precious Stones

Precious stones or gems, those minerals sought after for their beauty and brilliance (colour, luminosity), as well as for their durability, are so varied and numerous that it is difficult to give a complete list. They fall into two groups: gems and hard stones.

Gems, or precious stones properly so called (diamonds, rubies, sapphires, emeralds, topazes, etc.), possessing in an eminent degree the above-described characteristics and not found in abundance in nature, are usually employed with rare metals for adornment (jewellery). Hard stones (amethysts, lapis-lazuli, malachite, etc.), which are found in fairly abundant quantities, are generally less hard and less opaque than gems. They are used for the manufacture, not only of jewellery, but of various other objects.

Precious stones are characterised by their specific gravity, generally exceeding 2.5, by their hardness (measured on the Mohs scale), their index of refraction, their chemical composition, which varies but is sometimes sufficiently well known for their artificial reproduction.
Artificial precious stones possess the same constitution and characteristics as natural precious stones, from which it is difficult to distinguish them with the naked eye. Industry can make hyacinth-stones, rubies, corundum, emeralds, sapphires, garnets and topazes; also microscopic diamond crystals.

Imitation precious stones are produced in the glass and crystal industry and are made of special types of glass or crystal (strass or paste to which bismuth or thallium is added) which may be colourless or have added to them certain metallic oxides for colouring.

Industrial Processes

Precious stones, properly so called, are reduced to a regular size, with plane or curved surfaces varying according to the nature of the stone, its proportions and the current fashion. They are then sawn by steel threads or metals discs dusted with diamond powder, and polished with a mixture of water and diamond dust (facets) or hard emery powder for softer stones.

The working of hard stones, generally by means of grindstones, is often a home industry carried on in small country workshops. According to pre-war authors, workers reclining on hollow semi-cylindrical wooden benches were in the habit of holding the stones to be polished against the grinding wheels by pressing against the bench with their feet. Often two polishers were engaged at each grindstone, one on each side.

Prior to polishing, it was the custom to groove, by dry working, the surface of the grindstone to the form of the object to be polished. After polishing, the grindstones had to be readjusted each time. These processes are now falling into disuse, for extension of the use of mechanical power has transformed the type of apparatus employed. Workers at present sit in front of the polishing stone instead of reclining on benches.

Only the manufacture of rubies has at the present time acquired any degree of industrial importance.

Sources of Risk

Cutting of precious stones up till quite recently has involved exposure to the risk of lead poisoning — use of grindstones or of lead "dops" — to the inhalation of dusts sometimes containing lead or other toxic or harmful products. For instance, the operator, in order to see the facets better is in the habit of rubbing them against the palm of his hand rather than cleaning them with a cloth, with the result that particles of lead are subsequently absorbed when he carries his hand to his mouth in eating or smoking.

In cutting establishments for precious stones, even managers are exposed to these risks, and many have been the victims of lead poisoning, often with fatal results (Talsky). Certain authors state that the making of "dops" exposes workers either to lead fumes or to smoke from stoves. At the present time, the use of carborundum, iron, copper, etc., grindstones, and the elimination of "dops" of tin or of lead or other constituents has resulted in the almost total disappearance of this source of injury. When metallic alloys are melted especially in domestic workshops, by means of coal stoves, the workers are exposed to the risk of carbon monoxide poisoning.

In cutting shops for hard stones the risk arises from mineral dusts liberated during dry cutting of grooves on grindstones, and during the polishing of the stones (crushing, cutting, polishing, piercing of holes, etc.). These types of dusts, which are extremely abundant, have a mainly mechanical action causing violent irritation of the accessible mucous membranes, especially those of the respiratory passage, and penetrate readily into the pulmonary tissue.

Under the older method of working, the worker lay on his stomach on his bench. This very tiring posture caused compression of the thorax and abdomen. In order to keep the stones in contact with the grindstones, the worker was obliged to exert an effort with his limbs and in certain cases with his whole body. When polishing large objects, the worker pressed his feet against blocks fixed on the flooring and pushed with all his strength. Finally, he was continually looking downwards to watch the work, which was tiring for the head.

When polishing is done by the wet method on a large grindstone, the head, neck, arm and chest of the worker are, because of their proximity to the grindstone, continuously subjected to a spray of dust, water and mud. Despite the use of means of protection (clothing, headgear, cloths) the clothing and the body are often soaked.

The floor of the workroom is often wet, even at a distance from the grindstones, and the humidity of the
surrounding air renders heating of the workrooms necessary even in summer.

Finally, polishing on grindstones demands, especially in the case of large objects, a high expenditure of energy. According to his strength and his habits, the polisher remains in the forced posture half-an-hour, one hour or even two-hours, until a sensation of fatigue in the chest and abdomen compels him to rise and take a rest.

**STATISTICS**

The statistics available are relatively few. According to those of Sommerfeld for the district of Birkefeld, relating to the period 1910-1912, the tuberculosis mortality rate per 100 deaths from all causes was 13.51 for agricultural districts and amounted to 25.38 in districts where polishing of precious stones was effected.

General mortality from all causes for the whole population varied in the district in question between 10.81 and 16.32 per thousand.

If the tuberculosis mortality rate be examined, it will be found that for the whole district of Birkefeld it was 27.15 per 100 deaths from all causes, 15.96 only for workers engaged in agriculture but 37.7 for industrial workers. The average age at death for the two latter groups was above 55.4 and 37.6.

Amongst polishers of precious stones, out of 35 deaths 37 were due to tuberculosis (67.08 per cent.) and 18 to other diseases (32.91 per cent.). From the fact that during the same period deaths from tuberculosis in the industrial district in question amounted to 37 per cent. and from other diseases to 63, Sommerfeld considers that the high tuberculosis mortality of this industry may be ascribed to working conditions, since amongst polishers in the Birkefeld district it exceeded by 30.09 per cent. the mortality for the general population.

**PATHOLOGY**

The injuries reported are to be explained by the dangers inherent in the materials manipulated and by the unfavourable conditions under which the work is often executed. These injuries are chiefly lead poisoning and pulmonary tuberculosis. The latter is caused not only by the action of dust, but also by the working posture, which often leads to stasis of the portal system in consequence of pressure on the lower part of the stomach and interferes with circulation in the lungs, already unfavourably affected by defective pulmonary ventilation.

Bad conditions, defective installations, dampness of the workrooms favour the outbreak of general troubles, chills, respiratory catarrh, rheumatism, nephritis, etc. Mention should likewise be made of general fatigue due to forced posture during work, as well as ocular and nervous fatigue occasioned by the close attention required during polishing.

**HYGIENE**

In certain regions in Germany (Oldenburg), stone-cutting establishments are subject to special legislative regulations: impermeable flooring in the workrooms which must be smooth and free from grooves in order to permit of ready cleansing. The same holds good of the pits in which the grindstones are fixed. Raw materials, scraps and residues must be kept in the workroom in special closed-receptacles.

The walls and ceiling of the workrooms must as far as possible be smooth and washed at least once per annum. Workrooms should be constructed in such a way that opening of doors and windows permits of adequate renewal of air during rest periods.

The flooring of the workrooms must be maintained in a constant state of cleanliness, and likewise the apparatus and machines used for cutting, crushing and sawing of stones. Recent developments in technical methods have certainly improved the precious stones industry and made it healthier.

The increasingly extensive use of grindstones made of carborundum, copper, iron, box wood, etc., and the replacing of lead "dops" have eliminated the risks of lead poisoning. Finally, the transformation of domestic workshops into factories represents an important hygienic improvement, since all adequate measures are enforced for eliminating dust (wet polishing, exhaust ventilation, etc.) and for ensuring personal hygiene (working clothes, seals, washing accommodation, etc.).

Amongst the legislative measures there should be mentioned the Order issued by the State of Oldenburg prohibiting the employment of young persons under sixteen years in the crushing and polishing of hard stones (agate).

**BIBLIOGRAPHY**

***
Primers or Percussion Caps

DEFINITION

A primer is a preparation capable of ignition when struck or rubbed or brought into contact with an electric spark, thus causing the detonation of a cartridge or charge of explosive material.

INDUSTRIAL PREPARATION

Most primers have a fulminate of mercury basis (see that article). There are various kinds of primers in use.

Harmless primers, such as used in toy manufacture, generally consist of a basis of fulminate of mercury agglomerated with a small quantity of gum and water. A small quantity of this is placed on a square of red paper (8 sq. mm.) and covered with a thin sheet of paper of the same size. Such primers detonate at the least shock and may also be made of red phosphorus and chlorate of potassium.

Primers for shooting and sport (hunting) have a fulminate of mercury basis. They are composed of a little tube of red copper, 4-5 mm. in diameter and 5-6 mm. high, at the foot of which is place 20-40 mg. of fulminate of mercury, according to the use to which the primer is to be put. The fulminate is then covered with a very thin layer of gum-lac in order to preserve its humidity and keep it in place. Sometimes the fulminate is mixed with 25-40 per cent. of powdered saltpetre to augment the ignition flame and diminish slightly the instantaneousness of combustion. The addition of nitre attenuates the shattering effects of the fulminate.

Primers for dynamite are of copper, 4-5 cm. in diameter, 30 mm. long and open on one side, with a charge of fulminate of mercury at the foot, varying according to the use for which the primer is intended.

With ordinary primers the explosion is caused by shock, but with dynamite primers ignition is caused by a mine fuse or Bickford fuse.

In electric primers ignition is due to a spark from an electric current used for mine explosion at a distance to avert danger to the operator. The older type of platinum wire primers are based on the principle of the incandescence of the platinum wire by an electric current, the wire being plunged into a charge of powder to cause ignition. A fusing composition causing the ignition of a fulminate capsule is fixed in the mouth of the primer.

Small arms factories usually restrict themselves to filling caps and primers, but do not manufacture the fulminate themselves.

HYGIENE

The fulminate may be made into charges for the percussion caps in a dry or a moist state and the latter system is preferable since it eliminates risk from dust. Such great precaution, however, is required throughout all stages of the work to prevent accidental explosion where the fulminate is handled in a dry state that these very precautions, demanding strict avoidance of dust, good ventilation, scrupulous cleanliness, and segregation of processes, etc. (see Dangers, article "Explosives"), reduce to a great extent the risk of poisoning. For this reason additional contact with the powder is reduced to a minimum and only occurs in initial weighing and mixing (with potassium chlorate, etc.). Weighing charges, loading and pressing can be so arranged that a man behind a heavy steel or thick concrete barricade can control the mechanism by a lever, guiding himself by watching a mirror above the machine. Other substances added to the charge—chlorate of potash, antimony sulphite, ground glass, or sulphur—are not harmful. Exposure to dust where such occurs causes fulminate dermatitis (known also as fulminate itch) chiefly among workers engaged in weighing, loading, pressing and inspecting primed shells. In certain arsenals the men are given carbolised vaseline to anoint the skin after washing. An ointment made of balsam of Peru with zinc ointment and a little carbolic acid is also used.

Workrooms in which fulminate caps, for toy pistols are made should be isolated from dwellings and constructed of light material. Explosive and inflammable material should not be stored in the workroom, but taken as required from the magazine. A limited stock of primers only should be kept in the magazine. Heating apparatus for the drying rooms should be placed on the outside of these and as far away as possible. Steam heating or hot water pipes should be installed. Still more rigorous measures are necessary for the manufacture of
primers for shooting, sport, etc. (see article "Explosives"). Panes of window glass should not be used, but should be replaced by white oily paper. The fulminate of mercury should be kept under water till required. Granulation should not be done by a spatula but by the hand on a table covered with a leaden slab and surrounded by a sheet metal guard of 11-12 cm. in thickness. The fulminate should be passed through a sieve outside the workroom, a hair sieve, furnished with lead plates at the bottom, being used. Very small quantities of the product should be handled at one time and the explosive mixture should be dealt with in a circumscribed space where accidental explosion of a charge would not endanger the whole staff. The workers should be protected as far as possible against accidental explosion. The charging rooms should be frequently cleaned and smoking absolutely forbidden. Daylight only should be utilised. The greatest precautions must be taken when cutting the sheet of paper covered with fulminate of mercury. (See articles "Fulminate of Mercury", "Explosives").

Printing Trades

French: Industries polygraphiques. —
German: Polygraphische Industrie. —
Italian: Industria poligrafica. —
Spanish: Industrias polígraficas.

In this article the pathology of the numerous categories of workers in the printing trades (composers, machine minders, lithographers, stereotypers, etc.) will be examined rapidly, but as completely as possible.

Printing had already been industrialised for three centuries since the invention of movable type when Ramazzini first drew the attention of scientists to some of the risks to which workers in this profession are exposed.

Although to-day the printing trade is amongst those which have benefited most by improvements in technical methods, it is nevertheless true that the morbidity rates for those employed remains, for complex reasons, fairly high.

Technical Data

Until recently, printing works were usually situated in the centre of towns to facilitate distribution, and often installed on the ground floors of old buildings. More recently, however, transport facilities have conducted to the building in the suburbs of large premises of one or more stories.

Further, while all the work in the older and smaller premises was done in the same workshop, modern printing works have separate workshops for the different processes (composing, printing, stereotyping, blockmaking, etc.).

The equipment of the composing room in a printing establishment consists of:

(a) single or double frames to hold the type cases. On the Continent the frames are often topped by shelves and pigeon holes. The case, in the form of a tray, is made of wood; it is about 14 in. deep and is provided with numerous small "boxes", each of which contains a particular character; the box is lined with one or more layers of thin cardboard to soften the slight shocks to the tips of the fingers when the characters are picked up; or the bottom of the box may be made of wire gauze with a drawer below to collect the dust. The work of cleaning the cases is thus facilitated, but in practice this kind of case is inconvenient as the metal base is either too rigid or too flexible and the characters easily stick to the wire, thus hindering the work of the compositor.

(b) The stone, on which the work is imposed, and randoms on which the composed work is placed before imposition or before the type is distributed. Standing type is sometimes kept in the lower part of the randoms.

(c) Shelves, to hold the "furniture" (wood or metal pieces, lower than the type, which serve to fill up blanks).

The implements used by the compositor are few, but characteristic of the trade, consisting of: composing sticks, tweezers and bodkins, and galleys.

The stick is the most important implement for the printer; it serves to hold the letters extracted one by one from the case to form the words and lines. It consists of a thin flat piece of metal usually about 10 in. long and 2 in. wide with flanges on the back and right hand side and on the left an adjustable slide which can be fixed to the particular "measure" or length of line required for the work in hand.

Tweezers and bodkins are used to facilitate manipulation of the characters on lines during correction.
The galley is an oblong tray to which the type is transferred from the composing stick.

Under the name of "type" are comprised all the letters used in printing. In a more restricted sense this term may be used to designate the entire collection of types of the same series and all the letters, spaces, etc., contained in the same case.

Type varies not only according to the form and size of the letter, but also according to the chemical composition depending on the proportion of lead (from 61 to 85 per cent.), antimony (from 15 to 33 per cent.) or tin (from 3 to 8 per cent.). The degree of hardness of the type depends on the proportion of antimony it contains, which may even amount to 75 per cent: in the case of very hard type. It must conform to a standard height, in order that the face may present a uniform surface.

Besides the letters there are dashes, punctuation marks, spaces and quads (for insertion between the words), which consist almost entirely of lead, a little tin, and at times traces of antimony.

The paper used in printing forms the subject of another article and will not further be referred to here.

On the other hand, printing inks require some mention. The ink used is a varnish composed of seccative oils and resin, mixed intimately with lamp-black so as to constitute a perfectly homogeneous black mass, clear and unalterable by air, drying rapidly, capable of impregnating the paper without penetrating it, of pleasant odour, and easily removed from the form and size of the type depend on the proportion of antimony it contains, which may even amount to 75 per cent. in the case of very hard type. It must conform to a standard height, in order that the face may present a uniform surface.

cribe the methods followed in Linotype printing. This machine does not furnish ordinary single letters, but letters cast together in the form of a "slug", or line of type. The machine effects consecutively the composition, the justification of the line, the casting of the lines in slugs and the distribution of the "matrices", i.e. the moulds into the edges of which the letters are cut. After final use the slugs are melted down for recharging the Linotype machine. This machine consists essentially of a keyboard similar to that of a typewriter, magazines containing matrices, casting apparatus, and a distributing system; an assembly box on which the matrices are arranged to form the lines, a mould the length of a line and some millimetres in height, which receives the quantity of molten metal required to form the slug and a metal pot to hold the alloy for casting the slugs. The metal pot heated by gas or electricity, or failing these, by a special petrol lamp, is closed by a cover provided with a pipe to remove the fumes from the molten metal, and an exhaust device.

The operator seated before his keyboard fixes the assembly box to the required length and composes his text by tapping the keys with his fingers, as with a typewriter. Each key pressed brings down from the magazine the corresponding matrix, which arrives in the assembly box. When the key for the space is touched, it brings down a double wedged spaceband, and several of these, when the line is completed, automatically effect justification. The line, once composed, the release of the slug from the matrices and the distribution of these into the correct channel in the magazine is effected automatically.

Proofs are then pulled and sent for correction by comparison with the manuscript. The corrections marked on the proof are effected by the operator.

The next operation is to make the type up into pages after final revision by the author. The pages are so arranged that when the sheet is folded they fall into correct sequence. This is called "imposition" and includes placing the pages within an iron frame called a "chase"; the determined space between the pages is filled up with "furniture" about half in lower than the type so that it does not get inked in printing. The whole is then locked up in the "chase" by wedges or "quoins". At this stage it is known as a "forme" and is ready for printing.

Printing. — The forme then goes to the press — work that was formerly entrusted to the compositors, but is now trusted to the qualified workmen known as "machine minders" — operate numerous types of machine founded on the principle of pressure exerted by a plate known as a "platen" on a sheet of paper placed in contact with the surface of characters previously inked. Plates are of "light" and "heavy" types, set in action by treadle, though motor power is now usually employed. "Heavy plates" are of exceptional strength and are used for high-grade printing. Rotary machines, periodic or continuous, and rotary presses are used for printing a very large number of copies for which the pages must be stereotyped beforehand in the form of curved plates fixed on cylinders, between which the sheets to be printed must pass.

Special mention should be made of the ink rollers, which are made of a basic mixture of gelatine and molasses. An inked roller takes the ink from the feeding duct, whence it passes to a metal surface where uniform distribution is effected; the inking rollers take their supply from this disc and pass it on to the type.

After printing, Linotype and Monotype metal is sent back to be melted down, while all movable type is "distributed", an operation which consists in replacing the type used in the appropriate boxes. This is usually done by a compositor and is light work. In the case of hand composition, after having cleaned the type to be distributed with a brush dipped in lye, the compositor takes in the palm of his left hand a handful of lines, which he keeps in position with his thumb, while with the thumb and index finger of his right hand he takes the letters, which with a movement of the thumb, index and middle fingers he replaces in the appropriate boxes.

Stereotyping. — Stereotyping comprises the preparation of duplicate plates of type large relief printing blocks. The plates allow successive copies to be printed, thus releasing the type for other use. Use of the plates is essential in work on rotary machines. The plate is prepared by taking a mould of the forme on a sheet of "papier maché" or an superimposed sheets of paper, between which paste size mixed with Spanish white is spread. Into this mould, dried flat for an ordinary plate, or on a cylinder for a plate intended for a rotary machine, is poured the molten metal in order to obtain stereotyped
plates to serve for printing. These plates may of course be prepared by the alternative process of electrotyping (for the preparation of blocks, see article "Photo-engravers").

Lithography. — Lithography is the art of tracing, by means of a greasy substance on a special stone, characters or drawings with a view to their reproduction by printing. The reproduction may be black or coloured. The raw materials used in the industry of lithography may be subdivided into three groups: (1) raw material used for support; (2) raw materials properly so called; (3) accessory raw materials.

To the first group belong the natural stone or the artificial stone made of zinc, aluminium, etc. The natural stones are of different kinds: a bluish stone (the hardest), a yellow stone (soft), a slaty grey (medium), white, reddish grey, etc. The fairly high price of natural stones has given rise to the manufacture of various artificial stones, but none of these is equal to the natural.

To the second group belong the inks, the crayons for drawing and writing, the lithographic inks for copying or, for transfer, the inks and colours for printing, and the tracing paper, printing paper, etc. Lastly among the accessory materials figure various acids, notably nitric acid, spirits, and certain chemical substances, sponges, pumice stone, sealing wax, etc.

Lithographic work properly so called is done directly on the stone by means of a lithographic crayon or lithographic ink, by pen or pencil or by the method of transfer, by the aid of which the lines drawn on paper are transferred on to the stone.

The drawing may be transferred to a zinc or aluminium plate instead of to a stone, a method which is said to yield superior reproduction of fine tints. The same method is used, except that the acid solution is weaker than in the case of transfer to stone. The drawing is placed in a "damp book" consisting of damp blotters with a rubber cover. After twenty to sixty minutes it is removed and dropped on to the stone or plate, being covered with "backing" — a clear sheet of paper and a sheet of compressed and greased fibre-board — and run through the press. Special transfer paper requires to be soaked off, but ordinary tracing paper can be pulled off without further treatment. The stone after drying is then treated with gum arabic and nitric acid, or the zinc plate by gum arabic, chromic acid and phosphoric acid or the aluminium plate by gum arabic and phosphoric acid. The acid eats away any invisible particles of grease and does not affect the drawing itself, and the gum arabic desensitises the surface not drawn on. After drying, the surface is washed with clean water, sponged with a solution of gum arabic, rubbed down and dried, in the case of a plate the acid solution being washed off without drying. The stone is again washed with turpentine leaving the drawing invisible and rinsed with water on a sponge. The printing ink is then applied with a roller covered with leather, the stone or plate resting on the bed of the press, and prints are pulled by the application of sliding pressure.

Making of ledger. — Ruled lines on paper may be more or less complicated according to what the paper is intended for. Ruling may be "continuous", simple or uniform, or "discontinuous"; the lines vertical, horizontal, in different colours, etc. Formerly, and even at the present time, the system of ruling by means of a pen machine was used.

In modern technique disc machines are employed, some simple for ruling continuous lines, others complicated allowing for desired breaks in the tracing of various lines and for discontinuous ruling.

The black lines, the titles and the headings to the columns are set up in the composing room; the coloured lines are made by means of different inks with a basis of Prussian blue, indigo, aniline, etc.

Slachovský (1924), after making an enquiry into the aniline colours used in the making of the ledgers stated that "Water Blue Z III" only set up cutaneous lesions, that "366 Brilliant Green extra Krist" acts injuriously if it comes into contact with the mucous membrane and that "56 Methyl Violet" injures the skin and may cause injury when absorbed internally.

Stitching and binding. — The sheets of paper after printing and folding are next sent to be stitched. This is increasingly done automatically by machines. But in many workrooms stitching is still done by hand or at least partly only by machinery. Pamphlets are stitched by machine with galvanised steel or brass wire. The machine cuts the wire and forms it into hooks, bending the two ends. In the case of bound books, the machine stitches the book with a thread and binds the parts together, surrounding with the thread strips attached to the back of the volume, which is then brushed with
strong glue. The pages of the volume are then cut even; sometimes the edges are coloured or gilded; the back is then rounded by machine, and the volume goes to have its cover put on, the two halves of which are bound to the body of the volume by means of additional strips and bands of cloth. All this is glued inside on to the cover. The back is next made up of pasteboard, rounded by machine and stamped and the whole covered with a piece of cloth. The external covering follows — applied with strong glue — next the finishing, the title, etc.

**Sources of Dangers**

The printer's health is exposed to many risks. First, the working conditions may not comply with the requirements of hygiene, as, for instance, small rooms with insufficient cubic space, and inadequate ventilation. Further, either the natural or artificial lighting may not be satisfactory and it is a fact that eye troubles are rather frequent among readers, compositors and lithographers. The kind of work, involving a relatively stationary position may be harmful to the worker during cold weather if the room is not sufficiently warmed. On the other hand, the means of heating under conditions unfavourable to health (by stoves) provide another source of danger.

Moreover, the standing position and the attitude assumed may injure the worker, especially in the case of compositors of weak constitution; long continued standing may induce flat-foot, varicose veins and ulcers of the legs. The tools may cause skin lesions and give rise to trade calllosities. Manipulation of the characters either by hand or machine is a serious cause of danger; hand compositors are exposed to the risk of lead poisoning and the toxic action of the antimony which enters into the composition of alloys. In the case of typefounders, harmful gases may escape from the melting pot and become the vehicle of lead and arsenic, the latter being sometimes present as an impurity in the antimony used.

The Swiss National Accident Insurance Fund in Lucerne asked Professor E. Waser to analyse the air coming from the metal pots of composing machines as to its contents in lead oxide, paying special attention to the pots heated by electricity. While the formation of lead dust in the workrooms cannot be altogether avoided, so far as relates to the melting pots, Waser came to the same negative conclusion as previous research workers (Roth, Leymann, Carozzi, Heise, Froboise, etc.), namely, that the air above the metal pots of composing machines contains no lead and the amount of lead dust in this air is remarkably small. He did not consider it necessary to provide ventilating pipes over the metal pots heated by electricity as no fumes were given off.

The radiant heat, particularly from the composing machines, is yet another factor causing inconvenience to the worker.

Cleaning type cases raises toxic dust when carried out without due precautions.

The use of various liquids for washing the characters, machines, blocks, and the use of various solvents for the inks (xylene, benzene, alkaline solutions, petroleum, formalin, etc.) also increase the risks run. A recent process known by the name "Pantone", especially used in England, employs a paste with mercury as a basis for cleaning silver typographic plates as well as for typographical operations. Mercury fumes may be given off from this paste at room temperature and thus constitute a source of poisoning (Koelsch).

The basic substances entering into the composition of coloured ink, notably chromates, vermilion, mithium, etc., may also affect the health of the workers when not manipulated with care.

Lastly, injuries, especially to the hand, are common among compositors, pressmen, printers and inachinists.

**Statistics**

Although the morbidity and mortality figures of the printing profession have been studied for many years past both from the point of view of general causes of ill-health and causes peculiar to the trade, the first important study systematically carried out as a result of numerous observations and population data is that of Carozzi (1910). It embraced the whole of the printing trade in Italy, with special reference to the city of Milan, over a period of a year. His conclusions have been confirmed by later investigations in many towns and countries (Raneflett, Rome; Hoffmann, in the United States; recently Seitz in Saxony; Schwarz in Germany, Bradford Hill in Great Britain, etc.).

Fuchseine oxidised by arsenic acid is more brilliant than that produced by nitrobenzoal. It appears that makers are now again using arsenic for inks. In certain typewriter ribbons as much as 5-15 mg. per metre has been found.
Carozzi showed that the average morbidity from all diseases among printers (compositors and machine minders) was notably higher than that of other industrial groups taken as a whole.

Diseases of the digestive system were the most frequent, if not the most severe, followed closely by diseases of the respiratory organs. Pulmonary tuberculosis seems to bear a relation to the poor conformation of these workers. Together with bad conditions of work and the prevalence of lead poisoning among these workers, the same is true of neurasthenia, which is widespread in the industry and is due to a variety of causes.

Nutritional maladies, although by no means specific to this class, merit special attention because their frequency is out of all proportion higher than that of other industrial groups considered as a whole. In Saxony, Seitz found a relatively high mortality among the various categories of salaried officials, which made him consider that conditions of work were sufficiently satisfactory. On the other hand, at Leipzig 43.5 per cent., at Chemnitz 23.5 per cent., and at Dresden 25.5 per cent. suffered from headache and gastro-intestinal troubles. In these three cities about 8.5 per cent. had suffered from lead symptoms; but Seitz insists on the fact that the complaints were mainly subjective.

The mortality figures are the direct consequence of the high morbidity affecting mainly the group between sixteen and thirty-five years of age. Pulmonary tuberculosis (very high both in the acute and the chronic form) dominates the picture, together with acute and chronic respiratory troubles and infections. Carozzi considers this due to the lack of good physique among those who take up the trade. Generally speaking, they are feeble, physically defective and would certainly be rejected by thorough medical entrance examination. It should be added that under the conditions of work that prevail to-day the physique of young persons is better, which explains the slow but constant increase in the average duration of life among these workers as shown by statistics.

Carozzi also investigated the infantile mortality among printers and showed that it and miscarriage reached a high percentage (36.2%).

Comparing these data with those collected by Hamilton, Hoffmann, Seitz, Raneletti and with statistics furnished by Great Britain, the Netherlands and Austria, Carozzi was able to show that it was also high in the United States (35 per cent.), in Great Britain (31 per cent.), in Berlin (48 per cent.), in the Netherlands (18 per cent.), etc.; and further enquiries conducted in those countries showed that the most frequent cause of death was due to respiratory and digestive diseases, from gout and rheumatism, and from nervous diseases. Less high were the figures for lead poisoning (in its recognised clinical form), which constituted only a slight addition to the pathology of the profession.

There will here be given but a brief summary of the enquiries published during recent years.

In Germany, according to information furnished by the Printers' Union for the year 1929, the total number of cases of sickness was 39,400, which accounted for 1,124,929 days of illness. Of the cases noted, in the order of frequency, were infectious diseases, 9,175; respiratory diseases, 4,070 (of which 888 were pulmonary); nervous diseases, 3,635; digestive, 3,427 (of which 1,827 were gastric); tumours, 2,752; gout and rheumatism, 2,318; circulatory diseases, 1,988; diseases of the generative and venereal organs, 871; saturnism totalled 349. The number of deaths totalled 795, of which 93 were due to diseases of the lungs, 64 to pneumonia, 10 to heart disease, 34 to diseases of the intestine, 24 of the arteries, 39 of the kidneys, 14 from tumours, 13 from diseases of the liver, and 7 from lead poisoning.

Per 1,000 members the number of cases of sickness was 250 in 1920 (of which 48 were due to respiratory diseases, 20 to nervous and 23 to digestive); of 246 in 1924 (of which respectively 30, 29, 38); 378 in 1928 (of which respectively 46, 46, 41) and 402 in 1929 (of which respectively 47, 40, 29).

Statistics show that it is between the ages of fifty-one to sixty-five that death claims its largest tribute. As compared with 258 deaths at this age group, 160 occurred in the age group 36-50 and 116 in the age group 21-35 years. For the age group 18-20 there were 9 deaths, and for the age group 66 and over, 252 deaths.

In Saxony, Seitz found a relatively high stability among the various categories of salaried officials, which made him consider that conditions of work were sufficiently satisfactory. On the other hand, at Leipzig 45.5 per cent., at Chemnitz 25.5 per cent. and at Dresden 25.5 per cent. suffered from headache and gastro-intestinal troubles. In these three cities about 8.5 per cent. had suffered from lead symptoms; but Seitz insists on the fact that the complaints were mainly subjective.

The cases of sickness based on the objective signs registered between 1 January 1922 and 30 June 1923 among the members of the Sickness Fund of Saxony were distributed as follows:

In 1929 Seitz extended his study of the physical and social conditions to cover all German printers. Unfortunately, he did this by means of a questionnaire, so that there was no serious control over the data received. Seitz received 41,778 replies (7,168 machine minders, 20,165 compositors, 1,798 proof-readers and workers engaged in making up the pages, i.e. stone-hands), of which 31,283 only were thought of value. The enquiry also covered housing, tuberculosis among members of the family, etc., and showed that 0.98 per cent. of printers were tubercular (in Bavaria Kolesch found 0.49 per cent., Leipzig Sickness Fund, 0.13 to 0.44 per cent.).

Hoffman's enquiry in the United States and Canada dealt with hygienic and sanitary conditions and was made by means of a questionnaire addressed to associations of employers and workmen. From the replies of 2,096 employers relating to the years 1922-1923, the number of sick persons among a body of 1,000,704 workers was 697, or a percentage of 0.69, the comparative lowness of which must be placed to the credit of the hygienic conditions of printing works in America.

The data concerning mortality were furnished to Hoffman by the International Typographical Union. In 1929 no death was attributed to lead poisoning, but the causes of death which might result from the action of lead (nephritis) are always frequent enough, although they too seem to be diminishing. The mortality per 100,000 members and for certain causes of death work out as follows:

<table>
<thead>
<tr>
<th>Years</th>

It is necessary to emphasise once again the fact that it is the age group 20-49 years that suffers chiefly from tuberculosis and respiratory diseases (pneumonia in particular) and that nephritis occurs amongst these workmen at a fairly early age (between thirty-five and fifty-four years).

As regards pulmonary tuberculosis, the following values from 100 deaths from all causes of each age group were found:

<table>
<thead>

The percentage of deaths from tuberculosis at every age rose from 20.9 (1912-1918) to 14.9 (1919-1923) and 8.2 (1925-1929). The deaths from lead poisoning during the period 1914-1923 numbered 64, 8 of which were among workers in age group 18-30 years; 12 in age group 31-40, 23 in age group 41-50; 14 in age group 51-60 and 7 in age group above 60 years. An enquiry (1927) in the Philippines by Villafranca and Igasiano brought into relief the very high mortality amongst printers, attributed by them to long hours, lack of air space, work at night, work at high pressure, and lead poisoning.

In Great Britain the National Society of Operative Printers and Assistants shows for the period 1909-1922 640 deaths distributed as follows:

of the very high mortality from pulmonary tuberculosis. Like the previous authorities quoted, Bradford Hill attributes this mortality to the poor physique of those who take up the work and to unfavourable working conditions. With reason he stresses the importance of the problem under review for over 250,000 workers are engaged in the printing industries. By a comparison of the data as to 36,000 members from some nine printing associations with those furnished by Friendly Societies, Bradford Hill reveals the fact that printers show a high average of sickness and incapacity from the first years of employment onwards. For the age group 16-19 years the position is very unfavourable when compared with the general population: the same fact is brought out for tuberculosis, which, however, affects machine minders at a later age than it does hand compositors.

For Italy it is possible to present figures drawn from the very detailed statistics of the "Cassa Malattia Poligrafici" of Milan. During the period 1925-1927 this Fund received notice of 187 deaths, of which 42 were due to all forms of tuberculosis (37 pulmonary tuberculosis), 20 to respiratory diseases; 21 to diseases of the heart and blood vessels, and 126 to others, etc. The morbidity of members (male and female of this Fund during the same period showed the following values: number of cases of sickness, 30,955; number of cases of respiratory diseases, 1,471 (of which 105 were pulmonary tuberculosis, 79 alveolar bronchitis and 65 catarrh of the pulmonary apices); diseases of the stomach and intestines, 1,062; of the heart and blood vessels, 237; of the nervous system, 387 (of which 168 were cases of neuroses); of the kidneys, 104 (of which 47 cases were chronic nephritis).

Cagetti (1930) brings out the frequency of pulmonary tuberculosis as a cause of death: of 100 cases of death in the same occupational group during the period 1921-1925, compositors and lithographers showed the figure of 22.8 (the highest), followed by the workers in the metal trades 21.7; for masons and sailors on the other hand the figures were 9.2 and 9.3 per cent. respectively.

By taking as 1,000 the mortality from all causes of all employed and retired persons between twenty and sixty-five years of age and comparing the figures of mortality due to various causes to those for the printing trades the figures in the table below have been obtained.

A very interesting study is that of Bradford Hill (1925), published by the Industrial Health Research Board (No. 54) relating to 32,969 persons, of whom 14,507 were compositors, observed over a period of five years. These data confirm the fact...
In the U.S.S.R., Bensman in 1925 studied the health condition of the workers in the printing industry at Krasnodar. His enquiry covering 328 workers, of whom 34 per cent. presented a more or less marked diminution in haemoglobin and 44 per cent. all stages of tuberculosis. Kaminski analysed 1,489 cases of sickness among printers in Kharkow and found that the number of days lost through sickness due to tuberculosis among hand compositors and machine minders (369 per cent. of the total days lost from illness, as compared with other groups in the same industry 17.3 per cent.) was very high.

PATHOLOGY

In Germany Seitz (1929) and in Austria Brezina and Lebzelter have undertaken enquiries into the physical state and constitution of printers. Lack of space unfortunately prevents summarising these interesting studies. Reference should also be made to the researches of Bargeron (1929) published by the Lannelongue Institute in Paris.

In addition to the maladies affecting printers in common with other workers, under the same environmental conditions (cubic space and area, ventilation, etc.), these, are others aggravated by the concomitant action of such conditions when defective, as well as by the action of lead, especially chronic or less intense anaemia manifesting itself in pallor of the skin and mucous membrane and a state of well-marked organic decline. Examination of the blood, however, merely reveals ordinary oligaeemia with predominance of oligochromaeemia; the white blood cells present a normal differential count, although the number is about the normal lower limit (Pieraccini). It is also possible to find punctate basophilia due to lead absorption (see below).

Insufficient natural lighting or, as is often the case, inadequate artificial lighting, reading difficult manuscript, the fineness of the work to be done, constant change in the position of the glance, as well as of accommodation, all favour eyestrain and explain the incidence of visual defects among compositors (diminution in acuity of vision, errors of refraction and accommodation and muscular co-ordination).

Among printers with eyestrain, Mosse succeeding in showing that vision was normal after Sunday rest and that visual troubles came on towards the middle of the week's work. For a long time Cohn and Hirsch have laid stress on the frequency of myopia among printers. Walther looks on this as an undoubtedly occupational disease, even where the presence of the existence of school myopia is recognised.

Hitzing has described among these workers, as well as among machine minders, a form of conjunctivitis which he attributes partly to irritation from the paper dust.

Occupational stigmata localised on the hands and caused by the tools are characteristic. In addition to a callosity in the palm, the right hand presents a callosity on the internal border in the neighbourhood of the metacarpophalangeal joint which is 2 cm. long and 1 cm. wide; two at the anterior face of the ball of the thumb and index finger (Chevalier and Vernois); another callosity is situated on the upper extremity of the line between the thenar and hypothenar eminences, due to the pressure of the composed lines when they are lifted by the compositor to be placed on the galley (Carozzi), and a fifth callosity on the internal border of the dorsal side at the level of the middle line of the palm, resulting from pressure from the page cord during tying up of the pages. Further, intensive and prolonged work, especially in winter, with the cord may raise the skin at the point indicated and set up painful fissures involving temporary incapacity for work.

Among compositors there is found rubbing away of the free edge of the nail of the right thumb, especially on the radial side, and this is even more marked on the nail of the index finger where the wearing away takes place at the cubital edge. The skin of these two fingers take on a dull hue very much more pronounced than that of the other fingers and the rest of the hand with formation of small flat callosities on the tips due to shock of these fingers against the little metallic cubes during manipulation of the characters. The colour of the skin is attributed to the alloy (Pieraccini and Casagli).

Eczea of the hands and forearms, hyperidrosis, etc., due to contact with irritant substances (turpentine, benzol, petrol, strong 1yes, chromates, etc.) are very frequent at the present time (Silberstein).

Introduction into lithography of the process of chrome reproduction has favoured the development of cases of eczea. An enquiry by Engelhardt and Mayer (1931) covering fourteen lithographic printing works and relating to 114 workers showed eczea present in 30, of whom 84 per cent. were hyper-sensitive to potassium bi-chromate; among the other 84 workers 7 only reacted to the sensitisation test.
The affected persons had ulcers on the septum, but without ulceration of the mucous membrane. Cases of eczema among these workers cannot be denied. In photo-mechanical transfer of texts and designs, bichromate of potash or ammonium is used mixed with organic substances (albumen, gelatine, gum arabic, etc.). Up till a few years ago the danger of eczema from chromates was considered of little importance, but for some years past, on the other hand, the process-engraving industries furnish a large number of cases (McCord, Higginbotham and McGuire, 1930). This incidence may be explained by the development of advertisement, of illustrated papers and rapid reproduction of pictures, etc., by means ofchrome processes.

In Great Britain, Overton (1929) conducted an inquiry in thirty-one printing works, examining nearly 150 workers engaged on lithographic processes and photolithography; about 7 per cent. of the workers were found to have dermatitis, due probably to chronic acid or chromium compounds used during the operations of transferring and lithographic printing. Paraffin and turpentine were also held responsible. An inquiry made by the German Union of Printers and Engravers affecting 9,400 persons employed in process engraving revealed the fact that in the first quarter of 1930, 202 cases of skin maladies were reported, especially eczema (101 of the patients suffered several times); 130 of these 202 cases attributed the condition to zinc mordants, chrome salts and other substances used in engraving.

Frequently in winter compositors suffer from rhagades (painful fissures), which easily become infected, for they correspond with the small callosities of the thumb and index finger already referred to involving long periods of incapacity from work. These lesions are said to be due to the action of the damp type and coldness of the premises during the winter months. As a result of these conditions liability to injurious effects from traumatism is heightened. They do not occur among workmen in dry and well-heated rooms (Pieraccini and Casaglì).

The printing profession does not demand forced attitudes or bad posture to an extent sufficient to set up marked alterations in the trunk and limbs. It is however, the compositor's posture before the type cases, with his back slightly bent, his head stretched forward or looking towards his manuscript, must exercise an unfavourable effect on the health (Oliver and Pieraccini).

The continuous swaying movement which is characteristic of the machine minder tending certain printing machines should be mentioned.

The constant standing position necessitated by the work in printing offices accounts for the fairly frequent occurrence of flat foot (about 57 per cent.) and varicose veins in the leg, associated sometimes with ulcers. These are favoured by hard weather and too long lead circulation, habitual constipation, and most often by the constitutional biological type and anatomical predisposition of the worker. Constant standing may also cause movable kidney and sometimes ptosis of the intestines which are fairly frequent among these workers: lumbago and cramps in the muscles of the back (machine compositors), pains and cramp of the thigh (hand compositors and machine minders, etc.).

Certain habits such as holding the type between the teeth, cleaning the type and cases by blowing on them to remove the dust, eating in the workshop without previously washing the hands, etc., naturally favour the penetration of poison into the system.

Several authors take the view that lead poisoning among those engaged in the printing trade is no more frequent than in other categories of workpeople handling substances containing lead. As a matter of fact the statistics given rather strengthen this view. According to A. Seitz, cases of saturnism at Leipzig reached the figures of 8.1 per cent. of the persons examined, and in the enquiry of the Union of German Compositors saturnism in 1929 showed a percentage of 0.89 cases of sickness. Data provided by Jehle, however, limits it to 1.92 per hundred printers (Vienna) and those of the Sickness Fund to 3.3. In Great Britain lead poisoning worked out at 3 cases per hundred printers, and at Milan Carozzi found 1.7 (8.6 for compositors alone) and Ranelletti, at Rome, 3.3 per hundred workers (4.1 per cent. of cases of sickness: with one case only among 539 machine minders and feeders, of whom 246 were men).

In 1927 Koiransky examined 512 printers for punctate basophilia in Moscow and found it in 13.3 per cent.; polychromasia in 8 per cent. The punctate basophilia showed itself especially among the hand compositors (15.8 per cent.), casters (15.8) and machine minders (15.2); among the stereotypers the percentage was only 4.2.

The lead and antimony which enters
The channels of entry are the same as for lead poisoning (see that article). In 1927 N. Sach, in an examination of 395 Russian printers, found that affections of the mouth were very frequent (more than 69 per cent.); he attributed them not only to the absence of dental hygiene but also to the action of the lead, because it is well known that abnormal conditions of the mucous membrane of the mouth facilitate the absorption of poison. Whilst the blue line has been found in 6.3 per cent. of the workpeople — 15.8 per cent. in the compositors and 7.5 in the hand compositors — colic only affected 0.8 and paralysis 0.6. But these conclusions do not mean that the risk of lead poisoning in the printing industry does not exist or is negligible. It only means that lead poisoning is not so severe among printers as among other categories (painters, engravers, etc.). In reality this form of poisoning almost always assumes a slight form affecting especially the digestive and circulatory systems, the liver and kidneys. Good hygienic conditions of the workshops on the one hand, the small quantities of metalised lead absorbed very slowly into the system on the other, explain why these are not sufficient to produce the characteristic clinical symptoms, but none the less they exercise an injurious effect, manifested by anaemia and a general lowered resistance favourable to the development of tuberculosis and by a series of symptoms (stomatitis, dental caries, digestive and nutritional troubles, etc.) spoken of as "petit saturnism" (slight saturnism).

There is no need to repeat what has already been said (Statistics) as to the very high incidence of respiratory diseases and tuberculosis in particular among printers.

It is difficult to admit natural selection, as certain authorities do (Bensman in particular), as sufficient to exclude those who are not strong from the printing industry.

The views of Carozzi, no longer of quite recent date but confirmed by other authorities, show that on the contrary it is the less vigorous who take up this trade; they are young persons of nearly average health, the victims of over-exhaustion, mental and physical, since very often in the evenings after their work they strive to study with a view to improving their position.

The Institute of Legal Medicine in Siena, directed by Bianchi, is taking up the study of occupational biotype and the first of these studies (Baisi, 1930) dealing with printers has been published. Although the enquiry relates to only a small number, the author believes that he has been able to show that those who enter this profession are especially individuals of a very feeble type.

The researches will perhaps show on which of the various categories of general constitutional type absorption of lead exercises its effect and will likewise reveal the relation existing between trade morbidity, occupation and constitution.

The absence of selection, the social origin often involving physical defect, the sacrifices that these workers make to improve their knowledge, the early age at which they enter the trade, the working conditions, the absence of movement and physical exercise and lastly the action of lead dust, all these conditions — even admitting an antagonism between lead poisoning and tuberculosis — represent causes predisposing to respiratory diseases.

Maladies of the digestive tract hold second place, taking the form of gastritis, dyspepsia, atony and obstinate constipation which some authorities attribute to the sedentary life, lack of movement, the necessity for resuming work directly after meals, a strained attitude; while others (Carozzi) regard
it as a slight form of lead poisoning especially in its preparatory phase.

This hypothesis finds confirmation in the verselet, while, into, who for a long time has reported on the frequency of gastric trouble in pre-saturnism, and in the clinical and anatomopathological findings which prove a saturnine origin for certain forms of enteritis in printers (Massini, Fabris).

Similarly, it is to the action of lead that derangement of the liver and of the cardio-vascular system is due, which, in order of frequency, follow closely the respiratory and gastro-intestinal maladies.

Latyscheff (1927) from an examination in ten of the principal printing works in Moscow of 1,200 workmen, of whom 88 were compositors, arrived at the conclusion that lead, in contra-distinction to other sympathico-tonic poisons, markedly increases occurrence of tubercular lesions; it affects the normal relations of the endocrine glands; causes, on account of the hypertonicity of the sympathetic system, secretion of hyper-acid gastric juice with increase in the content of acids and mineral and acid substances. Anaemia and nutritional diseases are most common amongst women as they are less resistant. This enquiry emphasises yet again the high incidence of saturnism in its slighter forms, affecting lungs, heart and digestive apparatus.

The pathology of the cardio-vascular apparatus is characterised by an increase of arterial pressure, by pathological alterations causing arteriosclerosis, by arteritis and organic heart changes involving the kidneys. The experiments and clinical investigations of Preti and Devoto of toxic arteriosclerosis have demonstrated the special action of lead on organic changes, an action causing a urio-acid diathesis, a condition extremely favourable to the development of cardio-vascular maladies.

To sum up, although it does not cause the classical signs, lead dominates the whole pathology of those employed in the industry, and prepares and predisposes the whole system to the insidious onslaught of different disease forms.

An etiological association between gout and saturnism (Pieraccini) is held by some and denied by other experts (Hahn), or considered doubtful (Silberschmidt), while the clinical observations of Preti, confirmed by the previous experiences of Rambousek and statistics generally, attribute considerable responsibility to this etiological factor.

Much less certain, and indeed denied by some authorities (Hahn, Silberstein), is the part played by lead in the etiology of certain nervous troubles (headache, irritability, insomnia, tremor, distaste for work) found among printers and attributed by Carozzi not so much to lead as to long hours, accelerated rhythm, strained attention, factors aggravated by night work and the effect of alcohol and tobacco which are abused by some printers. Among 600 printers examined by Carozzi, none was found to be affected with organic or severe functional nervous lesions; but he did find among some of them a diminution in the sensibility of the fingers, slight tremor of the hands only, exaggerated during the evening as a result of fatigue. Fatigue is also the cause of muscular cramp of the hands among compositors and especially linotype operators; among these latter the symptomatology and eio-pathogenesis are identical with those of the cramp experienced by typists. Jacobi has reported also two cases of tetanus; others have described temporary radial paralysis as characteristic and, more rarely, lead encephalopathy, favoured by alcoholic excess. Certain peripheral nervous lesions (neuritis, neuralgia) attributed to the effect of certain working tools, are exceptionally rare. Among 174 such cases reported up to 1901 in medical literature, Baratis has only found two among printers. Hahn has also noticed that typefounders (who are more exposed than printers to the effect of lead) show a figure for nervous diseases as low as that of printers, whilst lead poisoning is less frequent and neurasthenia more frequent.

After lead, account must be taken of antimony, which may set up morbid changes. The first cases of poisoning were described by Schrumpf and Zabel (1910) in three compositors. Other cases have been reported subsequently by Walther, of Chicago, who was able to demonstrate the presence of antimony in the urine.

The results of the enquiries, however, do not lead to any definite conclusion (see article "Antimony").

In addition to poisoning by benzene and also by benzene used by the machine minders, noted as early as 1910 by Carozzi, since when it has become more frequent, there must also be taken into account now the possibility of poisoning by xylol and toluol, reported by Stocke (1929) among makers of blocks for illustration (Tiefdruckverfahren). The oil colours are dissolved in substances generally known under the name of "xylol" which is
used to wash the blocks, but they really consist of benzol at 30 per cent., containing also appreciable quantities of carbon bisulphide. In one machine minder Brocher (1930) reported a fatal case of chronic benzol poisoning, with a clinical picture of atrophic panmyelopathy (aplastic anaemia); in the blood he found 80 per cent. lymphocytosis and 90 per cent. punctate basophilia.

A new occupational risk menacing the workers is mercurial poisoning, reported by Koelsch and due to a recently introduced technical process (see article “Photo-engravers”). In some categories the possibilities of troubles caused by the use of bronze colours has to be taken into consideration; these colours consist of an impalpable dust containing a fairly high percentage of copper and traces of lead (Carozzi). (See also article “Bronze”.)

HYGIENE

Hygienic measures for the printing industry are self-evident from the descriptions already provided. General measures of hygiene are the same as those for all industrial establishments.

On the other hand special measures are required in printing workrooms.

The number of rooms should be in proportion to the importance of the establishment and, even in the case of the smallest printing works, the composing room, especially if linotype machines are used, should be separated from the printing room.

Cubic space and floor space per workman in the different rooms should be adequate; in certain countries legislative measures specify precise figures for each section. There should be ample ventilation, without, however, creating too strong a draught, which in itself is a source of illness or discomfort. Dust should be eliminated, as this is the most important source of injury. So far as cleaning the cases is concerned, good technical apparatus is at present available for removal of the dust by fixed or mobile exhaust apparatus.

The number of benches and uncovered shelves should be restricted as far as possible.

The fittings should be constructed in a uniform manner without cracks and should be covered if possible with washable varnish; similarly, the walls should be varnished at least to a certain height so as to permit of removal of dust by damp methods. Localised ventilation should be applied to the metal pots of the machines.

Good natural and artificial lighting should be provided (see article “Lighting”). According to recommendations that have been made, printing rooms should have the following amounts of light expressed in lux:

For details readers are referred to numerous reports, especially the English ones (L. Gaster, 1923; Goodenough on Gas Lighting, 1912; J. Eck on Electrical Lighting, etc.).

Washing and cloakroom accommodation and water-closets should be installed; there should be a supply of drinking water and water for personal cleanliness, etc. This is very important, in view of contact with lead, antimony, and in some departments with chromates, benzene and other solvents (see also article “Photo-engravers”).

Overall should be provided for the workpeople; eating, drinking and smoking in the workrooms should be prohibited; workers should be obliged to wash before leaving work and before eating; the bad habit of putting type into the mouth should be prohibited and likewise any other method of working favouring the inhalation or swallowing of poisonous dusts.

The prohibition of spitting, especially on the floor, should be enforced.

In rooms where ruling has to be done, the use of sulphur pigments should be prohibited and no poisonous colours used (Stackovsky); precautions should be taken to avoid splashing of ink and dirtying the hands. Gloves should be used for cleaning machines.
and for handling the ink ribbons. The hands should be cleaned with denatured alcohol or other effective solvent.

Thorough and strictly applied selection of workers should be adopted in view of the fact that experts are agreed in attributing a certain percentage of illness to the fact that workers are engaged at too young an age and are generally of feeble constitution.

It is for this reason that certain laws require a medical examination prior to commencement of work and sometimes even a periodical one thereafter. Thus for example, in Italy, the Code of Industrial Hygiene requires special examination of the cardio-vascular system, the state of the blood and condition of the kidneys. Such measures will contribute to the diminution of sickness and mortality rates amongst these workers, as they will serve to bring to light early manifestations of broncho-pulmonary disease of a tubercular character or the early symptoms of lead poisoning.

LEGISLATION

In general, women are excluded from work in casting lead (stereotyping, compositing); sometimes from work at polytype machines. In Norway this only applies to women who are pregnant. In Argentina workers in the printing industry only work six hours a day, the industry being closed during the week-end (Law 11 March 1930).

A draft Code of Regulations for the printing industry was discussed by the International Association for the Legal Protection of Workers at its Conferences of 1908, 1910 and 1912.

Special rules have been enacted: in Germany (31 July 1897, 1 July 1907, 22 December 1908, relative to plant, and work effected in printing establishments; 18 December 1908 on linotype machines; in Saxony an Order of 1910 applies to the cleaning of cases by means of suction apparatus); in Austria (23 August 1911 and 17 July 1912); in Denmark (17 January 1904 and 17 January 1910; an Order of 31 May 1907 deals with photo-typography and lithographic printing; a Decree of 1906 excludes young persons under eighteen years of age from work connected with stereotyping); in Finland (25 May and 7 June 1917); in Great Britain (11 April 1911 on typographic bronzing and lithographic printing); in Greece (11 and 24 February 1914); in the Netherlands (21 August 1918); in Switzerland (Federal Instructions to inspectors have been issued relating to measures for preventing injury to the health of compositors and type casters. February 1898); in Czechoslovakia (26 May 1925 and 25 June 1966); in the U.S.S.R. (19 May 1924), etc.

In the Netherlands notification of cases of inflammation of the joints and subcutaneous cellular tissue in printers is compulsory. Compensation for lead poisoning and its sequela (as in the first column of the formula in Great Britain for industrial diseases) for persons employed in the printing industries is provided by the Convention of 1925 and countries ratifying the same. Lead poisoning comes within the Compensation Act also in France when it affects machine compositors, and in Italy and the U.S.S.R. compensation is provided for progressive myopia among proof readers.

(Florence.)

Pyridine

Pyridine (C₅H₅N) is a colourless liquid, with a specially disagreeable odour; it is relatively volatile at ordinary temperature and boils at 115° C. It is used for denaturing alcohol, purifying synthetic indigo, preparing anthraquinone and, in certain processes, for indanthrene colouring matters, etc.

Amongst the homologues of pyridine should be mentioned the picolines (methylpyridines), the lutidines (dimethylpyridines), collidines, pyridones, etc. Pyridine bases are found in liquid products derived from the pyrogenic destruction of hydrocarbonic and nitrogenous products, in the fumes given off during melting and saponification of fatty acids (with acrolein).

Pyridine is prepared from coal tar subsequent to extraction of phenol, the pyridine oil obtained being treated with sulphuric acid. The sulphate thus formed is extracted by various methods. It can also be got from quinoline or synthetically.

The injuries caused by pyridine occur either in course of its preparation or its use (denaturing of alcohol, etc.) or again in course of the use of products thus denatured (alcohol, lacquers, etc.) and affect polishers, gilders, pencil manufacturers, etc. In the form of fumes, pyridine exercises an irritating action in the respiratory passages — inflammation, coughing — on the mucous membrane — eyes and nose. When ingested it causes various symp-

...
ton's: sialorrhoea, headaches, vertigo, prostration, dyspnoea, trembling, etc. Hamilton mentions that inhalation of pyridine fumes "excites" the workers. It causes dryness of the skin and makes it specially sensitive to the sun's rays, and also eczema — polish-er's eczema particularly among cabinet makers especially. The fact, however, that such workers utilise other irritant substances leaves it open to doubt whether the dermatitis in ques-tion is exclusively due to pyridine. Workers coming in contact with this substance complain, besides, of a particular form of pain in the hands and face when they go out after washing in water.

A peculiar harmful effect of pyridine on the haemoglobin was noted by Zey-nek in 1925.

Injuries due to pyridine are compensated by law in Finland.

---

**Pyroligneous Acid**

Pyroligneous acid (see articles “Acetic Acid” and “Timber Industry”) is rectified by distillation to separate it from the tarry substances with which it is mixed.

Buildings in which purification of pyroligneous acid takes place should be remote from dwelling houses, the flooring should be of cement, and the workshops thoroughly ventilated. The processes of distillation, rectification and concentration should be effected in closed apparatus. Large exhaust hoods should be placed above the apparatus enabling the fumes given off to be led into a high chimney. The gaseous and volatile products which do not under go condensation should be burnt. Waste water should be neutralised before being allowed to leave the factory.

***
Quinine

Quinine is one of the numerous alkaloids of the quinine or cinchona tree (belonging to the genus Rubiaceae), comprising many species, all indigenous to South America and now acclimatised in other countries (Ceylon, Java, etc.). The quantity of alkaloids varies according to the species, the state of the plant, the climate and the season. Cultivated plants yield much more (especially of quinine) than the wild plants. Furthermore, choice of certain varieties, methods of culture and of industrial treatment enable an excess of one kind of alkaloid or another to be obtained according to preference. Thus the harvesting of bark designated by the term “moussaga” has the effect of producing a considerable increase in the quinine content.

Pure quinine (hydrated quinine C₆H₈N₄·3H₂O) takes the form of fine white crystalline needles with a bitter taste melting at 51° C. Heated to above 100° C. quinine loses its crystallisation water, resumes its solid form and then melts at 172-175° C. Very slightly soluble in water, it is more easily soluble in alcohol, ether, chloroform and still more so in various acids accompanied by formation of the corresponding salts.

The harvesting of the bark is effected by cutting down and stripping the tree (South America) or by barking only (India, Java) and by “moussasure” or covering with moss the parts stripped of bark. The pieces of bark, after being dried in the sun, sorted as to size, ground in crushers or pounded with a mortar, are thereafter finely pulvurised in mills suited to the purpose. The powder is made into a paste with milk of lime, to which a little soda has been added, in vats provided with stirrers, and then subjected to heat treatment in closed apparatus with oils (shale or paraffin, lignoine, benzine, tetra-chlorethane or even ether). These products dissolve and fix the alkaloids given off. When left to settle the solvent becomes separated and can be decanted. The residue is again treated with the solvent in order to exhaust it. The various parts of the solvent are collected and mixed with a solution diluted with sulphuric acid which has the effect of extracting all the acids present in the form of soluble sulphates. The alkaloid is distilled to recover the solvent, which on liberation may be utilised for further extractions.

The sulphate solution is heated, concentrated and left to cool. The sulphate of quinine which separates out in a crystallised and impure state when left to settle is dissolved in water or precipitated by ammonia, then the product is allowed to cool and crystallises in fixing 3 molecules of crystallisation water.

Amongst the other alkaloids present in the mother liquors may be recalled cinchonine, which is the alkaloid of second importance in quinquina, and a mixture of amorphous alkaloids known under the name of quinoidine which can be extracted by appropriate treatment.

Sails of quinine may be obtained in a pulverulent state; manipulation and packing of these in packets or bottles involve a series of operations generally effected in different places by special groups of workers.

The quinquina bark like its alkaloids is used in pharmacy and as an insecticide for moths to protect furs and woollen materials, etc.

Sources of Risk

Amongst workers engaged in removing the quinquina bark in the Java plantations cutaneous troubles analogous to those due to quinine have been noted (Jaquet, Besiner, Brocq, Thibierge). Similar lesions have been reported by Cherallier (1852), Bazin (1862), Leroy des Barres and Courtois-Suffit (1928) amongst workers engaged in boiling the quinquina bark for various pharmaceutical preparations.

It is however chiefly the grinding of bark in the open which causes harm, which may be notably diminished or even eliminated by the use of devices to prevent liberation and diffusion of dust and contact with powdered quinquina.

Boiling or extraction by oils or acids may likewise constitute a source of
risk. According to Blamoutier and Joannon (1922) the proportion of workers affected in this department of the factory amounted to about one-fifth, despite the fact that these operations were effected in closed apparatus.

Drying and manipulation of salts of quinine constitute, according to well-recognised authorities (Chevalier, Bazin, etc.), a source of risk. Certain experts even consider that disease symptoms are particularly occasioned by the preparation of powdered quinine (Dold and P. White), which operation is, however, esteemed by others to be harmless (Blamoutier and Joannon). However that may be, cases of affections due to quinine are known to have occurred amongst hairdressers affected with papular eczema of the hands and especially of the fingers following on the application of lotions with a quinine basis (Kober), amongst pharmaceutical chemists and druggists, etc. Cazeneuve (1930) noticed amongst workers tending machines for the manufacture of compressed tablets of salts of quinine several cases of skin troubles, which however healed very readily on application of soothing ointments. Traces of quinine powder liberated by these machines were partially absorbed by the buccal passage (as revealed by the bitter taste experienced by the women workers), and the effect of these contributed to increase that exercised by the direct action on the skin of the hands and face.

Another source of risk is to be sought in the various products (solvents and acids) handled in course of preparation of the quinine. Several cases of poisoning have been caused by tetrachloroethylene.

TOXIC ACTION

Quinine is a poison of the protoplasm; in large doses it paralyses and kills the cells (Robert). Quinine is, however, of no interest from the aspect of industrial medicine except as regards its local irritant action. Cutaneous troubles caused by quinine used as a medicament are very well known, and forms of occupational dermatitis due to quinine dermatitis do not essentially differ from these as regards their etiology; they represent a manifestation of special susceptibility of the individual affected like most other form of dermatitis.

The means of entry into the system is said to be principally internal absorption (digestive and respiratory passages). It is a fact that visitors to a quinine factory become aware, after a certain time, of a bitter taste due to the quinine dust inhaled and swallowed and which the workers no longer experience. Nevertheless, it cannot be denied that quinine may also traverse the epidermis when favoured by erosions; in this case likewise it exerts its effect after having been absorbed by the system (Blamoutier and Joannon).

The other factors capable of diminishing the resistance of the body (alcoholism, tuberculosis, etc.) seem to be without special importance in this instance, nor can personal cleanliness be said to diminish liability to troubles provoked by quinine.

The dose of the toxic product would appear to play a distinct role in the genesis of accidents provoked by quinine. So far no light has been thrown on the exact nature of the susceptibility for quinine, susceptibility the existence of which must, however, be recognised.

It has been observed that certain newly engaged workers who have not suffered any effects after an average lapse of time of fifteen days from commencing work would appear to be definitely immune. There is therefore on employment a species of trial which decides the fate of the worker, and this early occurrence of reaction attenuates to some extent the trying effects of quinine eczema. Nevertheless, in very rare cases, chiefly after a severe illness, workers who have never had skin trouble have suffered from a slight eruption on return to the factory. Their natural immunity had weakened without, however, disappearing entirely, for the eruption was not repeated.

On the other hand, the majority of workers, who seem to develop a certain degree of tolerance, after having suffered from effects are well aware of the persistence of their susceptibility; when suffering from quinine eczema they do not return to the factory to draw their pay but send their wives. Where the wife of a worker who has had to leave his employment on account of intolerance of the product is also employed in the preparation of quinine, she is obliged to give up her work altogether in order to avoid prolonging her husband's condition or causing him relapses, since the substances impregnating her clothing suffice to provoke the symptoms. This latent susceptibility persists even after quitting the factory and may be evoked by the slightest cause (use of apparatus or instruments which have been in contact with quinine, passing near a quinine factory, taking quinine as a medicinal remedy: Lewin). Cutaneous lesions noted amongst wives and children of workers who
bring home traces of the alkaloid in their clothing are to be ascribed to phenomena of individual susceptibility. It is highly probable that in the case of specially sensitive workers anaphylactic phenomena come into play. Workers suffering from quinine eruptions rapidly (from a few hours to fifteen days' time) progress towards either of two states: either one of apparent intolerance, during which the system becomes progressively modified by "preparatory doses" of the quinine; or the other of intolerance, during which the system reacts to doses causing outbreak of symptoms, even with slight amounts of the substance. Simply remaining for some little time in the factory without being at work there at times suffices to cause an outbreak of dermatitis. Blamoutier and Joannon refer to the case of a mechanic who spent a half-day in a factory to effect repairs and who suffered next day from the typical eruption.

**STATISTICS**

Statistical data are scarce, but in the reports of factory inspectors in the various countries cases of dermatitis caused by handling quinine have been reported. (See especially the reports of the English and German factory inspectors and those of the Swiss National Accident Insurance Fund.)

**PATHOLOGY**

Injuries consist essentially in forms of dermatitis situated on the extremities and on the scrotum. Skin trouble affecting this part of the body was reported as far back as 1852 by Chevalier and is, according to Blamoutier and Joannon, of early appearance, though at times delayed for a long time (after four weeks). At the outset the trouble usually consists in transient erythema accompanied by a burning sensation and pruritis (even without eruption situated in the folds of the skin (elbows, armpits, groin) as well as on the face, which becomes oedematous and slightly reddened. It is chiefly, moreover, round the eyes that the foremen look for symptoms in newly engaged workers in order to remove immediately susceptible subjects. Manifestation of large quantities of quinine, particularly for its preparation in powdered form, causes cutaneous affections, particularly on the eyelids (Lehmann, Dold).

There follows a period characterised by a sensation of burning, situated on the face, neck, bends of the joints, on the genital organs and the inner surface of the thighs. The eyelids are red and inflamed; the eyes swollen and watering and the patient has difficulty in opening them and on the uniformly red surface of skin are noted, in groups or disseminated, vesicles of varying size, often acuminate, in general small and containing a purulent or citrine liquid. On being opened they emit a thready, sticky, viscous and serous liquid forming yellowish crusts. According to Blamoutier and Joannon, the hands, forearms and the whole of the trunk are in general scarcely affected — which statement is in contrast with many at times the clinical description: "most usually on the hands and forearms" (Leroy des Barres, Courtois-Suffit, Chevalier); generally on the backs of the forearms, on the lateral sides of the fingers and at times on their palmar surface (Glaser). The most usual form of these affections is that known as "quinine itch" (Chininkrätze, gale de la quinine). Those employed on peeling and stripping the quinquina bark may suffer from a more simple form, characterised by very small vesicles and presenting the appearance of orange skin (Thibierge, quoted by Prosser White, and Ullmann).

According to Lewin, the clinical forms which may be met with are as follows: (a) isolated erythema located on the trunk, the face, the limbs, or simultaneously on various parts of the body, which may at times be generalised and sometimes resemble measles. The forms of exanthema described by Glaser as affecting the wives and children of workers come within this category. It is mostly a case of mono- or polymorphic lesions generally with very rapid development which are of slight degree and disappear equally rapidly, but which may in other cases last for several weeks and which are followed in most cases by desquamation. In some rare cases there is (a) pigmentation of the skin; (b) eruption of a scarlatina form type (the most frequent form) accompanied by general disorders (oppression, excitement, delirium, etc.); in serious cases there may occur erysipeloid dermatitis; (c) gangrenous dermatitis: very rare, referred to by Blamoutier and Joannon; (d) multiform exuding erythema: rare; (e) purpuritic or confluent urticaria; (f) bulbous exanthema resembling pemphagus; (g) petechial form.

Lehmann also reports an obstinate cough as an effect and Loewy amaurosis due to constriction of the blood vessels.
QUININE

HYGIENE

Industrial processes, particularly the grinding of bark, should as far as possible be effectuated in closed apparatus. Hand work should wherever possible be replaced by automatic work, especially in the transport and manipulation of quinquina. Extraction of the alkaloids by solvents should be done in closed apparatus. There should be adequately disposed local-exhaust ventilation for capturing and recovering the dusts and fumes from the solvents, the commercial value of which is obvious. Facilities for personal hygiene should be provided (baths, wash basins, working clothes, etc.). The bad habit practised by workmen engaged in quinine extraction of cleaning their hands after work with a very diluted solution of sulphuric acid to remove more readily the shale oil should be prohibited (Blamoutier and Joannon).

Where skin trouble is persistent, the workers in question should be removed from the operations exposing them to risks.

Certain authorities recommend the use of biological sensibility reaction tests either on entering the trade or during the first few days in the factory to determine susceptibility and permit of removing those affected prior to the occurrence of dermatitis. For this purpose slight scratches are made and dusted with quinquina or painted with 1/10, 1/100 or 1/1000 solutions. Fifteen minutes later susceptible subjects present in situ oedema and redness not noted in the case of individuals who can stand quinine in internal doses (Boener).

It might likewise be possible to attempt to desensitise subjects affected (Blamoutier and Joannon).

LEGISLATION

Legislative enactments require notification of skin diseases due to quinine (eczema and dermatitis) in the Netherlands, and compensation of injuries due to quinine in Switzerland and in those countries in which skin diseases (due to liquids, dusts, etc.) have been inscribed in the schedule of occupational diseases entitling the worker to compensation (see these articles).

BIBLIOGRAPHY

Radium and Radioactive Substances

PROPERTIES

Radioactive ores are of very varying kinds; examples are: carriotite, a vanadate of uranium and of potassium, found in Colorado; autunite, an anhydrous phosphate of uranium and calcium, found in Portugal; betafite, a niobotitanate of uranium, from Madagascar; pitch-blende, an oxide of uranium; chalcolite or tobernite, a phospho-uranate of copper; curite, a uranate of lead, and kasolite, a silico-uranate of lead, from Katanga.

These ores appear in the strata in varying proportions, and with extremely variable strengths of oxide. Radium is found in all the ores of uranium from which it originates during the process of disintegration in the proportion of about 3,400,000 parts of uranium to 1 part of radium. Whilst at Katanga, for example, 1 gramme of radium is obtained from 10 to 20 tons of ore, elsewhere, and especially in America, 1 gramme is only yielded by 200 to 500 tons of ore.

Radium, of which the molecular weight is 226, has been prepared in the metallic state by Mme. Curie and Debierne. But it is generally used in the form of its compounds, as the bromide, chloride, sulphate, or carbonate. The radiations emitted by preparations with a radium base are not homogeneous for they contain alpha, beta, and gamma rays.

INDUSTRIAL OPERATIONS

The manufacture of radium is still carried on to-day by the methods employed by Mme. Curie and Debierne. It includes three stages arranged systematically: grinding the ore; treatment with acids to eliminate such inert materials as uranium, iron, copper, lead, aluminium, and silica; treatment for separating the radium from lead and barium, which hold it in the form of insoluble sulphates, and for eliminating sulphuric acid.

Radium, during these processes, exists in an insoluble form, mixed with silica, which is removed at the commencement of the treatment by the action of hydrochloric acid.

Each of these operations necessitates filtrations and washings. Thus radium is concentrated from 1 part by weight for 10 to 20 million parts by weight of inert matter down to 1 part for 125,000 of inert matter, which is chiefly barium.

A second stage follows, in the course of which the sulphates obtained are transformed into carbonates, which are in their turn transformed into chlorides. In the impure solution of chloride of barium and radium so obtained, the radium is still found in the proportion of 1 part per 125,000 of barium.

The third phase of the manufacture consists in purification and concentration; it is carried out by fractional crystallisation, first in aqueous solution, then in hydrochloric solution, and finally in hydrobromic solution.

The enriched crystals are dissolved in boiling distilled water up to saturation point, and, after having been evaporated, are allowed to crystallise; impoverished solutions are similarly treated. In this way crystals are obtained of which the radium content always goes on increasing, and solutions of which the content always goes on diminishing. Crystals with a radium content of 0.05 per cent. are set aside and sent to the laboratory, where the work of crystallisation is only carried on when 2-3 grm. of radium have been amassed. Each series of operations involves, besides crystallisation, purification by sulphuretted hydrogen in order to remove the last traces of lead, and the transformation of chlorides into bromides, a process which allows a more advantageous coefficient of concentration to the crystallisation. The strength in radium is thus brought from 0.05 to 97-98 per cent., which is
the usual strength of the product when ready for sale.

This long procedure, which lasts several months and requires hundreds of operations, gives a small white mass, rather like table salt; it is very luminous in the dark; its radioactive power, which is not influenced by any chemical process, is proportional to the fraction of the radium element present in the salt. No effort is made to procure radium in the metallic state. The bromide of radium is obtained; it is dried, put into glass tubes, sealed at the blow-pipe, and estimated for radioactivity at the laboratory attached to the factory.

There is no need to enter into details concerning the technique for determining the quantity of radium found. It is enough to say that use is made of a method of measurement based on the electric conductivity or ionisation acquired by air under the action of radioactive substances. The speed of discharge of an insulated conductor, placed in the presence of a quantity of radium to be estimated, is measured by comparing the rate of discharge produced under the same conditions by a known standard quantity of radium. All the uses for which radium is required, as applied to therapeutic purposes, have to be borne in mind. The apparatus for containing radium consists of small cells, needles, and tubes made of platinum treated with iridium, very small in size and very delicate in construction.

The manufacture is, in all its various stages, encompassed by a series of preventive measures designed to protect the personnel exposed to the radium as much as possible. Not only are tables covered with lead, lead shields, and india-rubber gloves used, but regularly every day the emanations remaining in the solutions are pumped out; the operations of refilling are carried out with all possible rapidity, and the personnel is periodically subjected to medical supervision, which includes monthly examinations and analyses of the blood.

The chemical properties of mesothorium are almost the same as those of radium. It is extracted from monazites by a process which is analogous to that used for the extraction of radium. Mesothorium is very often mixed with radium, and it is naturally difficult to distinguish between the action of the two bodies.

**Sources of Risk**

The first observations on cutaneous lesions caused by radioactive bodies date from 1900, when Giesel and Walkhoff made the first experimental researches with radioactive substances. On the basis of these results, it has been possible to find an explanation of the cause of the cutaneous lesions found in 1901 on Becquerel himself, following the handling of a tube containing radium, which he had carried in his pocket for several hours.

Dobudutz has collected at least six cases of dermatitis occurring among persons employed in the preparation of products with a radium basis. The lesions were generally situated at the ends of the fingers, and especially on the thumb, the index and middle finger; in two cases a slight atrophy was found also. There is frequently degeneration of the nails, which fall off, this being caused by the action of the beta rays, and perhaps by secondary, very penetrating rays.

Mesernitzky has also reported cases of cutaneous lesions, localised on the fingers of three persons employed in the laboratory of Mme. Curie, due to radium emanations of from 50 to 130 milli-Curie.

Gudzenz and Halberstaedter in 1914, and Th. Ordway in 1916, published a series of cases of occupational dermatitis and of lesions of the nails due to radioactive bodies, reported up to the years mentioned.

Friedlaender reports a case of chronic dermatitis caused by mesothorium, observed in a woman working in an incandescent mantle factory. The lesion, which was localised in the upper limbs, appeared after she had been handling a 1 per cent. aqueous solution of nitrate of cerium and thorium for two years. The necrosis of the jaw observed in America among women workers who handle luminescent paints is also attributed to mesothorium (see further on).

The occurrence of injuries caused by radioactive preparations on the skin, in the case of doctors and others who use them for therapeutic purposes, is extremely rare, and is even denied by some experts. But it should be noted that whilst the doctors only use the most minute quantities of radium, those who prepare the substances and the technical experts who study the physical and chemical properties of radium handle very much larger amounts.

Cases of cutaneous lesions localised on the eyelids have also been noted. Attention has been drawn by Joist to the danger of explosion from bromide of radium when it comes in contact with water; two cases of severe irritation of the eyes have been reported.

**Pathology**

The various elements of the radium series emit three types of rays: alpha, beta and gamma, the last of which are chiefly used in medicine. The alpha rays are the least penetrating, and only possess a speed equal to that of light. The alpha and beta rays can be separated from the gamma rays.
by making the mixture of the three rays pass through screens of adequate thickness. Alpha rays are positive electrons; they cannot penetrate metals. Beta rays are negative electrons; they can penetrate thin screens of aluminium. Gamma rays, which have a speed equal to that of light, are, from the electrical point of view, neutral, but they possess a great power for penetrating opaque bodies, so that they can pass through a lump of lead 19 cm. thick.

Daily exposure to rays of radioactive substances is a source of danger not only to those who handle them — doctors, hospital attendants, the personnel of research laboratories and therapeutic clinics — but also to persons employed in the industry who prepare or manipulate radioactive bodies and to workers engaged in the extraction of radioactive ores (see also article "Tumours of Occupational Origin").

Today this danger is only slight for those composing the first group, who are sufficiently protected and supervised, so as to prevent any local injury, such as radium dermatitis or sterilisation, or such general damage as anaemia or leucopenia. However, serious or even fatal cases are known to occur among persons of this group. Thus, for example, Siebenrock in 1911 recorded a fatal case of leucæmia (without any other indication) in a chemist who handled radium, and Schwartz a case of leucæmia in a chemist engaged in the preparation of radium.

A case of aplastic anaemia has been reported in the case of a woman who had worked for several years in a radium institute, and, neglecting every precaution, while carrying boxes of radium, placed them on her chest for fear of losing them. This woman, after experiencing a transitory dermatitis of the hands, showed signs of becoming anaemic, with red cells below a million, leucopenia, relative mononucleosis, and a scarcity of thrombocytes; the development was swift and fatal, the total period from the beginning being eight months. (Case studied by Brulé and Boulin, 1922.)

A radiologist, reported by Dominici, succumbed to aplastic pernicious anaemia due to radium. He was in the habit of carrying pieces of radium in his pockets, and showed pigmentation of the skin on his body at this level.

Following three fatal cases of anaemia with leucopenia among the personnel of the Radium Institute of London, Mottram undertook in 1922 an enquiry, which lasted a year, into the conditions of the personnel exposed to radia-

izations. He came to the conclusion that these workers are subject to blood changes, greater in proportion to the length of time they are exposed to radiations. He examined 40 adults, 20 of whom were specially employed on radium and 18 on X-rays. He found the number of lymphocytes and of polymorphonuclear neutrophile leucocytes abnormally low, especially among the radium specialists. The gamma rays of radium act on the bone marrow, whilst the less penetrating X-rays exert their action more particularly on the lymphocytes and the lymphoid tissues which are not protected by the bones.

During one year, 1922-1923, Williams examined 13 persons employed in the United States in measuring the radio-activity of radium preparations.

Two persons, one of whom was in employment actually at the time of the enquiry, while the other had been previously employed, showed symptoms indicative of the effects of radiations on the skin of the hands and fingers, with pain, anaesthesia, burns and destruction of the skin, as well as of the parts underlying the seat of the lesion.

The general symptoms were headache, malaise, weakness, fatigue, sleeplessness, and vertigo.

Blood changes have also been reported. A tendency appears for the white polymorphonuclear neutrophile cells to fall below normal, with a diminution in the number of small lymphocytes, an increase above normal of the large lymphocytes, and a tendency to decrease in the number of white cells in general, as well as of red cells.

Amongst workmen exposed to radiations, a diminution occurs in the arterial pressure, which falls below the normal.

There is quite a series of occupational pernicious anaemias, due to X-rays, to radium and thorium which cause the aplastic type and result in progressive destruction of the haemopoietic centres after prolonged exposure to the harmful agents. Such is the case in two observations of Emile Weil and Lacassagne (1925) on two engineers manipulating thorium, both of whom died, one from myelogenous leucæmia and the other from aplastic anaemia. In 1924 Amundsen recorded leucopenia in 15 persons in contact with radioactive substances.

It must be admitted that, in addition to blood changes, exposure to radiations also causes leucæmia. This form of leucæmia may perhaps be characterised by the concomitant action
of the radiations on the genital organs, for atrophy of the testicles or ovaries is found both clinically and anatomically.

It is a curious fact that in the case of robust men, without any defects and approximately of the same age, the same radiations of thorium may cause in one aplastic anaemia and in another leucæmia. It is difficult at the present time to explain this phenomenon; can it be due to the nature of the constitution? (Case of Weil and Lacassagne.)

With the cases observed by Lacassagne and Emile Weil, these give, up to the year 1925, 8 cases of leucaemia by radioactive bodies, and exactly 5 cases amongst radiologists, 1 in a person who handled radium, 1 in a person who handled thorium, and 1 following the therapeutic use of these bodies.

E. Rud examined, in 1924, the blood of 18 persons, of whom 6 were doctors and 6 hospital attendants employed in radium and X-rays institutes, without finding any appreciable blood changes.

Certain other experimental researches into the action of radium on the blood lead to the conclusion that prolonged exposure lowers the number of blood platelets. This change is followed by a return to the normal; then by an elevation above normal; and finally by a second return to the normal figure. (Mottram.)

In addition to these various occupational illnesses caused by the handling of radioactive bodies among persons who work in laboratories with therapeutic preparations of radium without proper protection and supervision, quite a number of very serious or fatal illnesses must be mentioned occurring among women workers who handle luminous paint with a basis of sulphide of zinc and which is the consequence of an attack on the haemopoietic organs and pernicious anaemia.

The person affected complains of gingivitis, generally complicated by alveolar-dental pyorrhoea; the teeth become painful and loose, and may fall out spontaneously. Removal of teeth has the same disappointing result as in the case of phosphorous necrosis. The bone necrosis begins with destruction of the alveolar border; its course is slow and progressive, and the lesion may lead to the spontaneous fracture of the lower jaw. When it attacks the upper jaw it is less. It may lead to perforation of the bony partition, and even break into the sinus. The pain is terrible. Although one may come across slight forms, which tend to get well after the removal of some teeth, and the resection of part of the jaw, there are others which are complicated by suppurative parotitis and progressive cachexia, passing on to a fatal termination. But death in these cases is the consequence of an attack on the haemopoietic organs and pernicious anaemia.

The enquiry held by American experts established that this serious lesion originated from the bad habit, when at work, of pointing the brush between the lips without washing it in the small phial of water provided for the use of the women workers. Particles of the radioactive mixture are in this way introduced into the buccal cavity, and deposited in the alveolar-dental spaces. It must be acknowledged,
However, that a hundred pointings of the
brush would not at the most introduce more than 25-50 millimicro-
grammes of radioactive element (one milligram a month), most of which would be
drawn into the digestive passages with the saliva. It is indeed hard to
believe that this infinitesimal amount of radio-active substance can cause
lesions as serious as those described
(Hoffmann). But other experts, such as
Martland, have estimated that these
women workers can paint 200 to 300
dials per day, and that in the course of
this work they carry their brush to their lips from one to forty times for
each watch. This procedure would represent the ingestion of 3 to 43 micro-
grammes of radioactive substance per
day: a quantity much higher than that
mentioned by Hoffmann. On the other
hand, experts have shown the presence of the substance in question in the
jaws by measuring the radioactivity of secondaries removed surgically. Mart-
land has detected radioactivity in the air expired, which he characterises as
one of the most important symptoms.
This radioactivity has been found in the
tissues after death, and in one case even five years after death (St. George,
Cettler, Müller).
Bridge, of the English Factory Med-
cial Inspection Department, made an
enquiry, in 1925, into the industry in
question, which, however, did not em-
ploy more than ten women. The paint
was made of a solution of sulphide of
zinc, containing about 0.0375 millimicro-
grammes of sulphide. He did not find
any ill-effects among these women, who
had worked for some years; but blood
examinations, made by A. B. Rosher,
showed, in the case of three women out
of seven, lymphocytosis, polycythaemia
and deposition in diploph-leuco-
cytes. No changes in the nails or skin of
the hands were found.
Flinn, of New York, in December 1926
again took up the study of this ques-
tion. From analysis of the facts, he
found himself unable to accept the
opinion that any occupational risk existed in the work of painting with
luminous solutions.
In 1926, Reitter and Martland re-
corded the death of a chemist in a
dial-painting factory, and in the same
year Martland found in the bones of the
jaws of one person approximately 150 micro-
grammes of radio-active substance, and the other were
mesothorium and its derivatives.
In 1927, two other cases were re-
corded, one being fatal, of necrosis and
anaemia; in 1928, another death, eight
years after the person had ceased work.
In November of the same year, the
death occurred from aplastic anaemia
of the chemist Sokowsky, the inventor
of the painting formula used by the
New Jersey factory.
In 1929, the United States Bureau of
Labour Statistics carried out an enquiry
covering 31 establishments and 253
workers exposed directly to radio-
active substances. The enquiry re-
vealed 23 deaths and 19 cases of
sickness attributable to radioactive sub-
stances, of which 15 deaths and 18
cases of sickness were due to the paint
in question. The report published
summarises the 42 cases, certain of
which had already been recorded by
other authorities.
In the same year, the Bureau of
Aeronautics of the United States Navy
enacted precautionary measures for its
personnel, and Martland published a
recapitulatory study in which he points
to the presence of signs of osteitis con-
fined to those bones subjected to
traumatism or to exterior pressure, or
supporting weights (scaphoid, spinal
vertebrae, head, femur, etc.), which
produce chronic lesions with pain and
restriction of movement. In these
cases there is in general no anaemia
or necrosis, due perhaps to the fact
that the mesothorium has had time to
resolve into its inert substance.
In 1931, Martland published another
study in which he reported 15 cases of
osteogenetic sarcoma among the 18
deaths (27 per cent.) which had occurred
between 1922 and 1931 among the
women workers of the New Jersey
factory and one case of sarcoma in a
deceased worker of a New York and
Connecticut factory. In addition he
reported one case of obvious and two
cases of probable signs of sarcoma in
three women workers of New Jersey
who were then still alive. In this
instance Martland remarked that all
the injuries met with were to be
attributed to accumulation in the bones
of ingested radioactive substances; the
internal bombardment of the system by
alpha radiations emanating from those
deposits set up not only sanguinary
lesions due to attack on the haeu-
opoietic organs, especially of the bone
marrow, but also injuries of the
nature of osteitis of which necrosis of
the jaw was none other than a particu-
lar form facilitated by the addition
of local microbic infection. He under-
lined the fact that the anaemia referred
to and due to exposure to ex-
ternal radiations (gamma) were of the
aplastic order. He also noted that the
formation of osteogenetic sarcomas
was but a consequence of the process of chronic inflammation of the bones met with in other diseases showing similar processes (Paget’s deforming osteitis, Recklinghausen’s fibrous cystitic osteitis).

According to an enquiry undertaken by the International Labour Office, the absence of radium necrosis in the Swiss, French, German, Australian, English, or Belgian watch factories, where as a rule, the painting is done by the use of a stylet and sucking is unknown lends support to the view that poisoning may arise through use of the brush.

Regaud, who has studied radium bone-necrosis of the jaws ascribed to certain defective radiations either from radium or X-rays, considers that it arises in these cases from soft gamma rays, primary beta, and above all secondary beta rays.

Continued action of alpha rays on the tissues, which completely absorb them, has been thoroughly investigated by means of polonium, the last radioactive body of the radium series.

Lacassagne and Lattès have shown that subcutaneous injection of a solution of polonium, which emits a pure alpha ray, can cause a local radio-dermatitis. If applied to the skin, this solution causes burns, particularly if it succeeds in reaching as far as the deep layer of the epidermis. Further, these experts have emphasised the fact that the quantity of polonium necessary to kill a rabbit by injection is about one thousand millionth part of a grammé.

Therefore it is not surprising that radium, mesothorium and radioradium, which are bodies which give off more intense emissions, have penetrated in the insoluble state into the alveolar dental region, and, after having accumulated there over years, especially under the influence of the bombardment of alpha rays, can lead to necrotic destruction of ligamentous tissue, then of periosteum, and lastly of the bone itself. The action of associated superimposed infections, which play an important part, cannot be overlooked.

Martland, Conlon, and Knef, when studying the general illnesses resulting from absorption by the digestive organs of radioactive bodies, in the course of an autopsy on a patient who had died of pernicious anaemia two years after having ceased to handle these substances, found that radioactivity reacts particularly on the organs of the reticulo-endothelial system.

In Europe there have been several contributions on this subject: that of Jaulin (1927), concerning 17 fatal cases in persons handling radium or X-rays; of Heim, Balsac, Agasse-Lafont and Feil (1930) who studied the personnel of a factory for mesothorium preparations; of Kupritz (1928); of De Laet (1928); of Schlundt, McGavock and Brown (1931) who carried out an enquiry among workers refining radioactive substances; of Woldrich (1931), etc.

By his researches on polonium Lacassagne arrived at conclusions similar to those of Martland given above, thus confirming the demonstration given by Dominici and Faure Beaulieu, as well as by Dominici, Petit and Jaboin, viz. that radioactive bodies persist for a long time in the system. This fact explains the serious lesions of the haemopoietic organs which may appear years after the introduction into the body of the radio-element, and advance to fatal pernicious anaemia.

**Prophylaxis**

Williams recommends the following prophylactic measures.

Examinations of the blood and arterial pressure, carried out at regular intervals, amongst persons employed in the radium department.

Complete medical examination of all employed, carried out at regular intervals.

Medical examination before engagement, including examination of the blood.

When radium is being manipulated, so far as is possible, all protective apparatus must be used — screens, carrying boxes lined with lead, pincers for handling, etc. Adequate ventilation must be provided in the rooms where the handling of radium is carried out.

The personnel must be instructed as to the necessity of reducing to a minimum such absolutely necessary exposure for which no protection from radiations can be afforded, and of not remaining longer than is necessary in the vicinity of radium.

During packing and unpacking of radium, at the receipt or despatch of goods, at the preparation, assembling and placing of parcels in position, and also packing paper and other equipment, all work should be done as rapidly as possible, so as to shorten as far as possible the time of unavoidable exposure to the radiations.
The periods of work of those exposed should be limited to five days a week, so that a period of two days intervenes between two periods of work; these days must not be counted as annual leave, or sick absenteeism.

A grant of thirty days' leave each year, should be made, to be taken, as far as circumstances allow, in two periods of two weeks each every six months.

The two days off work each week, as well as the annual holidays, should be spent in the open air.

A small automatic apparatus recently designed by Poole in 1926 makes it possible to eliminate the use of the hands when manipulating capillary tubes containing the emanation which is divided into fractions, after each operation, by dividing up the tube into small tubes, 1.5 cm. long, by means of a blowpipe.

In this way the extraction and purification of the emanation from radium, involving hitherto dangerous exposure for the manipulators, are rendered almost harmless.

A British committee set up in 1921 issued a code of protective measures, amended in 1925 and 1927, which served as a basis to the International Congress of Radiology (1928) in formulating its recommendations. These were amended by the International Committee on Rontgen rays and Radium, Paris, 1931. (See also the report on this subject of the Health Organisation of the League of Nations, 1931.)

**Legislation**

Compensation is granted for injuries due to radioactive substances in Austria, Belgium, Czechoslovakia, Danzig, Finland, France, Germany, Great Britain, Mexico, New Jersey, New York, Ohio, Poland, Sweden, Switzerland and the U.S.S.R.

---

**Rags**

This article deals first with rag-picking, and then with the operations of sorting and shredding of rags or shoddy.

Rag-picking consists of going through household refuse and picking out all articles which have any commercial value. Some rag-pickers go round in the early hours of the morning and collect rags and other refuse from the dustbins which have been placed in the street for the collection of refuse. Others, however, call at houses and buy unwanted objects of all kinds. As this is not a regular occupation, the latter class of rag-picker is generally at the same time a dealer in rabbit skins, a sweep, or a pedlar. The rags are taken to a rag-picker's home or to a depot used by several rag-pickers, where they are sorted. The operation of sorting consists in dividing each object according to the commercial value of the various materials of which it is composed, so that each kind of material can be classified separately. The principal materials distinguished are rags (wool, cotton, silk, linen, etc.), bones, scraps of metal, etc. The rags are then sold to rag dealers who act as middlemen and resell the goods to wholesale dealers. The rag dealers again sort the rags and classify them carefully before selling them to the wholesale dealers.

Besides rag-pickers, who collect their rags from dust bins, the contents of which they scatter on the pavement in order to facilitate their search, there are others who pick out rags from dustcarts in the course of their journey from private houses to refuse dumps. The latter activity is, however, in course of disappearance as the transport of refuse is at present increasingly effected by motor lorries furnished with hermetically sealed covers, which prevent rag-picking during transit.

Rag-picking is also engaged in in factories, where rag-pickers are sometimes allowed to come and remove their booty.
Rag-sorting is an essentially feminine industry. According to statistics prepared by Gilbert (Belgium), 5.4 women to 1 man are met with in this industry. The employment of young persons in the trade is very rare.

The rags arrive at the factory in bales. The bales are opened and the rags are generally placed in thrashing machines, such as the Voith machine. This operation, of course, liberates a considerable quantity of dust, the amount of which varies with the quality and cleanliness of the goods. The rags are then placed on a revolving cloth moving intermittently, which takes them over two small cylinders into closed vessels containing spikes. The heavier waste matter falls and the light dust is drawn by a ventilator into a dust-collector. The latter takes them over two small cylinders into closed vessels containing spikes. The dust which is collected is used for making cardboard or for the manufacture of fertilisers.

The work of sorting consists in tearing up the rags, classifying them in grades according to their material (linen, cotton, wool, etc.), colour, or thickness, and removing all buttons, buckles, and hooks, if they are not made of animal or vegetable fibre. The work is carried on simultaneously with the operation of shredding. The latter operation consists in dividing into strips cotton or linen rags which subsequently go through the cutting and willowing machines, and are then boiled.

The work is done by women, each of whom is given, in the morning, a sufficient amount for the day's or half-day's work. In many cases, rags are sorted in the large rag depots, but the operation is also frequently carried out in connection with shredding in a branch of the paper factory which purchases its rags direct and not through a wholesale dealer.

Rag-shredding rooms are well known to be unhealthy in many respects. The amount of dust liberated is enormous. The atmosphere in rag-shredding rooms is full of thick, clinging, and evil-smelling dust, which settles thickly on the walls, the floors, the furniture, and the workers' clothes. At all times of the year, but particularly in summer, dust settles on the hands and faces of the sorters, and combines with their perspiration to form a sort of paste. Clouds of dust rise into the air, even when rags are simply sorted, but still more dust is caused by the work of shredding or tearing rags, removing buttons, etc. In some workrooms the dust is so thick that the workers cannot breathe unless they tie a cloth or sponge in front of their mouths and noses.

Sviatolowsky has estimated the quantity of dust in rags to amount to from 40 to 70 per cent. The morbidity and mortality statistics for infectious diseases are above the average in those districts in which rag depots and paper factories are situated.

In 1925, Semenow analysed eighteen samples of dust and rags taken from the sorting department of several paper factories. He found, in certain samples, tuberculosis bacilli, mould (fungus: Aspergillus fumigatus), actinomices, particles of organic and inorganic dust, the former chiefly consisting of quartzic sand.
The amount of dust produced varies very considerably according to the nature of the rags. Old clothes produce an immense amount of dust, while new scraps from the dressmaking and clothing industry cause very much less. There is also a considerable difference in the nature of the dust. Rags of the kind mentioned are not liable to cause entrance upon the skin, as may happen with the dust from linen rags for paper factories and new woollen waste for the manufacture of shoddy. Rags are obtained from the most varied sources and may have been used for a large number of purposes. The dust which arises from them may contain mineral elements such as sand and glass, vegetable fibre (cotton, flax, wood, etc.), animal fibre (wool, hair, etc.), and living bodies, such as bacteria and mildew, which may cause putrefaction or more rarely disease (smallpox, tuberculosis, typhoid fever, diphtheria, erysipelas, and occasionally plague, cholera, etc.) or parasitic diseases.

A third feature is the quality of the dust. It is well known that hard particles of dust with sharp edges which easily cause injury act more rapidly and are more injurious than soft absorbent particles of dust. Dust from rags is generally considered less injurious than other kinds in this respect, as it consists for the most part of light absorbent particles rather than mineral particles.

Of these three features — the infectious nature of the dust, its quality (hardness, etc.), and its quantity — the one which gives rise to the principal risk in the rag-sorting and shredding trade is beyond doubt the last. The possibility of contracting infectious disease is far less important.

It would appear from the study of statistics that, apart from anthrax and erysipelas, infectious diseases contracted are more or less rare, since the infective agents lose their virulence by desiccation when the bales of rags are stored for a long time without being opened.

Statistics

Austria. — In 1879 the doctors of Lower Austria observed an acute respiratory disease of unknown nature which affected women engaged in sorting white rags but not those who sorted coloured rags. To this disease they applied the name Hadernkrankheit (rag-sorters' disease). Fourteen deaths occurred in twelve months in a single factory at Glognitz, but no bacteriological examination was made.

In 1887 Schultz, Krahnhals, Hergraven, and Hadecki made a report on an epidemic among women engaged in rag-sorting in an Austrian paper factory which caused seven deaths. Research showed that the disease was apparently an extremely serious one due to some germ closely resembling that responsible for malignant oedema. Other cases reported by Grube recalled the well-known features of the Bradford wool sorters' disease. There can be no doubt that the cases in question were in reality cases of internal anthrax.

Belgium. — In reply to enquiries made by the International Labour Office, the Belgian Factory Medical Inspection Department states that from its point of view the work of rag-sorting is not of special importance. It may, however, be worth while to give an account of some information collected by Dr. Gilbert in 1892.

Dr. Gilbert was not investigating the rag trade as such. His purpose was to enquire into the effect of conditions in the flax industry which is not considered as unhealthy in Belgium. For purposes of comparison he required another trade where similar conditions prevailed, both in the industry and in workers' homes. Such similar conditions he found in the rag trade. The rag workers lived under home conditions identical with those of the flax workers, and workers in the two trades were in many cases members of the same families. Further, rag-sorting is in a large number of cases carried on in the same towns in which the flax industry flourishes. The trade conditions are also very largely similar.

For these purposes, therefore, an enquiry was made covering about 2,000 workers in the rag-sorting industry. This represented a large majority, though not the whole, of the men and women employed on rag-sorting in Belgium. The industry is not for the most part carried on in large undertakings, but in a very considerable number of small depots, each of which employs only two or three workers. The conditions of a large factory are therefore absent, and the health conditions of the workers closely approach those of the general population.

Owing to the disagreeable nature of the industry the workers mostly leave it after a comparatively short time. A small class of persons engaged in independent business form an exception.

There is no special evidence to show that rag-sorting is an unhealthy trade. Possibly the fairly high level of health conditions must be attributed in part to the fact that many of the workers enter the industry at a comparatively late stage in their lives. Or again, it may be that the trade is regarded as a bad one and therefore persons of delicate physique avoid it. Rag workers reach a high standard of general physical development, as their work requires considerable muscular strength. A comparison with the flax industry showed that the general state of health of workers in the rag trade was considerably above that of workers in the flax trade, even in the least unhealthy branches of that industry.
France. — The effect of the trade in rags and old clothes which had not been disinfected on the spread of smallpox and other infectious diseases was investigated in 1879 by Gilbert. This author also states that during an epidemic the district of Paris, in which the largest number of rag-sorters and old-clothes dealers lived had two or three times as many deaths from smallpox as other parts of the town.

In 1885 Pouchet reported four cases of infection among rag workers, and Blaise quotes the following figures collected by Ballestre (of Nice) for the years 1885-1887: 73 smallpox cases out of a total of 186 among the general population of Nice over the same period and 29 diphtheria cases out of a similar total of 169. More than one-third of the cases of measles which were notified occurred near rag depots.

A detailed report dealing with the economic and social aspect of the rag industry in Paris was published in 1903 by the German Paper Manufacturers’ Association in the next year, 1888, showed that the percentage of smallpox and anthrax among rag-sorters was 16 per cent. and their general morbidity rate 45.3 per cent., while the respective figures for other workers in the same factories were 10.7 per cent. and 30.3 per cent.

Dreyfus, in Weyl’s treatise on industrial diseases of 1897, contributes a chapter on the subject. His figures, however, only cover sixty workers employed in a rag-sorting workshop in the country during a period of seven years; 7 per cent. per year of the workers suffered from injuries to the skin and 35.5 per cent. from other diseases, giving a total of 42.5 per cent.

Germany. — In 1877 Ordmann pointed out, in connection with the smallpox epidemics of 1882-1884, the influence of the rag trade and the handling of wool from Buenos Ayres on the spread of smallpox in Germany. In 1880 there was an epidemic of smallpox among rag-sorters in Abenheim, Hesse, which was caused by rags imported from Marseilles, where there was a serious epidemic. In 1897 Filkenburg mentioned the fact that rag-sorters had been known to contract erysipelas from rags, at the same time stating that smallpox and anthrax constituted more serious dangers.

In 1884 a statistical enquiry was made into health conditions in the Saxony paper factories, which showed the comparative prevalence of disease among rag-sorters and other workers in these factories, and revealed not only that the general frequency of disease was very much higher among the rag-sorters than among the other workers in the same factories, but also that this higher disease rate was overwhelmingly due to respiratory trouble.

A more general enquiry carried out at the suggestion of the German Paper Manufacturers’ Association in the next year, 1885, showed that the percentage of morbidity from disease of the respiratory organs among rag-sorters was 16 per cent. and their general morbidity rate 45.3 per cent., while the respective figures for other workers in the same paper factories were only 10.7 per cent. and 30.3 per cent.

Wittgen writing in 1913 gave a detailed account of health conditions among women employed in rag-sorting rooms in Hanover. From an examination of the medical records of the local health insurance society, which cover the four largest rag-sorting workshops, Wittgen collected figures covering 1,602 persons (including an average of 267 workers per year). The following figures are Wittgen’s percentages per 1,000 women employed in the Hanover rag industry from 1907 to 1912 (only such disease as involved loss of working time or medical treatment was recorded):

Wittgen further states that, while the number of cases of sickness for the five years per 1,000 rag workers in Hanover was thus 1,124, it was only 589 per 1,000 for all workers in the Hanover insurance society (630 per 1,000 over the same period for all workers on the books of the Leipzig society).
Brerina reports that, for the period 1920-1922, influenza and diseases of the respiratory organs reached a high percentage in the rag-sorting industry. In a large rag-sorting workshop in the district of Trier, there was found in 1922, amongst 397 persons employed, 190 cases of illness, 90 per cent. of which were due to the following causes: influenza, bronchitis, sore throat, pulmonary catarrh, itch and carbuncles.

In the State of Hesse there were reported for the same period, amongst rag-sorters, numerous cases of pulmonary diseases (chiefly of which were tubercular) and also of skin diseases.

An enquiry effected in Prussia (1925) by the factory inspectors related to 36 establishments (50 in 1924) giving employment to 972 persons (791 in 1922). Health conditions in these establishments left much to be desired. Sorting was often done in the store-rooms; the sorting tables were rarely provided with an adequate mechanical exhaust device, and when there was one, the workers complained of the draught created by the apparatus. The employers rarely provide working clothes for their workers. The use of sorting tables providing for removal of the heavy dust, which falls into a box situated under the table, and the installation of dust-exhaust devices at the level of the work table to remove the lighter dust, even in accordance with experience to be a better system from the point of view of practical necessity.

It is not rare for the workers to find stones, animal dung and even dead cats amongst the rags.

The dust raised during the process of sorting naturally comprises elements derived from such material. In general the dust is of an organic nature, rich in albuminoids. The nature of this dust might provide an explanation of the general, though not specific, immunity acquired by these workers. In fact, young apprentices suffer at the commencement of the work from attacks of fever (carders' and sorters' fever) which may well be due to the action of the proteins.

The workers examined are generally aged workers who have been engaged for many years in the establishments. The labour turnover is relatively slight. There were found, in fact, 42 per cent. of the workers between forty and fifty-nine years of age, and 7.6 over sixty.

The state of health of the workers was satisfactory. In 1924, 91 out of 397 men employed had been ill, and 273 out of 605 women (791 in 1922) employed had been ill, and 273 out of 605 workers between forty and fifty-nine years of age, and 7.6 over sixty.

The state of health of the workers was satisfactory. In 1924, 91 out of 397 men employed had been ill, and 273 out of 605 women (791 in 1922) employed had been ill, and 273 out of 605 workers between forty and fifty-nine years of age, and 7.6 over sixty.

Great Britain. — At one time the rag industry in Great Britain was concentrated in the town of Batley, in Yorkshire, which was known as the 'Rag Metropolis' because it dealt with rags from all over the world. An interesting description of the industry is given in an article by John A. E. Stuart (1902) in Oliver's treatise on dangerous occupations.

In 1876 B. W. Richardson quoted figures given in an article published in 1859 by J. J. Murray, of Edinburgh, who had carried out an enquiry into conditions among Edinburgh rag-sorters and other rag workers. The enquiry showed the remarkable fact that infectious disease was almost non-existent among the workers, who only complained of chronic cough and irritation of the throat owing to the inhalation of dust.

In 1888 Parsons gave an account of a serious epidemic which had broken out during the preceding year in two paper works, and eight other epidemics which occurred between 1875 and 1881.

Three other epidemics also occurred in paper works during 1844.

disinfected hospital refuse before it was sent to rag dealers.

Italy. — An enquiry undertaken in 1886 by Corradi showed that rag workers did not suffer from any special diseases except those due to the dusty nature of their work. Corradi considered, however, that there was a possibility that bacilli with more power of resistance might be diffused by means of rags.

A more recent enquiry by Giglioli (1914) into the rag industry at Pontorme also showed that these workers are exposed to very little risk even if the industry is carried on at home, probably because in Italy the work is done in the open air. In the opinion of Professor Loriga (1923), the rag industry does not seriously endanger the health of the workers, and this view was confirmed by medical examination of the women employed in the sorting rooms. He observed some cases of injury to the fingers, but whitlow and phlegmon were not more common than among other workers.

For Allevi's enquiry, see article "Scavengers".

Netherlands. — Several cases of smallpox were reported from paper factories in Maastricht. At a shoddy factory in Lemiers 26 workers out of a total of 45 contracted typhus in some cases, whereas workers who have been slightly injured by objects found among the rags have died of tetanus.

At the Health Congress held in The Hague in 1884 Ruych reported 40 well-authenticated cases of smallpox contracted in the rag industry in the years 1870 and 1871.

According to the reports of the Dutch Factory Inspectors for 1907 and 1908 many rag-sorters suffer from diseases of the respiratory system and are predisposed to tuberculosis.

The inspectors state that in properly equipped workshops sanitary conditions are more satisfactory, but that even there adequate hygienic measures are not always taken.

Switzerland. — A United States investigation, Whittington, written in 1887, mentions the account given by Sondernger, Biemer, and Zehnder of a small epidemic of cholera (17 cases with 11 deaths) which occurred in 1867 in a paper factory at Kriessettr. This factory imported rags from Zurich, where a serious cholera epidemic was raging at the time.

Schuler and Burkhardt ascertained by an enquiry published some years ago that the proportion of disease among rag-sorters to disease among other workers in the paper industry was 1.6 to 1 for diseases of all kinds and 1.4 to 1 for diseases of the respiratory system.

The Factory Inspectors' Report for 1916-1917 points out that the tearing of old and frequently dirty rags by machinery is liable to be dangerous, because wounds might be caused by pieces of metal contained in the rags.

Union of Socialist Soviet Republics. — An enquiry carried out in 1921-1922 in four rag-sorting establishments at Petrograd showed conditions in these to be extremely bad. The work was effected in small courtyards or in open sheds, in which the women workers were exposed to all weathers. The women worked sitting on the ground or on heaps of dirty rags, were neither provided with working clothes nor soap nor towels. The women sorted on an average 240 kg. of rags (large pieces) per day. In addition to this work, they had also to open the bales of rags, which arrived at the depot in carts.

In February 1922 these workshops employed 220 women rag-sorters. The work done in the workshops years for export. The rags arrived from different parts of the country: Southern Russia, Siberia and Central Russia.

Medical examination of 1511 women workers revealed: 66 cases of anaemia, 31 of digestive trouble, 33 of chronic bronchitis, 35 of contagious skin diseases, 31 of eye disease, 32 of muscular pains in the legs, the arms and the back.

United States. — In 1875 the Lewis brothers reported the occurrence of cases of smallpox, measles, and other infectious diseases in a New York paper factory. They examined statistics referring to 23,170 rag-sorters for a period of twenty-five and a half years. In 1887 C. F. Whittington reported cases of infectious diseases such as measles, scarlet fever, and erysipelas in small rag works, but he did not find any cases in the large rag works of the United States.

More recently, in 1913-1914, an enquiry covering twenty paper factories was carried out in the State of Ohio. The workers in question employed 274 workers, including 203 men, on rag-sorting. The workers were generally unwilling to make any statement, but some complained of the evil effects of dust, of their working hours, and of unsanitary conditions. It was not possible to collect any figures of sickness among rag-sorters either at the time of the enquiry or in previous years.

An enquiry covering nine paper factories, which employed 153 workers, including 128 women, showed that their state of health appeared somewhat poor. There was a great prevalence of symptoms obviously due to the irritation of the mucous membranes by dust.

Hoffman points out that, in general, unsatisfactory statistics on this trade are available; he gives the following figures (1918) of the distribution of deaths by age-groups from respiratory diseases among 3,926 rag-sorters (1,220 men and 1,706 women):
Pathology

The system is protected from dusty disease by the natural means of defence of the respiratory system, namely, the ciliated epithelium and the involuntary movements which cause coughing and sneezing and thus eliminate the foreign dust. If, however, dust is present in excessive quantities, it gives rise to ordinary catarrh, which is easily cured when the patient ceases to breathe dust, but which gradually develops into chronic catarrh if the patient continues to engage in a dusty occupation. Chronic catarrh damages the respiratory organs in such a way that they are unable to resist certain diseases such as tuberculosis and pneumonia.

On the other hand, attacks of fever of an acute form — rag-sorters' disease — are often met with amongst rag-sorters (chiefly amongst young workers and those who are new to the trade). The symptoms of this illness are similar to those of serious bronchial catarrh and influenza. Amongst old workers there are found cases of bronchitis, signs of emphysema, obstructions in the ears with temporary deafness, cases of blepharitis and particularly a characteristic form of acne due to dust from the rags.

The infectious diseases most frequently met with amongst the workers in the rag industry are: smallpox; anthrax and erysipelas. It would, however, appear from statistics that cases of anthrax are very infrequent. There should also be noted cases of tetanus and internal anthrax (Bradford), of measles and scarlet fever and more rarely of plague and cholera, as well as irritation of the mucous membrane due to dust.

Hygiene

Rag depots are considered by legislative authorities to be dangerous from a health point of view, for it is undoubtedly true that they present serious disadvantages and even risk: foetid odours due to the fact that they sometimes include animal bones and skins as well as all sorts of organic material in a state of decomposition; danger from fire resulting from the accumulation of old papers, old linen and cloth more or less impregnated with grease; danger of contamination when they include products which have not been washed or disinfected. They must be away from the neighbourhood of dwelling houses, they must be well ventilated; all windows and openings communicating with the street or neighbouring properties must be kept closed; rags must not be sorted or dried in the street; the floors of the store-rooms and workshops must be watertight; bones and the skins of animals may not be stored without special permission; the store-rooms and workshops must have good natural light, and all artificial lights (even if not in the rooms themselves) must be surrounded by glass and wire-netting if electric light is not installed. All exposed wood must be covered with plaster. The premises must be frequently washed with plenty of water and with solutions of chloride of lime or formalin. There must be an abundant water supply for the cleaning of the depot and for use in case of fire. The rags must be stored in bales not more than 3 metres in height and 2 metres in length, separated from other dangerous goods by an interval of at least 50 cm., and different materials such as paper, rags, etc., must be stored separately.

Other regulations contain the following provisions: whitewashing of the walls with a waterproof solution or with lime (in the latter case this should be done at least annually); prohibition of storing rags in a disgusting or putrefying condition or coming from localities in which infectious diseases have occurred; transport of rags in tarred sacks and in specially closed vehicles in conformity with the local municipal provisions as regards hours, etc.

The principal danger is from dust, but "shoddy fever", "flock fever", and other forms of respiratory disease do not seem to be dangerous illnesses; they apparently resemble mild attacks of chronic influenza. The only way that of infection is greatly reduced by the effects of desiccation on many disease germs. Those germs which resist desiccation are well known, and the danger from them is usually the subject of preventive legislation, which covers the rag trade in common with other trades handling such goods. The special danger arising in the rag trade from the infectious nature of linen rags derived from hospital waste has for the most part been eliminated by regulations making disinfection of such waste compulsory before sale.

At the same time enormous volumes of dust arising in the course of the sorting and shredding processes, as well as the risk from germs inherent in the dirt of the soiled rags, the vast mass of which do not come under the class of dangerous or infected goods, seem at first sight to create such risky conditions that it can hardly be re-
garded as surprising if special precautions are imposed in this trade. The extent to which these precautions should apply has been considerably discussed. Expense is a large factor; also the nature of the exact process to be applied for disinfection — dry, wet, or steam under pressure.

The precautionary processes advisable fall into three stages — thrashing, disinfecting, and drawing off the dust during the final processes of shredding, etc. Thrashing, which means elimination of the initial dust by mechanical processes, can only be done by machinery the fact that such machinery cannot be installed except in a factory is a good reason for prohibiting rag-sorting as a home trade. The thrashing machine should be provided with an efficient exhaust system and the dust should be removed and burned.

It is sometimes objected that if rags are dusted by machinery before sorting they suffer a loss in weight, which some manufacturers estimate at 20 per cent. The operation of dusting by machinery cannot, however, be considered as a reliable means of removing disease germs from rags. Disinfection is clearly the only certain protection against infection. As the danger is particularly great when the bale is opened, disinfection would require to be carried out before this operation. It is, however, well known that the highly compressed bales in which rags are usually packed cannot be satisfactorily disinfected right through. None of the methods proposed for disinfecting the contents of the bale without opening it have proved really satisfactory, and it is therefore necessary to disinfect after the bales have been opened.

Some authorities advise that the rags should be moistened or impregnated with a disinfectant solution before sorting. There has been suggested a solution of chloride of lime at the rate of half a litre per square metre of surface and 50 cm. thickness, followed subsequently by thorough disinfection by a dry process. Another alternative suggested is soaking the rags in milk of lime.

Carbolic acid is the disinfectant preferred in spite of its high cost, for solution of sublimate soon loses its effects by contact with metal objects and may be rubbed in with wool. It is not practicable to treat rags with boiling lye or with chlorine, but other processes, e.g., the now frequent use of formaldehyde vapour, may certainly produce satisfactory results. Whatever solution is used, however, rags which have been treated in this way require a long and expensive drying process.

Industrial experience has shown that the treatment of rags by wet processes to prevent dust is not to be recommended, in the first place because it is liable to rot the rags, in the second place because unpleasant effluvia are produced. The best method is disinfection by steam under pressure. This process has been in use for some time (as early as 1897 in New York). At the present time, however, authorities are unanimous in recommending the process. Drying from the effects of steam can easily be carried out in the apparatus used for disinfection. The technical difficulties are so great and the cost of disinfection so high where chemical disinfectants are employed that Loriga does not see the practical possibility of recommending disinfection of rags to prevent danger from infection which is relatively slight.

In municipal establishments for the destruction of dust in a number of towns in Great Britain, Germany and the United States, it is already customary to disinfect the rags by steam under pressure or by dry heat at 110° to 120° C. before they are sent to the depots. The practice may be generally recommended.

Some authorities who are in favour of disinfection consider that it should not be left to the dealers, as they cannot guarantee its efficacy. If really adequate disinfection is to be ensured it should be carried out by the public authorities. This, however, can scarcely be considered practicable.

After the rags have been thrashed, and, if necessary, disinfected, they are sent to the sorting rooms.

Here some investigators have recommended masks, but these are of course uncomfortable and impractical when work is carried on, as in this case, for a long period. It has also been recommended that gloves should be worn. It is more usual, and generally esteemed efficacious, if the sorting and shredding tables are provided with exhaust apparatus fixed under a wire netting for drawing off the dust.

Some manufacturers have set up apparatus by which dust is extracted upwards. In this case the nozzle is above and in front of the knife. This system, however, has not produced satisfactory results in comparison with the down-draught system. The heavy dust is not removed from the workroom, and only that part of the light dust which is produced between the knife and the exhaust nozzle is removed, while that part which is produced near the mouth of the operator remains in the workroom.
Manufacturers were, for a long time, unwilling to place open stoves in rag-sorting rooms, owing to the danger of fire, and did not wish to incur the expenditure involved in installing hot-air and hot-water heating systems. One manufacturer, however, realising the inconvenience which arose in winter from the draught created by the exhaust fans, at once installed a steam-heating system in the sorting room (France).

Workers should not be employed unless they have been vaccinated, and vaccination should take place every five years. Persons who have any open sores on their hands and face should be temporarily forbidden to work. Workers should be informed of the dangers to which they are exposed.

Special working clothes should be worn, and undertakings should be obliged to provide properly equipped washing and cloak rooms.

LEGISLATION

The employment of women in collecting and washing rags and bones is prohibited in Argentina, and in France in the operations of tearing and shredding rags, as well as employment in workshops where acid fumes are given off during treatment of rags by hydrochloric acid.

The employment of boys under sixteen years of age is prohibited under similar conditions to those for women in Canada (Quebec), Great Britain, the Netherlands, Spain, Switzerland and the United States; the employment of young persons under fifteen years of age is prohibited in Italy and in Japan; of young persons under eighteen years of age in Denmark, Finland, France and Norway. The employment of young girls under eighteen years of age is forbidden in Canada (Quebec), Denmark, Finland, France, Great Britain and Norway and under twenty-one years in Italy, Japan, Spain.

In Germany an Order of 8 December 1900 regulates the employment of young persons in the manipulation of fibre, hair or rags unless dust exhaust apparatus is installed. This condition is also exacted by other legislative provisions (France, Italy). Section 4 of the German Act of 30 May 1914 prohibits the employment of young persons in the shredding of rags. The earliest measures prohibited by law were intended to prevent infection of the general population by germs from soiled rags. In Austria the Act of 28 June 1870 laid down that rags contaminated with infectious matter must be burned.

In 1901 the Austrian health services recommended that the dust should be withdrawn by machinery from rags before sorting, the machine for dust removal to be provided with an exhaust device, and that the dust collected in filters should be precipitated into water or burnt.

At the sorting tables evacuation of dust was to be effected by the downward draught method, and sorting of rags in the workers' homes was prohibited.

In Great Britain section 126 of the Public Health Act of 1875 imposed a penalty upon any person who "gives, lends, sells, transmits or exposes without previous disinfection any bedding, clothing, rags or other things which have been exposed to infection by any dangerous disease".

In Great Britain the committee appointed to study the risk from anthrax infection in industry concluded that it was advisable to recommend washing and mechanical dusting of all rags prior to any manipulation with the exception of clipings of new material. Its recommendations include also the provision of adequate facilities for personal hygiene of the workers and the application of suitable means, mechanical or other, for reducing to a minimum the production of dust and assuring its removal from the workroom.

The periodical medical examination of the workers was likewise recommended.

The French Decree of 27 May 1853 made it temporarily compulsory to disinfect imported rags. The Decree of 15 April 1855 rendered this measure permanent.

In 1890 the Consultative Committee of Public Hygiene of France approved of the strictest possible regulation of the rag industry and affirmed the necessity for protection of public health in this sphere. The Decree of 1 October 1913 prohibits the utilisation of hospital refuse. The Academy of Medicine, after hearing a report by Wurtz in 1914, insisted on the demand for the prohibition in Paris and the suburbs of rag-sorting in courtyards or in the street, household refuse to be dealt with exclusively in municipal institutions for dust distribution and incineration, and dust and refuse removed in such a way that no dirt or dust may be scattered in the street or in the air.

In Italy a Circular of the Ministry of the Interior, dated 15 March 1919, prohibited the use of rags and waste from hospitals in the clothing trade without previous disinfection.

In Great Britain the Anthrax Prevention Act of 1919 empowered the authorities from time to time as occasion arose by Order-in-Council to control the importation and also to order the disinfection of goods liable to be infected with anthrax, such goods to include rags.

Amongst legislative measures applied may be recalled that of Austria (Order of 25 September 1911) relative to paper factories; paragraph (b) deals with the use and treatment of rags and includes a series of hygienic measures in connection with the various processes; compulsory vaccination of the workers, exclusion of persons suffering from respiratory diseases and cutaneous lesions.

In Belgium the Royal Order of 4 February 1895 provides for vaccination of workers employed in handling rags and the Danish Regulation concerning textile
laboratories and dated 23 January 1908 also contains hygienic measures relative to the manipulation of rags.

A Circular issued by the Prussian Ministry for Trade and Commerce in 1894 (confirmed by a later Circular dated 25 February 1895) contains very detailed regulations. An Order concerning the installation and working of rag-sorting workshops was issued on 28 March 1928.

In Norway, the Resolution relative to such depots is dated 26 November 1925.

The carrying on of the trade as a home industry is, from the point of view of the health expert, even more important than factory work. In the rag-sorter’s home thrashing cannot be undertaken by machinery, nor can exhaust apparatus be fitted to tables. In 1915 the authorities in Saxony discussed an Order calculated to prohibit the practice of the trade as a home industry, except in the case of rags which had been previously threshered. It was pointed out that any form of thrashing or of disinfection applied to the home industry would be very expensive and even then not entirely efficacious. Even after thrashing the cutting and tearing of rags causes clouds of dust which can be dealt with in a factory in which exhaust apparatus is installed, but which in the worker’s home would rise each time any person present made the slightest movement. Eventually the Order which in the worker’s home would rise each time any person present made the slightest movement. Eventually the Order was put within the competence of the Federal Minister of Labour. However, it was pointed out that any form of thrashing or of disinfection applied to the home industry would be very expensive and even then not entirely efficacious.

In 1915 the authorities in Saxony discussed an Order calculated to prohibit the practice of the trade as a home industry, except in the case of rags which had been previously threshered. It was pointed out that any form of thrashing or of disinfection applied to the home industry would be very expensive and even then not entirely efficacious. Even after thrashing the cutting and tearing of rags causes clouds of dust which can be dealt with in a factory in which exhaust apparatus is installed, but which in the worker’s home would rise each time any person present made the slightest movement. Eventually the Order was put within the competence of the Federal Minister of Labour.

In Finland a resolution dated 13 December 1924 regulates the work of sorting and shredding rags; in U.S.S.R. a compulsory Order dated 3 November 1922 dealing with paper factories contains measures for the protection of workers engaged in the sorting and shredding of rags.

Pulmonary affections occurring amongst workers in the trade as well as tetanus are subject to compulsory notification in the Netherlands. Erysipelas, anthrax, plague and smallpox are compensated under Japanese law.

### Red Lead

**French:** Minium. — **German:** Mennige oder Minium. — **Italian and Spanish:** Minio.

**CHEMISTRY**

Red lead (Pb₂O₄), of which the composition varies between PbO₂, 2PbO, and Pb₂O₃, is the red oxide of lead. It is the product of the combustion of lead metal and consists of a mixture of lead dioxide and lead oxide. The quality depends on its more or less perfect oxidation and the purity of the lead employed. The red lead obtained from the calcination of white lead (a process employed in Great Britain and one giving a more beautiful product than when lead is used as the starting point) bears another name: orange lead (French: mine orangé, rouge de Paris, orange minéral, cinabre de Saturne, etc. — German: Orange Mennige. — Italian: Minio aranciato. — Spanish: Minio arangiado).

Red lead has the appearance of a fine powder, heavy, orange-red in colour, the shade varying with the method of manufacture; it is the richer in colour and the content in peroxide is raised. On slight application of heat the colour becomes paler. Calcined in the air the red lead changes to brown, then to yellow and becomes converted into litharge. It is insoluble in water and dilute hydrochloric acid; it dissolves in strong boiling acid, giving off chlorine and forming lead chloride. Weak acids decompose it. Its covering power is excellent, but it is poisonous and is blackened by hydrogen sulphide. The commercial red lead of highest quality only contains 97 per cent. of pure red lead (Pb₂O₄); this content can fall to about 60 or even 40 per cent. Further, very often, fraudulent addition is made of other compounds, such as native barytes, when ground and tinted red, aniline colour, pounded brick, colcothar, chalk, clay, gypsum, lead sulphate, colours with a basis of iron or other substances in which the shade is intensified by using artificial organic colours (coloured red by eosin, cinnabar, and vermilion substitutes made up of a mixture of red lead, baryum sulphate, sulphate and carbonate of lead and eosin, sold under fancy names).

**BIBLIOGRAPHY**

**POKROVSKAIA, M., in Gigiena Truda, 1923, Nos. 3 and 4, and 1925, No. 4. Moscow.** (In Russian.)
At the present time red lead has a strong competitor in "grey" red lead, or "arcanol", a lead colour containing the latter partly in finely separated, partly in oxidised condition. The advantages gained are said to be increased output, possibility of preserving in good condition for an unlimited period, small oil consumption, excellent drying capacity, efficacious protection of metallic objects against rust and impermeability of the dry paint to water.

**MANUFACTURE**

Metallic lead heated to 450 to 500°C, in contact with air on the floor of a reverberatory furnace becomes converted into protoxide or massicot. The layer of oxide formed requires to be continually removed and a too high temperature which would convert the massicot into litharge — less satisfactory for the manufacture of red lead — must be avoided. The red lead is then removed, ground with water and filtered over a metal sheet. After drying it is again oxidised in the presence of much air at about 30°C. After withdrawal from the furnace it is cooled, the massicot then having a greenish colour which changes to pink or yellow according to the amount of oxygen present.

The oxidation of the massicot is effected in refractory muffle furnaces which are charged either by hand or mechanically. The massicot is fetched on a truck which is placed against the door of a furnace and provided with a ventilating flue. The muffles are placed in the upper part of the furnace where the massicot is made, thus utilising the heat expended in the manufacture of the red lead. The oxidation of the massicot can be carried out also on the flat floor of a reverberatory furnace heated by gas. The massicot requires to be frequently raked in order to bring fresh surfaces into contact with the air.

The yellow tint of the massicot turns to red on the formation of red lead.

Minium is also made commercially by super-oxidising the massicot with nitrate of soda in accordance with the formula: 3 Pb O + Na NO₃ = Pb₃ O₄ + Na NO₃. The sodium nitrate is separated from the red lead by washing, concentrating, and successive crystallisation.

The minium obtained is washed, dried and ground into a fine powder, sieved and packed in barrels or sacks.

**Dangers.** — The first processes are less dangerous than the later ones. During the melting, however, the workmen are exposed to the risk of inhaling lead fumes given off on opening the furnace doors. The use of ventilating hoods only slightly improves this. "Rabbling" and feeding the furnaces with massicot for conversion into red lead are very arduous and give similar risk. "Rabbling" can be done mechanically by stirrers. In Great Britain now the operations are done automatically (Chester method) and the mechanics are the persons who run risk in attending to the efficient working of the plant.

The processes of removal from the furnaces, drying, grinding, sieving, filling of small cases by hand, placing of these in reserve storage, and and packing of barrels by hand naturally expose the workers to the risk of poisonous dust if not carried on with the necessary precautions.

**USES**

It is used as a jointing paste for pipes and boilers, as the first coat of oil paint for the preservation of iron (railways, bridges, ships, etc.). It is used in the painting industry, in the manufacture of accumulators, in the pottery industry, for backing mirrors to prevent oxidation of the metallic film, in the manufacture of glass, crystal, coloured papers, fine colours, matches, in dyeing, for colouring wax, etc.

**TOXICITY**

Although certain writers consider the toxicity of red lead as minimal, most think it is, on the contrary, as toxic as white lead. The danger is sufficiently important for attention to be directed to it: as a matter of fact, in a German red lead factory, in spite of the precautionary measures taken, 1.2 milligrammes of lead, estimated as oxide of lead, was found in 191 litres of air in the sieving room. In another factory, on analysis of the dust being made at three different points, near the grinding rolls and close to the sieves and furnaces, a percentage of dust reckoned as oxide of lead was found amounting to 64.8, 73.8, and 81.8.

Workmen using red lead, either as colours, jointing paste, etc. (see above), are also exposed to the danger of lead poisoning.

**STATISTICS**

*Austria.* — In 1913, the Factory Department called attention to the danger from the use of spraying red lead. According to Teleky, in 1913, 50 per cent. of painters on steel work were affected with lead poisoning.
Belgium. — The State Railway Company reported cases of saturnism among their employees habitually engaged in handling red lead.

France. — See "Lead, Poisoning by".

Germany. — Good organisation from the technical and hygienic point of view in a red lead factory enabled the lead poisoning risk to be much reduced between 1899 and 1903. Among an average of 42 workers, there was only one case of colic and five of gastritis. In another works, on the contrary, where the conditions were bad, during the same period and with an average of 28 workmen, there were 18.6 cases of colic (35 in a single year) and 4.2 of gastritis. According to Wächter, red lead comes second to white lead as a cause of cases of saturnism.

Prussia. — Between 1914 and 1918 a remarkable diminution of cases of lead poisoning in steel constructional work was achieved by the use of substitutes (red oxide of lead). In the same country in 1919, 99 slight cases occurred in a factory where locally applied exhaust ventilation for the dust was considered satisfactory and where alteration of work had been arranged.

Great Britain. — According to the report of the Medical Inspector of Factories, of 108 cases during the 10 years 1900 to 1909, 47 affected furnace workers, 43 packing and sieving, and 16 other workers. Of the 108 cases 30 were severe, 31 moderate, and 47 not severe. The symptoms were distributed as follows: 87 colic, 28 anaemia, 8 spastic paraplegia, 9 encephalopathy and 13 rheumatism. Collis found, in a group of factories visited between 1905 and 1909, and employing 171 persons, that 5 per cent. were attacked by plumbism and 13 rheumatism.

Between 1910 and 1923 the number of cases in the manufacture of red lead (as distinct from manufacture of litharge and white lead and also use of red lead) was 1914, i.e. an average of 9 cases per annum.

According to Oliver, a quarter of the cases of lead poisoning by red lead show severe symptoms, and the English statistics rather confirm Layet's opinion, namely, that red lead provoked more easily than other lead compounds severe and fatal forms of lead poisoning.

Netherlands. — Poisoning cases were reported in the metallurgical industry.

United States. — According to Hamilton, the risk was very small in many factories where there was little escape of dust and where efficient mechanical methods offering adequate protection against fumes and dust had been developed. On the contrary, in badly organised work, especially where hand work was done, the risks were even greater than in the white lead works. Thus, in one factory, during 16 months there were 7 cases of lead poisoning among 12 workmen, as compared with 14 among 65 in white lead works; that is, a proportion of 58.3 for red lead as against 22.5 for white lead. The duration of employment of the workpeople was less than a year. Severe cases of encephalopathy have been reported (three) amongst workmen employed in the dry rubbing of surfaces painted with red lead.

Pathology

See article "Lead, Poisoning by".

Hygiene

The precautionary measures which follow apply equally to litharge and massicot. The furnaces should be built either in the open air or in large workrooms with free ventilation (Belgium) or provided with efficient exhaust arrangements (Great Britain), as also should all operations for the cooling of litharge and red lead. In "rabbling" and removal of the material from the furnaces, the workmen ought not to be exposed to fumes and dust. If the furnaces are not in the open air, exhaust hoods with strong draught should be placed above the working doors (Belgium, France, etc.). In Germany all newly constructed furnaces must have mechanical charging, and from 1 January 1925 furnaces which have no mechanical charging and emptying devices must be withdrawn from use.

In order to avoid escape of the dust, the massicot should be slightly moistened, which can be readily done if the drying is not carried too far. As an additional precaution, the workmen may wear a wet sponge over the mouth. In the same way, removal of the material from the furnace can be done by mechanically-worked shovels. The material should be emptied into a partially closed trolley connected up with the exhaust and moistened beforehand.

During wet grinding and crushing of the material (when either wet or in closed apparatus) and removal of the massicot from the bins, actual contact of the hands with the oxide or risk from splashes should be avoided.

Pulverising and sieving should be done in apparatus hermetically closed, which should not be opened until a sufficient time has been allowed to elapse for all dust to have settled. Transport, packing and settling should be done in a manner preventing the raising of dust. The floor of the workroom should be in sound condition and kept damp if necessary. The material should be conveyed to the furnaces in a moist condition or in closed receptacles so as prevent the escape of dust into rooms where work is being carried on. The clearing of sacks which have contained lead com-
pounds should either be done when well wetted or in closed apparatus. Spells of work at the furnaces, etc. (Great Britain) should not last for more than three hours without a break of half an hour, nor should furnaces be approached except when ventilation is good.

To-day new methods enable red lead to be manufactured without escape of dust and without contact with the workers' hands. The lead is converted into amorphous protoxide (massicot) instead of crystalline protoxide (litharge). The blocks of lead are transported automatically from the factory entrance to the furnace. The furnace is provided with a ventilating hood. The interior of the vat has an air pressure lower than that of the outside air and the mixing of the lead is done automatically. The lead-oxide dust enters into two circuits according to whether it is fine or coarse dust. The coarse dust falls by force of gravity and is led off by a screw to the silo. The fine dust, carried off by the current of air, passes along an endless screw to the silo. The silo house contains filters and its interior has an air pressure lower than that of the outside air and the mixing of the lead is done automatically. The lead-oxide dust enters into two circuits according to whether it is fine or coarse dust. The coarse dust falls by force of gravity and is led off by a screw to the silo. The fine dust, carried off by the current of air, passes along an endless screw to the silo. The fine dust, carried off by the current of air, passes along an endless screw to the silo. The fine dust, carried off by the current of air, passes along an endless screw to the silo. The fine dust, carried off by the current of air, passes along an endless screw to the silo. The fine dust, carried off by the current of air, passes along an endless screw to the silo. The fine dust, carried off by the current of air, passes along an endless screw to the silo.

This is then taken by a bucket conveyor to the silos and eventually by a funnel to the barrels. The packing is accomplished without any escape of dust and without contact with the workers' hands. This is, roughly, the modern method used in a French red lead factory described by Tournois (1928) in which the number of cases of lead poisoning recorded among the workers were 5 in 1924, 11 in 1925, 46 in 1926, 4 in 1927, and 2 in 1928. The new equipment was installed in 1926.

Personal hygiene should be encouraged in every way, as in all dangerous trades, by provision of overalls, respirators, a messroom, and washing accommodation. Alternation of employment should be practiced in the case of the most dangerous kinds of work.

Periodical medical examination should be carried out on persons employed in the manufacture of red lead, litharge and massicot; this is required monthly in Great Britain, Netherlands, and the States of California, New Jersey and Ohio; quarterly for the lead industry in Austria, France, and Yugoslav; and bi-monthly or even weekly in Germany.

Substitutes. — Pure red lead is one of the best pigments for painting metal, with the special object of protecting it from rust. Well prepared it has good covering power, leaving a solid surface. On account of its great natural density, however, weight for weight it does not yield coats so thick as those obtained with other colours. Analysis of a number of red leads (French, Belgian, and German) has shown that it contains from 73 to 97.2 per cent. of red lead, the remainder being litharge. The foreign substances which are commonly added in the commercial brands have been described. Efforts have been made to substitute for red lead other less poisonous substances in the painting of iron. From recent inquiries it would seem that colours with a basis of red lead are unnecessary for the priming coats on iron and even for all the coats except those to be placed under water. Thaus (1914) considered that red lead could be replaced by leadless colours, especially the superficial coats and where exposure to weather was not in question. These substitutes could be the oxides of antimony, manganese, iron, aluminium (bauxite), graphite, lithopones, different mixtures of paints, etc. (See article "Painting Industry").

LEGISLATION

In addition to general measures enacted for the protection of workers against dust and fumes and special regulations in force for red lead, litharge and massicot in Belgium (1910), France (1913), Germany (1916), Western Australia (1923), Victoria (1920) and in certain States of the United States (Illinois, 1911; New Jersey, 1914; Ohio, 1913; Pennsylvania, 1913). The principal requirements have been referred to in the preceding paragraphs.

For international legislation, see the article "Lead".

Women are excluded from the manufacture of red lead, litharge and massicot in Argentina, France, Germany, Great Britain, Japan, Lower Poland, Netherlands, Switzerland, and several States of the United States, etc.; pregnant women in Norway.

Young persons of 15 years are excluded in the State of Delaware, in Italy and Japan; under 16 years in Argentina, Belgium, Germany, Great Britain, Greece, Spain and most of the United States, etc.; under 18 years in Netherlands, Norway, Poland, Slovenia, Switzerland, under 21 years in

Refrigerating Plants

The cold storage industry is daily increasing in importance.

Cold is produced in laboratories and small industries through the absorption of heat by certain saline solutions — a scientific phenomenon established by Boyle in 1655 — and more particularly by the use of mixtures of salt and ice, according to Réamur’s discoveries in 1734 which Fahrenheit utilised for fixing the zero of his thermometer.

The cold storage industry, on the other hand, is based on the expansion of compressed gases and the evaporation of certain liquids which occur with the absorption of heat. These methods are founded on phenomena to which are attached the names of Faraday and Muschenbroek, and represent the principle underlying the Carré, Pictet and Linde machines.

The production of cold by expansion may in theory be effected with any gas, but in practice, air is mostly used in air-freezing machines. These machines were completely abandoned in the early days after they were first used, because of unsatisfactory results; but they have recently returned to favour with the new Leblanc process used in the high-pressure freezing machines of the Leblanc and Linde and the Leblanc and Vickers systems. The advantage of this type of machine, from the hygienic point of view, is that it uses nothing but a non-toxic product as its freezing agent, viz. air, whereas other freezing machines use gases.

From an economical point of view, steam as a freezing agent can only be made use of when large quantities of water are available for cooling at a cheap rate, or when it is essential to have a non-dangerous freezing agent, as for example on ships, where leaks in ammonia or sulphurous anhydride machines would make the holds uninhabitable. In such cases engines ejecting steam are used, as in the Gensecke system in Germany, and in the Leblanc-Westinghouse systems in other countries; these engines utilise the energy freed by ejecting a jet of steam in order to obtain aspiration and partial compression of steam or of a saline solution.

The production of cold by the evaporation of liquids is effected by means of machines in which are used as freezing agents chemical products which remain sufficiently volatile at the lowest temperatures attained, and remain liquid at the highest temperatures and pressures realised during the running of the machines. Among compounds volatile, but easy to liquefy, those most commonly used are ammonia, carbon dioxide, sulphur dioxide, and, in some particular conditions, ether, ethane, methyl chloride, ethyl chloride and numerous other products.

Gas freezing machines are worked on the principles of absorption and, as a general rule, of compression.

The first type — absorption machines — depend on the property belonging to certain liquids of being able to absorb, without undergoing any essential modification, gases or vapours coming from other liquids, and to give them up again in vacuo with the absorption of heat, i.e. with cooling of the surrounding atmosphere or of the particular refrigerating receptacle used. This system is only put to practical use in the case of the absorption of the vapour of ammonia by water and of the vapour of water by sulphuric acid. Experimenters have also tried to substitute absorbed substances, e.g. halogen compounds of various metals and chlorides of calcium, and have constructed absorbing machines...
Containing activated charcol as an absorbing substance.

The second type of machines are compression machines; they contain a compressor which by aspiration draws in a line of pipes, gas suitably arranged in a special carbon dioxide, sulphurous anhydride, or chloride of methyl, compresses it, and then sends it into a water condenser where it is liquefied and cooled. This freezing fluid is next passed into an evaporator connected with the aspiration pipe of the compressor. The compressor, by aspirating a certain quantity of gas, causes the evaporation of an equivalent quantity of liquid which involves the absorption of heat, i.e., the production of cold. Evaporators act as refrigerators by extracting from the atmosphere that is to be cooled the calories necessary for the production of the evaporation. They are generally composed of a bundle of large-sized pipes, through which the compressed and cooled gas passes. The vapours are then taken up again by the compressor and the cycle recommences.

Compression machines have some disadvantages, such as noise and shaking, unavoidable leaks from stuffing boxes, and the necessity for refilling which only make it possible to use them at a factory. Absorption machines do not possess these disadvantages, they are used in plants for domestic use, the use of which tends to become more and more extensive.

Freezing machines are calibrated in "frigories", one frigorie being the amount of heat required to be abstracted from a mass of 1,030 grms. of distilled water to reduce its temperature 1° C. The cold produced may be transmitted either directly by cooling the surrounding air, or indirectly.

In the first case, the bundle of expansion pipes is suspended from the ceiling or from the walls of the places to be cooled. This method of distribution, called "direct expansion", has the disadvantage of allowing a certain amount of humidity to remain in the atmosphere of the refrigerating chambers, which may be prejudicial to the preservation of some kinds of provisions.

In the second case installations of closed pipes, containing either cooled air or freezing brine, are used. The method known as the dry cold (frigid sec) consists in making chilled air circulate through a bundle of direct-expansion pipes, enclosed in a special place called a refrigerator. In these conditions the air driven forward by a fan becomes cooled on coming in contact with the expansion coil and the moisture it contains is deposited on the cold pipes in the form of rime. The air, cold and dry, is next taken up again and distributed by wooden channels suitably arranged in the places to be cooled. The air can be cooled still further by passing it over systems of brine pipes, or through a shower of powdered brine. In different cases the air can then according to requirements be cleaned from dust by filtration, dried, sterilised or oxygenated, and then pumped into the refrigerating chambers. Chilled brine can also be circulated in the places to be cooled. Either for cooling the air, or for circulation in the coils, plain water can be used instead of brine, when it is not desired to reduce below 0° C.; but, when it is solutions of chloride of calcium, of magnesium and of sodium are used, and, more rarely, solutions which are still more difficult to freeze, such as glycerine or alcohol.

Solid carbon dioxide has been tried for the last two years under the name of "dry ice" to replace ice in the refrigerator vans on railways.

It is obtained by decompressing liquefied carbon dioxide of which a third or more can then be collected in the form of snow. Carbon dioxide arrives in the evaporating apparatus under a pressure of 70 atm., expands in a receptacle and the cold produced by the evaporation is precipitated in the form of snow, which is retained by the filter, whilst the gaseous part, which is very cold, passes between the two walls and from the bottom of the apparatus is directed towards the suction pump of the compressor.

The snow is collected and compressed into blocks weighing about 17-18 kg. and sawn up.

**Industrial Applications of Cold**

Cold is used principally for making artificial ice, i.e., transparent ice from spring water or from pipe water supply, and crystal ice from distilled water. The evaporator of freezing machines is so arranged that a saline freezing solution surrounds the ice moulds, which are made of tinned iron or, better still, of galvanised iron, and are filled with water; the water solidifies in from twelve to eighteen hours and the blocks of ice are easily extracted from the moulds — which are of a slightly conical shape — after a short immersion in a bath of hot water to facilitate extraction. Installations for artificial ice are also used in skating rinks with systems of refrigerating
pipes containing a saline solution at —6° C. and —10° C., whilst the artificial tracks for luges and skis are prepared by mixtures of salt with or without refrigerating pipes.

The conservation of perishable food calls for cold to prevent the putrefaction of materials nourishing or otherwise, or, at any rate, to preserve their good appearance. The requisite chambers — whether warehouses for cold storage at ports supplied from refrigeration plants; or for cold storage at railway stations, or warehouses for transit, or for consumption, supplied from cold storage vans which are either refrigerated or kept at an equal temperature — are generally cooled by making freezing solutions circulate in closed pipes or more rarely in open channels in the places to be cooled. Various temperatures are used depending on the substances to be preserved: —12° to 10° C. for freezing fish; —10° to 6° C. for freezing meat; —8° to 3° C. for raw tobacco; —6° to 4° C. for preserving eggs, and preserving meat. Mention should also be made of refrigerators used for freezing eggs, and refrigerators at abattoirs for the preparation either of chilled meat, or of frozen or solidified meat.

Cold is also used for cooling large masses of water as electric generators, or various workplaces, such as explosives magazines on warships, which should not rise above 25° C.; food stores on merchant ships; cooling ships during voyages in hot climates, e.g. the Red Sea; theatres and cinemas; hospital warehouses, especially for chest cases and mortuaries, for which a temperature of —4° to 0° C. is sufficient, unless the requirements for autopsies necessitate freezing the bodies at —20° to —15° C.

In the chemical industry, cold is used industrially for numerous cooling operations, such as drying, extracting and freezing. For instance it is used to regulate the process of fermentation or other biological processes in breweries, yeast factories, bakeries, malt-houses; for the rapid cooling of wort in breweries; for cooling milk and cream in dairies; for granulating and washing crude margarine; for effecting better desugaring of molasses in sugar refineries; for some distilling operations, notably for that of distilling alcohol at a low temperature which gives greater purity to the product and greater simplification in the separation of empyreumatic oils. It is also used for cooling dye solutions, ensuring greater fixity of the colours; for cooling solutions used for mercerising and neutralising threads used in spinning.

The extraction of certain products is effected by cold in industries concerned with paraffin oil, lithopone and sulphur dioxide, and such other operations of the chemical industry as the separation of Glauber's salt and the salts of ammoniacal soda from the mother solutions, and the recovery of used acetones, ether, benzine and alcohol. The liquefaction of chlorine is simplified by intense cooling, as is also that of ammonia, carbon dioxide, air and rare gases; and with the extraction of helium from natural gases.

A kind of extraction by cold is done by drying certain products, for example, in the course of solidifying oils, in order to dry the hydrogen used for hardening oils; in blast furnaces for cooling; before the sintering of the coke; in glaziers' workshops, for brightening glazes, and in the preparation of pigments.

Substances are solidified by cold in numerous instances: in the manufacture of margarine, gelatine and glue; in the last case cooling makes it possible to reduce the period of drying from some weeks to twelve hours. In the manufacture of extracts from flowers by means of oil and alcohol, the oil is separated into clots by coagulating, while the alcohol is drained off with the extract.

In rubber and cable works cold is used to harden the pieces and slabs of rubber, since they can then be more easily worked and cut. In the manufacture of photographic plates and paper, the emulsion is solidified and dried. In films, the supporting material, i.e. on paper, plates or films. In making champagne, particles of lees which are deposited at the neck of the bottle are solidified by cooling the neck of the bottle intensely in a solution of glycerine for this way they can be removed without any loss of the wine.

An important application of cold for solidifying large masses is its use in the mining industry when sinking shafts, in order to fix shifting earth or moving and wet sand during the period of hooping until the shaft has been hooped or walled round. The freezing is effected by a concentric system of freezing pipes introduced into the shaft of the mine and kept advancing with the sinking.

Cold is also used in technical and scientific researches, when testing building materials and materials with regard to their resistance to very low temperatures or to sudden changes of temperature, and to determine the germinating power of seeds, the power
of growth of plants, and the vitality of parasite plants.

**Sources of Risk**

The occupational hazards for workers in the cold industry are very limited.

Exposure to low temperatures is the chief danger. But, as in the case of workers in the open air, cold is only important as a danger when the work carried out in freezing chambers is accompanied by heating the body through great exertion, such as por-terage in cold storage premises, or when there is frequent change from heat to cold, as in brewery work, in certain chemical works, and in small refrigerating works where the same person supervises simultaneously the steam engine, the dynamo and the refrigerating plant. The same holds good for ice factories where work requiring exertion, such as emptying moulds and discharging blocks of ice, is carried on at a low temperature — when such operations are not effected mechanically.

The injurious influence of cold increases with dampness of the air, which cannot always be avoided in the manufacture of ice; this matter must also be taken into account in other establishments which use cold. Moreover, cold and damp together exert an influence which is more injurious in proportion to any suddenness in the change of temperature, and to the skin being in a damp state or secreting sweat freely, in consequence of hard work at the same time or previously.

A second source of danger is represented by risks from escapes of gas from refrigerating machines, which present a danger varying according to the different products employed as freezing agents, whether ammonia, carbon dioxide, sulphur dioxide, or chlorides of ethyl, methyl, ethane or propane. These products constitute sources of poisoning for the personnel and dangerous contaminations for certain preserved materials; these troubles are all the more serious in that the chemical products are used under pressure which in ammonia machines reaches 9 atm., in sulphur dioxide machines 3.5 atm. and in carbon dioxide machines 50 to 60 atm. It follows that the smallest leaks give off quite an appreciable quantity of noxious vapours; and enormous quantities escape during serious accidents from the bursting of compressors or pipes. (See also article "Methyl Chloride").

There must not be overlooked the risks of explosions from excessive pressures, with ignition of explosive and combustible fumes at the moment of their escape. It should be borne in mind also that mineral oils, used for lubricating the compressors, may be transformed into hydrocarbons at the temperatures which are reached in running the engines; in that case they constitute inflammable and explosive mixtures.

In this connection the part played by static electricity, developed during the running of the engines, must be taken into account.

**Statistics**

It may be said that there do not exist any real statistics of occupational sickness and mortality relating to workers in the cold storage industry and in the manufacture of refrigerating plant.

In Great Britain the annual report of the Chief Factory Inspector for the period 1920-1922 mentions 7 cases of poisoning, one of which was fatal, in the industry of refrigerating by ammonia, as well as 6 cases of slight poisoning in a confectionery works.

In Germany information collected by the trade union of brewers and masters shows each year a number of more or less serious accidents from toxic products, but without specifying the actual number.

**Pathology**

Chief among diseases caused by cold must be mentioned diseases of the respiratory organs, rheumatic inflammations of muscles and nerves, and a great liability to infections of the mucous membranes. According to the constitution and individual susceptibility, the effect of cold makes itself felt upon different parts of the body, and causes organic injuries either directly by chilling, whence arise disorders of nutrition, of the muscles, articulations or nerves, or indirectly in consequence of the effect of infectious micro-organisms, the virulence of which becomes increased, or rather the resistance to which becomes lessened.

Among those working in the cold producing industry cases of necrosis of the limbs or parts of the limbs are rarely observed, in consequence of a more or less lasting retarding of the circulation. At the most there have quite rarely been observed cases of frostbite during work at very low temperatures, with liquid air for example, or of pruritus of the skin, and chilblains during prolonged repair work on very cold parts of engines or on refrigerating pipes. Among workers in refrigerating cham-
As regards general affections due to cold the reader is referred to the article "Air: Hot and Humid"

The injuries which arise from toxic products are more serious. While reference to various articles dealing with the products in question is indicated, certain points in particular may be noted here.

Ammonia escaping in a jet from a leak may cause burns, with the formation of blisters, due to the fatty protective layer of the skin being dissolved and the great affinity of ammonia for water. In the same way there may occur lachrymation, conjunctivitis, and, under certain conditions, keratitis. A strength of 0.15 per cent. of ammonia in the air causes definite irritation of the mucous membranes; and a greater strength, spasms of coughing with mucus expectoration which is thick and sometimes bloodstained, vomiting, psychic excitement and cramps which may have serious consequences. If the patient falls to the ground, that is if he falls into the zone of greatest concentration of carbon dioxide. It is, as a matter of fact, well known that, in consequence of its high specific gravity, carbon dioxide accumulates in the low parts of any place. As it is odourless, camphor is sometimes mixed with it when it is used in refrigerating machines, so that the smell may act as a warning.

The other freezing agents mentioned above, and less often used, have, in addition to similar effects on the mucous membranes, a narcotic action. The special effect of chlorine on the central nervous system should also be mentioned.

For methyl chloride, see that article.

**HYGIENE**

The best prophylaxis lies in the construction, fitting and correct installation of freezing machines. Such machines should not be placed in cellars if they are worked with heavy gases; and all communication between the engine-room and the upper floors of work-places, in the case of ammonia machines, should be avoided. Whenever possible two exits, opposite one another, should be provided, leading directly to the open air. Adequate ventilation should be provided and arranged so as to act at the floor level; the installation should be such that it can be controlled from a non-dangerous situation, outside the engine-room.

The material used in the construction of all parts of machines and pipes which work under pressure must be of irreproachable quality, the joints carefully made and the solderings perfect. Packings and screwed joints should be avoided. The suction and compression sides of compressors and pumps should be provided with the necessary manometers, as well as the oil separators of ammonia compressing machines. Taps and safety valves must be fixed at special points with adequate devices for evacuating the products in case of necessity.

During the working of the machines all indications of pressure and heating must be carefully watched, more particularly in the case of the compressor. Too much heat destroys the joints and the leather washers of carbon dioxide machines, or leads to the decomposition of ammonia with the formation of explosive gas. Work with a naked light must be forbidden in the vicinity of hot compressors; and it is still more important not to hunt for leaks with a light in the interior of a compressor which has been taken to pieces, nor in the pipes, or joints of the pipes. Leaks can be detected in ammonia installations by introducing into the pipes, or by spraying on to them, a solution of weak hydrochloric acid, which, in the case of a leak, leads to the formation of white fumes of ammonium chloride which are easily seen. With sulphur dioxide machines a weak solution of ammonia is used in the same way; and with carbon dioxide machines a solution of soap.

In other cases certain measures can be taken, e.g. the addition of ethyl bromide to ethyl chloride to make it non-inflammable.

Among measures of personal hygiene, the wearing of suitable working clothes which protect the worker against the rapid changes of temperature in the different places of work is of the greatest importance. Protection against humidity must be provided by wearing leather aprons, with the addition, when carrying ice, of coverings for the neck,
and gloves. During the repair of machines or pipes which are not tightly sealed, the possibility of a sudden escape of ammonia or sulphur dioxide must be borne in mind; and for this reason protective goggles and leather gloves which leave the ends of the fingers free must be provided for the personnel. The use of gas masks with absorbent charges giving efficient protection against the different gases should be provided for in case of escape of toxic products. It should be noted that gas masks can only be used when the strength of the escaped gases does not exceed a certain degree, which varies according to their nature, so that in any case a sufficient quantity of oxygen remains for respiration. Care must also be taken that masks fit well to the face and shape of the head of those who may have to wear them. Otherwise these masks will not be airtight, and they will expose their wearers to danger from penetration of the gases into the respiratory passages, and in consequence to poisoning.

In case of the escape of large quantities of toxic products, due to bursting of the machines or pipes, gas masks, which in several instances have proved unsatisfactory, should not be used. In the case of an explosion of an ammonia compressor, an attempt to penetrate into the place where the accident occurred showed that the gases penetrated through the clothing and the fabric material of the masks, causing pruritus and intense lachrymation, the absorption charges of the masks being rendered useless in a few seconds.

Oxygen respiratory helmets should be available for use, or outside air should be brought by a pipe, taking care that there are no leaks. It is still better to use respiratory helmets to which it is possible to send, from an unexposed situation, fresh air under pressure, which prevents the eventual penetration of toxic products to their interior, as well as atomised water. The wearing of wet macintosh garments is also advisable. The roping of workers who enter workplaces filled with poisonous gas should be absolutely compulsory.

The safety of workers requires that they should have sound knowledge of the use of refrigerating machines, of their working and repair work, and of how to act in case of breakdowns and accidents.

**Legislation**

Special measures for the transport of liquid and solidified gases, which should be kept in small stores and in small quantities, are laid down by the Prussian Ordinance of 2 August 1914. Similar Ordinances have been laid down in the other German States and in other countries.

It is desirable to mention that in Germany, subsection 23 of section 5 of the measures of protection laid down by the Trade Union of Malsters and Brewers makes it compulsory to provide for the workmen apparatus protective against toxic gases.

In Uruguay, the Decree of 27 January 1927, which regulates the conditions of work in the refrigerating industry, lays down the following provisions amongst others: the exclusion of persons under twenty years and over forty-five; half-yearly medical examination; the exclusion of persons who have been ill till they are in perfect health again; eight hours' work a day, with fifteen minutes' rest each hour or spells of three-quarters of an hour of work; the provision for workers of working clothes which assure good protection against cold; the air of refrigerating chambers must not be damp; means must be provided for ensuring dryness of the air; hot baths must be provided for the workers to be taken at the end of the day's work.

**Rice-Field Workers**

**Technical Data**

Rice (*Oryza sativa*) is an annual graminaceous plant cultivated on a large scale in southern and eastern Asia (China, Japan, Indo-China, India, etc.), in certain parts of Africa (Egypt, Madagascar, etc.), in North America (Georgia, Louisiana, Arkansas, etc.), in Central America, in certain regions of South America in southern Europe (Italy, Spain, etc.).

This cereal, which represents the fundamental foodstuff of about 600 million human beings, grows in submerged areas. It is usually cultivated in permanent rice fields, though in Italy and Java, for instance, it is a rotation crop. The permanent rice field is that in which the rice undergoes uninterrupted cultivation on the same spot, especially in marshy fields, which are flooded during the growing season, and drained before the next crop is planted.
regions or those subject to frequent inundation, but lacking sufficient drainage for dry cultivation. In rotation areas the cultivation of rice alternates in a periodic and more or less regular manner with other forms of dry cultivation.

The cultivation of rice begins in winter. After the usual ploughing and preparation of the ground, small dykes are constructed which serve to keep back the water and to divide the field into small plots more or less extensive in size, according to the inclination of the ground and the necessity for subdivision. Sowing, which may be effected by hand or machinery, takes place towards the end of March or the middle of April. The ground must then be covered with a layer of almost stagnant water 5 to 10 cm. in depth.

In order to facilitate the taking root of the plants, which must grow to about 8 cm., drainage has to be resorted to, sometimes repeatedly when the plantation is threatened by the presence of aquatic animals and vegetation. Such drainage also affects destruction of certain parasitic plants, though certain others develop in a manner which necessitates weeding of the field. In the cultivation of rice, weeding, on account of its mode of execution, represents the most unhealthy phase of the work and must be regarded as the operation which involves the greatest risk for the workers' health. Other phases of cultivation — such as the preparing of the ground, sowing, harvesting, beating, drying on a threshing floor in the sun or in driers — demand effort which differs but little from that common to all agricultural work. Eight days before the harvest the rice field is drained. Certain aquatic animals die in consequence, and the decomposition of these leads to putrescent emanations.

The weeding of the rice is effected when the plant has reached a certain height. It consists in pulling up all the weeds and leaving the cereal intact. This operation takes place two, or even three, times yearly, and occurs between the second half of May and the middle of June, thus occupying a space of time of about forty to fifty days. In view of the relatively limited time during which this work has to be accomplished, recourse is generally had to the employment of a very large number of workers coming from the neighbourhood, or even from distant parts of the country, who are lodged in overcrowded dormitories in farms (in Italian: cascinali), from which they leave in the morning for the rice fields. These workers are usually women, young persons or children of both sexes who are obliged to enter the water which, at the time in question, reaches a height of 20-25 cm. They work with bare feet in a very short coat and cap, in a single line and in serried ranks like soldiers. This operation involves a highly uncomfortable posture bent forward with lowered head, legs far apart, the longer leg advanced and supporting the left forearm, and with the trunk turned in such a way that the left shoulder is lowered. Occasionally the workers vary this attitude, working with the left hand and supporting the right forearm on the right leg or, again, by keeping the legs together and bending the back further. Constant attention is required in order to distinguish the weeds from the plant. The former are pulled out by hand and thrown with the other hand in heaps on the ground or on the borders of the rice field. At the beginning of the daily work of weeding the temperature is relatively cold, whilst towards the end of the day it is extremely hot, the water reaching a temperature of 18-36°C. The duration of work in several countries is eight hours, broken by a rest period of two and a half hours.

It is in consequence possible to record as characteristic disadvantages of the work the following conditions:

1. work with feet and hands submerged in stagnant or almost stagnant water of depth 20-25 cm. and at a temperature of 18-36°C.;
2. work in an uncomfortable position involving flexion of the body on the hips;
3. work in soft, muddy ground, putrefied by the decomposition of manure and uprooted weeds.

Preparation of rice involves three types of operation: preparation of the "paddy", husking and polishing.

Rice in the "paddy" separated from the ear by beating is placed in vats in contact with water at 33-47°C. According to the climate, for a period of about thirty hours. The water is drawn off and steam caused to pass through the rice for between ten and fifteen minutes. The rice is thereafter dried in a thin layer on flat threshing floors for about two days. Hot-air driers are sometimes used or, again, the rice may be set in motion mechanically.

Drying swells and detaches the husk, which adheres very firmly to the grain in fresh rice and hardens the latter. In this manner the peripheral layers, which are very rich in phosphoric acid and B vitamins, are not broken during husking and not easily detached in course of polishing.

Husking of rice is done either by hand by primitive methods or mechanically by means of perfected machinery. In the first instance the "paddy" is struck by heavy hammers or pestles of wood with iron hoops, in a hard, wooden or earthenware mortar, or by means of stamping mills which crush the "paddy", which is placed in a hollow depression formed of dry clay. These processes, which provide a mixture of husked rice, "paddy", and unhusked rice (later separated by winnowing), are inadequate for the treatment of large quantities of grain intended for export. Mechanical husking implies the following operations: previous passage of

---

RICE-FIELD WORKERS — 770 —
the "paddy" through a cleaning and separating machine, including ventilators and sifting screens; passage through a husking machine (composed of two concentric discs, one fixed and the other moving on a vertical axis) which detaches the exterior husk, which is then removed by winnowing in a second separator. The mixture of husked grains and others which are not husked then undergoes sorting in a third separator, which returns the unhusked grain to the husking machine, leaving the husked rice which constitutes the so-called "cargo rice." The latter then undergoes treatment which transforms it into polished rice.

Polishing is effected by machines arranged in cascade fashion, and consisting essentially of a solid cone turning at high speed around a vertical axis inside a fixed hollow cone of almost similar conical form. The grains pass between these two cones where they lose the seed and the progressively as the end of the weeding operations is approached. This increase was attributed by Ganora to diminished organic resistance as the work advances, which he found to be directly connected with the age (too young or too old) of the workers, the excessively long working hours, the lack of measures of protection (sleeping accommodation, feeding arrangements, etc.). In countries where measures are actually in force, the majority of occupational hazards which formerly menaced workers in the rice fields have greatly diminished.

Continual immersion of the feet and hands in water has in the end a very detrimental influence on the tegument. The water chiefly exerts an effect consisting in diminishing the fat in the tissues and consequently causing dryness of the skin. The epidermis is macerated and the capacity of resistance to small traumatisms caused by hard plants is therefore diminished. Wounds and rhagades ensue, often complicated by local inflammation (whitlows, phlegmons, circumscribed abscesses) caused by the aquatic flora rich in microbes. These infections find in the skin, deprived of its natural means of defence, a medium favourable to their development. There have in consequence occurred cases of septicemia and cases of tetanus.

At the commencement of the weeding period — the second fortnight in May — when the water in the rice fields is at rather a low temperature, there may be noted on the hands and feet of the workers vasomotor symptoms,

![Fig. 100. — Preparation of the rice-field (by means of the "Spianone").](image-url)
accompanied by a sensation of cold, heaviness and even paresthesia. The fingers become pale, the skin of the hands and fingers, especially of the thumb and first finger, becomes opaque and has a paralysed feeling. This sensation is followed after some hours by a sensation of heat and the parts affected become red and almost cyanotic. This syndrome, which in general recalls somewhat Raynaud's disease, is due to the effect of the cold water on the sensitive nerves of the skin. On the other hand, towards the end of the weeding period the work in very hot water finally renders the skin of the lower limbs — feet and legs — red and oedematous. There is maceration of the skin with painful rhagades, due largely to hyperaemia in consequence of lowering of the tone of the vascular system and of the tissues.

Formation of occupational callosities is of frequent occurrence. The women workers, who plunge their right hands into the water in order to seize and uproot the weeds, show on the cubital border of the hand wearing of the skin, which later not infrequently develops into erythema, intertrigo, broken skin and painful suppuration, which is relatively persistent. Later on, the epidermis becomes hypertrophied and gives rise to a true callosity, frequently developing fissures and rhagades.

Mantegazza (1909) has described under the name of "rice workers' dermatitis" the cutaneous affection which often suddenly attacks simultaneously whole shifts of workers at the very beginning of the season without distinction of age, constitution, sex, cutaneous resistance, etc. The affection is localized on the parts of the body in contact with the water and attacks particularly the ankles, toes and interdigital spaces, the lower third of the legs, and the hands.

In general, the leg most affected is that which is advanced in order to open a way between the stalks of rice and the weeds, whilst the other leg, which is behind on ground freed from weeds, often remains almost immune. The hand most affected is that which enters the water to uproot the weeds — the right hand in right-handed individuals and the left in left-handed, or both hands in the case of ambidextrous persons. The symptoms consist in intense irritation, sensation of heat and tension, more pronounced and disagreeable when the workers have left the water. At times the pain is so violent that it interferes with rest and sleep. The symptoms at first consist in erythema with large irregular patches which are slightly raised and oedematous. The local temperature is high; these patches are followed by the appearance of papulae about the size of a lentil or a pea with indefinite edges, a smooth, tense, shiny and elastic surface, and vivid red in colour. Occasionally the symptoms are arrested at this point or there may be a relapse. More frequently, small vesicles and phlyctenules the size of the head of a pin are formed which recall eczematous forms of dermatitis. The
content of these vesicules readily becomes turgid with formation of pus. The vesicules are always superficial, epidermic or sub-epidermic, and break easily, leaving erosions of variable size in accordance with the extent of the inflammatory process. In certain cases the more deeply seated parts of the skin are attacked by an inflammatory oedematosus infiltration.

In general, the lesion heals rapidly, more especially when it is arrested at the stage of erythema or papulae, and it does not progress when work in the rice fields is interrupted. In such cases improvement takes place twenty-four hours later. The subjective symp-

toms disappear after a short spell. The lesion sometimes leaves small scars and slight regularly disseminated pigmentation.

As regards the etiology of this disease form, which Mantegazza considers a true dermatitis and not an eczema, several hypotheses have been put forward. Leaving aside the hypothesis implicating the effect of excreta of ducks, geese or other animals suffering from certain epizootic affections or that of chemical manures and acidity of the ground, the attention of doctors has been directed to the possibility of the pathogenic action of certain plants. This hypothesis has been advanced in consequence of the observation that the parts affected are those in direct contact with the weeds. Various plants other than the rice plant have been said to be responsible, but Mantegazza is of the opinion that this form of dermatitis is due to the action of naiadaceae (Naia, minor and major), which are provided with leaves having their edges covered with conical needles, flat and adhering to the rest of the leaf, the free part of which terminates in a very fine point likely to prick the skin. To the mechanical action of these needles is added the effect of scratching by the victims and the further action of pathogenic germs living in the water. Wollbach and Todd have remarked the occurrence in Gambia, more frequently amongst women and children than amongst men, of chronic ulceration of the legs. The action of the water favours the outbreak on the unprotected skin of the legs of swellings and lesions resulting from small wounds which become very readily infected. Malaria would appear to find in the rice fields an important medium of diffusion. The irrigation waters offer favourable media to the development of the anopheles and the generative cycle is accomplished usually between thirty and sixty days, with the result that the period from May to September offers the possibility of the develop-

Fig. 192. — Attitude of a woman worker when weeding the field (according to Peracchi).
RICE-FIELD WORKERS

The frequent presence of these does not, however, always appear to correspond to a frequent incidence of cases of malaria, especially in those regions where improved sanitary and social conditions have been introduced (Giardina, Novelli, Alessandrini, Sampietro, Hermès, Kamp, Bentley, Kendrick, Nocht, etc.). Similar factors have also been observed in Argentina by Mazza and Rickard (1930).

In order that the anopheles should cause malaria, it has to become infected, that is to say, it must bite a person suffering from malaria and introduce into its blood sporozoites in the stage of gametes. The rice fields are submerged from the middle of April and, supposing that the female anopheles lays its eggs immediately after submersion, there would hardly be time for complete development of the insect during the weeding period, that is to say, towards the middle of May. At this moment a mosquito is in the larval stage or at most at the nymph stage; the insect reaches full development later when the workers have already quitted the rice fields and the anopheles thereafter rarely has an opportunity of becoming infected. Further, the operation of weeding disturbs the surface of the water which is apt to cause submersion of the majority of the nymphs and their destruction. The number of mosquitoes becomes considerable in July only and they can only be said to be abundant during the month of August, but the possibility of malarial infection by the anopheles is restricted since contact with man is rare.

It may be said in consequence that workers engaged in weeding are but rarely exposed to malaria (Preti). The same is true of the harvest workers, the harvest taking place between the second fortnight of September and the second fortnight of October, a time at which risk from contagion is not so great as might be supposed, more especially since the harvest work commences at an hour when the sun is already up and ceases before sunset. On this account, the possibility of mosquito bites is reduced in view of the nocturnal habits of these insects. It is further necessary to take into consideration that at this time of the year bad weather and cold nights considerably reduce the number of mosquitoes. Thus, malaria in the regions under rice cultivation can hardly be regarded as an occupational disease of the rice fields, but more accurately as a disease connected with habitation, the most important risk of contagion existing in the farms and stables which, in Italy especially, are the chosen spots for the development of mosquitoes. It is in these places that the majority of these mosquitoes bite their human victims, become infected and capable, in consequence, of transmitting infection. In regions where the farms are situated near or on the rice
fields, the development of the anopheles mosquito finds in the rice fields two essential conditions: a place of incubation (the rice field) and food (stables and habitations acting as the place of infection).

Chills also constitute an important cause of the injuries to health encountered: inflammation of the respiratory passages (rhinitis, bronchitis, pneumonia, etc.) or of the serous membranes (pleurisy, arthritis), of muscular or nervous affections (myositis, nephritides, etc.), the latter being connected with the vascular state of the skin.

In certain regions there have been noted manifestations of acute gastro-enteritis accompanied by lack of appetite, abdominal pain and diarrhoea, with high temperature, etc. These troubles are generally unimportant, sporadic, and possibly due to the absorption of impure water.

Other important affections are those relating to the working posture. Work in the rice fields does not demand excessive muscular effort. Of relatively short duration (forty to fifty days), it is eminently seasonal work. Nevertheless, it may, especially during the first days of work, give rise to fairly important symptoms of fatigue, particularly since at this moment the system has not had time to become adapted to the work. This fatigue often manifests itself in the outbreak of acute symptoms resembling those which precede an infectious disease, the worker suddenly becomes the victim of slight or violent shivering, the temperature rises to from 35° to 45° C. and remains at that figure for one or several days, falling thereafter with abundant sweating and without any further complications. During the period of fever, there is pain in the lumbar region and in the limbs, accompanied by headache and intense thirst. This state of fatigue seems to be due to the fact that the work causes repeated contraction of the same group of muscles (Preti). Though protected from the sun by wide-brimmed straw hats, the women workers work in a bent position and are sometimes attacked by sunstroke (before thunderstorms) under the action of the summer sun, augmented by reflection from the water.

The working posture which the woman worker is obliged to maintain may, according to certain authorities, cause deviation of the vertical column (cyphosis, lordosis) and pelvic deformity, especially in the case of young persons. This latter condition Preti has, however, not observed. It is probable that the limited duration of the work and the daily rest period attenuate to a large extent the effect which such an anti-physiological attitude might have on the bone structure.

The bent position, submersion of the feet in water, may give rise to complications in regard to menstruation, rendering it painful and abundant. Further, it has been noted that during pregnancy, troubles manifested by violent contraction of the uterine muscle fibre and by premature haemorrhages, and finally by miscarriage or premature or sudden delivery, occur. The contraction exercised during hours of work on the abdominal organs may involve alterations of the said organs and of the blood vessels, which finally lead to gastro-intestinal atony, dysuria and pre-malleolar oedema.

Lesions of the cornea, resulting from wounds due to the point of the spikelets on the rice during the harvest season have been reported by Gherardi (1921). In 10 per cent. of the cases, there was loss of sight, in 43 per cent. a more or less important diminution of sight. Forms of blepharitis and conjunctivitis due to exposure to the sun are frequent (reflection from the water).

No special data are available relative to the pathology of workers in the rice fields in China, Japan or Indo-China. In regard to those of Brazil, it is merely known that a considerable number of fatal cases due to serpent (asp) bites have been reported.

In regard to the pathology of workers engaged in the handling of rice, Bron, as early as 1860, has described cases of erythema of the face amongst workers engaged in unloading sacks of rice. This dermatitis was attributed to the action of a parasite in the rice. A similar epidemic was reported as having occurred at Le Havre in 1919, by Loir and Legagneur.

In 1921, Hodara investigated in Constantinople an epidemic characterised by an eruption with violent shivering, which broke out amongst dockers. The disease had an incubation period of one to two days, a duration of three to seven days, and even fifteen days. The cutaneous symptoms were localised on the face, hands, neck, forearms and back (shoulders).

Michelson, who also studied this affection (1921), speaks of two types of irritation: anaphylactic syndrome due to dust inhalation and mechanical action on the skin. Others are inclined to attribute it to parasites, and in particular to the "pediculoides vermiculosis".

Alderson and Rawlins (1925), under the designation "rice poisoning", have described a form of dermatitis which
they met with in California: erythema, with purulent folliculitis, and diffuse eczema, with secondary infection and irritation. These cutaneous troubles were localized on the hands, on the flexed side of the wrist, on the neck and on the chest. Etiology was very hard to establish. The authors admitted the presence of special susceptibility to the proteins of rice, for they did not meet with cases of dermatitis in the "polishing" department of the factory, but merely amongst those workers who handled the rice prior to cleaning ("paddy"). It is true that the authors did not effect cutaneous tests, but they likewise did not discover the presence of parasites in the rice. There occurred to them the possibility of attributing the symptoms to the action of the silica present in the "paddy". On the other hand, it must be admitted that such affections are, at least in part, due to such factors as a distinctly detrimental absence of cleanliness on the part of the workers and to the presence of traces of manure amongst the rice.

In the case reported by Van Geldern, the impetigo met with was accompanied by asthma (anaphylactic!).

A case of acariasis due to rice was reported in Italy (1927) by Ferrero. The disease was characterised at the outset by an erythematous-papular eruption, and eventually by the formation of vesicles and pustules. The patient suffered at the same time from attacks of coryza and very serious loss of weight. A parasitological examination of the plants has revealed the presence of numerous acari of the Pediculoides ventricosus family.

The rice dust exercises an action similar to that of other cereals (corn, wheat, etc.); it irritates the mucous membranes and especially the conjunctival mucous.

In factories in which rice is handled, there is also a possibility of explosions followed by outbreak of fire due to rice dust (see article "Dusts").

Hygiene

As regards the technique of work on the rice fields, there has for some time back been adopted a new system involving the transplanting of the rice. The rice is sown in a plot of ground in closely planted rows, and when the plants have attained a certain height the workers uproot them and transport them to the rice fields. This system does away with weeding, but the operations which replace it involve the same disadvantages as those encountered in weeding. The one advantage consists perhaps in the fact that it enables the submersion of the rice fields to occur one month earlier, which from the point of view of the development of the anopheles mosquito is of no great importance, since the production of mosquitoes does not occur during the first months of work on the rice fields.

Mechanical weeding is becoming extensively applied, but it does not eliminate entirely weeding by hand, though it reduces it to a great extent. Besides, from the hygienic and technical points of view represents a real progress.

In order to reduce the number of anopheles mosquitoes, the breeding of fish which are natural enemies to the larvae and nymphs of the mosquitoes, has been applied on the rice fields. The kinds of fish which give the best results are voracious varieties, such as carp. An indirect result of this method is that of obtaining, towards the end of the season of the rice fields, an excellent food product. The field anopheles mosquito is insensitive up to the moment at which it becomes infected. Such infection is, as has been seen, very rare on the rice fields. On the other hand, the most dangerous mosquitoes are those which surround the workers in their habitations. It is possible to exclude the penetration of the anopheles mosquito by the adoption of simple mosquito netting. Taking into consideration the short distances which the anopheles varieties fly, legislative provision has been adopted in Italy tending to impose on the provincial councils a fixed minimum distance between the temporary habitations of the workers and the rice fields.

With regard to measures for the protection of workers, it is necessary to take into consideration especially the living conditions and the type of work employed, the labour being supplied, as has been seen, by large drafts of immigrants. It is possible, under these circumstances, to understand the importance to be attached to the temporary habitations constructed for these workers; cabins for meals and quarters for the night; installation and maintenance of habitations and dormitories in accordance with the principles of hygiene; segregation of the sexes; requisite cubic air-space; ventilation; provision of drinking water; good feeding arrangements; medical supervision; prevention of malaria; detection of malaria cases constituting a danger on account of the dissemination of malaria, as well as detection of other social scourges; syphilis, open tuberculosis, contagious skin diseases, etc.; vaccination against smallpox, etc.; reduction of working hours, which
should be interrupted by adequate rest periods, etc. The work should not commence until after the sun has risen and should be stopped a few hours before sunset, with a view to preventing mosquito bites.

For the prevention of dermatitis, the wearing of simply made cloth leggings is to be recommended. It is also advisable to apply to the skin a protective oil or some greasy substance. Deformation of the bone structure due to bad posture should be prevented by excluding from work on the rice fields young persons, and particularly those under fourteen years of age.

Pregnant women should be excluded from work from the seventh month until fourteen days after birth. It must be admitted that in almost every case pregnant women refrain from engaging in work of this kind in the more civilised countries.

**Legislation**

Very detailed legislation relative to work in the rice fields exists in Italy. General regulations for the application of legal measures relative to the cultivation of rice (Part IV, Consolidated Text, Health Laws of 1 August 1907, No. 636); instructions for ensuring the provision of drinking water to workers engaged in the rice fields (Royal Decree of 29 March 1908, No. 157). There must likewise be taken into account measures concerning housing, provision of drinking water, prophylaxis in regard to disease, dormitories, etc., in Part III of the Regulation on industrial hygiene (14 April 1927), which deals with hygiene in agricultural undertakings. The most important points covered by Italian law are the following:

1. Determination of minimal distances between the rice fields and the workers' homes; running off and discharging of water from the rice fields;
2. Obligation on the part of the employers to provide adequate and free medical and pharmaceutical treatment;
3. Obligation to furnish immigrants with dormitories and hygienic housing, well aired and ventilated and with provision for segregation of the sexes;
4. Obligation to provide on each farm a room, the apertures of which are provided with mosquito nets, to accommodate workers suffering from malaria;
5. Exclusion from the work of children under fourteen, and pregnant women in the last month preceding birth and for a period of thirty days after birth;
6. Prohibition against commencement of work on the rice fields prior to sunrise, etc.

In Spain, the Royal Decree of 27 January 1924 lays down certain rules calculated to prevent malaria caused by work on the rice fields in the valley of Bas-Llobregat.

Data relative to health and sanitation laws in other countries engaged in the production of rice are not available.

For compensation of occupational injuries amongst rice workers, see articles "Occupational Diseases: Definition and Compensation" and "Malaria".

**Röntgen Ray Operators**

(Occupational Pathology of)

**Sources of Risk**

The use of X-rays for diagnosis and therapy, the manufacture of the necessary tubes and bulbs for X-rays, and electrical apparatus expose the operator, his assistants, and any workman employed in this industry to a series of physical and chemical agents which may act injuriously on the system. The dangers can be summarised as follows: direct biological action of the Röntgen rays on the organs and human tissues from prolonged and repeated exposure; effect of the toxic
gases developed in the places where the high tension currents are produced and the X-ray tubes are employed; and finally lesions from the electric currents in individuals imprudently coming into contact with the generators or connecting wire of low or high tension.

Radiologists, therefore, are brought continually under the influence of the X-rays, especially when making radiographs which oblige them to approach the sources and particularly to expose their hands (when manipulating the stand diaphragms, touching the patient and turning him towards the screen) and their face (which is brought near to the fluorescent screen for careful study of the slight images thrown on to it).

The medical man and his assistants employed in the room are further exposed to the action of X-rays during radiography, and especially during the long treatments by radiotherapy requiring constant supervision of the apparatus and the patient.

The workman making the X-ray tubes is exposed to the action of the rays when creating the vacuum which is, at the same time, subjected to currents of high tension a highly delicate and rather long process during which the workman must unceasingly watch the tube and manipulate the vacuum pumps.

Röntgen rays are known to be electromagnetic vibrations of ether of very short wave length and consequently of high frequency — vibrations which are transmitted in a straight line from their source (represented by the anti-cathode of the tube or bulb) with a speed of 300,000 km. a second.

As it is a question of the central projection of divergent rays, X-rays obey the law of dispersion on a given surface decreasing with the square of the distance.

Röntgen rays have greater intensity the greater the reproductive activity, the longer the cariokynetic process has lasted, and the less the morphology and functions of the cells differ.

Whatever is the truth, there is no doubt that when X-rays are absorbed by human tissues they exercise an action which differs according to the type of the cellular elements attacked.

In other words, normal and pathological tissues have differing degrees of radio-sensitivity and there is a law which summarises admirably this differing sensiveness of the tissues. This law, laid down by Bergonie and Tru-baudet as soon as radiology came into existence, is still in accordance with the facts despite the quantity of new facts and observations made since it was enounced and sometimes even appearing to contradict it. It is as follows:

X-rays have greater intensity the greater the reproductive activity, the longer the cariokynetic process has lasted, and the less the morphology and functions of the cells differ.

In other words, the mammary gland, for example, is very much more sensitive to the rays during pregnancy than during functional repose, and the first spermatogenetic cells are more
sensitive than the spermatozoids, while differentiated unicellular organisms can be regarded as almost completely indifferent to X-rays.

According to the law of Bergonie and Tribaudieu, it can, therefore, be said that for normal tissues a scale of radio-sensitivity exists following the affecting organs and tissues in descending order: lymphatics, testicles, ovaries, skin, mucous membranes, renal and hepatic tissue, blood vessels, connective tissue, muscular, nervous, cartilagenous, and lastly, osseous tissues.

Therefore, though it be admitted that every cellular element in human tissue is susceptible to the injurious action of X-rays, it must also be admitted that, from the practical point of view, the changes most easily and readily seen in persons subjected to the prolonged effect of X-rays are those in the skin, the sexual glands and the blood-forming organs.

Gases are given off into the air when the current is passing through the tubes. These gases finally so impregnate the atmosphere as to give it a characteristic smell and produce irritation of the throat. They are nitrous fumes and ozone. Nitrous fumes are given off mostly at the points where the revolving commutators act or the current is excited by sparking. On the other hand, a high tension connection or a tube giving out X-rays produces ozone.

The injurious effect of these gases is so far only imperfectly known. They set up an irritating dry cough and cause a prickling sensation in the throat. Probably they have a slight toxic action causing frequent headache in those working in an atmosphere saturated by these gases.

Lastly, reference must be made to the dangers to which the radiologist and his assistants are exposed from the currents of high or low tension. They may cause painful muscular twitchings varying from a passing paralytic arrest of the heart's action, and thus death from electrocution.

The danger lies in the intensity of the current traversing the human body where it makes a short circuit between the wire and the earth. This danger bears relation to the voltage, the resistance of the body and the points of contact. If the person has on leather shoes and has dry hands, resistance may be very high (50,000 ohms) and contact with the electric wires involves no danger. But if the hands and the feet are wet, and the body temperature is high, well, etc., resistance may be down to a few hundred ohms, and death ensue with currents of 90-100 volts.

The fortunately low intensity of the current used in medical radiology with high potential explains why in general the consequences are not serious.

**Pathology**

Röntgen's discovery in 1895 was followed all too rapidly by quite a series of injuries from six to twenty-four months later among the personnel using X-rays.

The first to draw attention to the danger was the engineer O. Leppin in 1886, followed two weeks later by W. Markuse.

The lesions set up multiplied so rapidly that in 1907 Dean, of London, in his statistics of occupational dermatitis caused by X-rays, cited 30 cases which had occurred in Great Britain. According to Krause, up to 1911, 26 cases of carcinoma had been recognised as due to X-rays among members of the medical staff and among these of the technical staff manipulating the apparatus, and 4 among patients treated. Hesse, at the same date, cited 94 cases of carcinoma, and to-day the number of victims unfortunately amounts to hundreds, several of whom, practitioners of high eminence, have watched their malady, accompanied by intense suffering, advance to a fatal conclusion.

The cutaneous lesions of radiologists excited by X-rays rarely take on acute form, even after an exposure of short duration but strong intensity. On the other hand, a dystrophic radio-dermatitis develops which begins insidiously and goes on slowly, but with advance to a fatal conclusion. This dermatitis is provoked by the action continuously repeated during years of quite small doses of radiations. Generally, the cutaneous lesions are localised on the hands (especially the left hand), the face and the chest. The hands and fingers are most often attacked on their dorsal aspect. The thumb nearly always escapes. It is not uncommon for the lesion to be situated on the wrist or forearm when the person has been accustomed to work with bare arms. For purposes of description may be chosen chronic radio-dermatitis of the hands.

The first precursors of radio-dermatitis are circulatory in nature. The fingers become reddish violet, with a sensation of fullness and often of dryness; next, the skin, especially on the back of the fingers, becomes thickened and loses its elasciity. Sometimes the hair falls off and more frequently breaks.
From the first the nails assume a special appearance. Longitudinal striae appear; they often become fragile and break, falling off in pieces or as a whole, while the edges become hypertrophied and crack. Sometimes the nails atrophy to such an extent as to disappear. As time goes on, the skin changes always become more marked as the sebaceous and sweat glands atrophy and telangiectatic and hyperkeratotic areas especially appear. Often ulceration first appears when the horny patches become detached and it progresses without granulations and without any inclination to cicatrisation. The constantly increasing atrophy of the skin causes the fingers to become thin in characteristic fashion, and finishes by bringing about ankylosis.

But the worst sign is that of cancerous degeneration, which attacks the cutaneous ulcers by preference: the edges become infiltrated and thickened, while the bottom discharges, bleeds readily and becomes covered with crusts.

This form, after years of very slow development, takes on a different appearance determined by the occurrence of metastases affecting the adjacent glands and the spread of the cancerous process to the internal organs.

Such is the course that has been observed in dozens of radiologists and led, at first to progressive mutilation, and later, often enough to the death of many pioneers of radiology.

According to Hesse, tumours caused by X-rays are much more malignant than are ordinary tumours of the skin. Hesse gives a mortality rate for these cancers of 20 per cent., Goeneri (1909) of 24 per cent. among 33 cases recorded in medical literature; Porter (1907) and White describe 6 fatal cases even after surgical intervention; Porter in 1909 collected 36 cases of carcinoma, of which 34 were occupational.

Cole, as the result of an enquiry (in 1924) into cases of occupational radio-dermatitis, shows the number to be very high. From histological study of a certain number of cases, he concludes that sclerosis of the nutrient vessels of the skin is the true basis of the radiodermatitis; disappearance of the glandular elements of the chorion (the chorion being thickened by a hyaline degeneration), and the appearance of new vessels (telangiectasies) in the chorion. At first the epidermis is little altered; slowly there is noted an epithelial proliferation with epithelial projections passing downwards.

In 1917, a French radiologist noticed the appearance on the thumbs, index and middle fingers of both his hands of crusts looking like papillomata. For two or three years, by redoubling precautions, the lesions remained free from pain although tending to increase in

![Fig. 104. — Occupational dermatitis due to X-rays.](image)
size. The radiologist himself treated most of the lesions except one, which developed an epitheliomatous ulceration discharging and spreading. He then destroyed it by diathermy and in two months secured complete cicatrisation and a cure which lasted for several years. Some time afterwards, another radiologist who observed blackish crusts on his two hands, principally on the fingers, noticed that, even when keeping away from every source of X-rays, the state of his hands got rather worse and that an epithelioma developed on the right side of the lower lip. Application of diathermy to these epitheliomata (due to Röntgen rays) was followed by healing without recurrence in the four following years.

At the present time, certain fatalities with leucaemic symptoms seem to have occurred more frequently among radiologists than would have been expected on the average — so much so indeed and under such conditions as to suggest an etio-pathogenic relationship between the continuous action of X-rays and the maladies in question (see the article "Radium").

The action of X-rays on the red blood cells is not very marked; certain writers have observed transitory diminution accompanied by granular degeneration and polychromatophilia (especially after a long exposure). Blondi showed (1908) that X-rays affect the red blood cell formation in such a way as to produce the picture of aplastic anaemia. This fact has been confirmed by Cesaris Demel. The specific weight of the blood is increased as well as its coagulability; the globular resistance, on the other hand, is diminished.

It is on the leucocytes and the haematopoietic organs that X-rays exert their baleful action...

After a brief period of leucocytosis,
characterised by an increase of the neutrophil polymorphonuclears, a leucopenia ensues as a result of diminution in activity and the leucopoietic function. In strong doses X-rays cause a destruction of the haemopoietic organs, and on the other hand, in small doses a leucocytosis.

The leucopenia affects especially the lymphocytes (Linser and Heller). In radiologists the polymorphonuclear leucocytes are affected (Jagié, Schwarz, etc.), and in certain cases the acidophil leucocytes. Aubertin, on the other hand, has shown an increase of the neutrophils and eosinophils. Politzer has described swelling of the nucleus, and more especially of the chromatic granulations in the polymorphonuclear neutrophils analogous to those of phosphorism.

Aubertin, who examined the blood of sixteen radiologists who had worked for six to eleven years without trouble of any kind, described in 6 cases, mononucleosis from diminution of the polymorphonuclear neutrophils without hypoeosinophilia (but on the contrary an increase of eosinophils) and a total diminution in the number of leucocytes (4,000). In 10 cases slight polynucleosis with eosinophilia existed.

The leucopenia is intense (Jagié, Schwartz, etc.); it is said to be even proportional to the intensity of the exposure.

The lymphatic follicles of the spleen, thymus, intestine and, in general, all the lymphoid tissue of the organism become atrophied in a few days. The destruction of the cells of the lymphatic system takes place without a latent period and rapidly in a selective way. The alterations in the splenic pulp and bone marrow take place on the contrary when a cutaneous reaction has already appeared (Heineke). The polymorphonuclear neutrophils are the elements in the white corpuscles which resist the longest.

The anti-leucocytic action of the X-rays may be primary or secondary; it is said to be due to the formation of leucocytotoxic and leukolytic substances (Röntgenian toxin) on which depend the primary leucocytosis and the secondary leucopenia. The existence, however, of this toxin is very doubtful and is even denied by some authorities.

At an advanced stage a lymphoid or myeloid leukaemia has been described in the radiologists (in Vienna, Munich and America) thus affected, with characteristic modifications in the blood count (leucocytes reduced to 5,300 and 6,000; notable diminution of the polymorphonuclears and especially of the acidophilis, which were completely destroyed; increase in the lymphocytes; the number of the red blood cells remains normal).

Vaquéz (1911) records the case of a radiologist who died from myeloid leukaemia; Taber (1924) the case of the radiologist Mordenhoff who died in 1922 from aplastic anaemia.

Besides this type of leucopenia with lymphocytosis, Aubertin has described a second type among professional radiologists with neutrophil and eosinophil leucocytes.

According to Gavazzeni, the radiologists are said further to run the risk of an aplastic anaemia with fatal results. This form, due to X-rays as well as to radium and thorium, is the result of progressive destruction of the blood-forming centres after a long exposure (Aubertin and Bordet).

The disease affecting the bone marrow is also the cause of purpura. The giant cells are affected and the formation of blood plates is checked. To a lesion which at first is partial, there follows a complete lesion of the bone marrow.

Lesions analogous to those set up by X-rays are produced by radium (see article "Radium").

In 1921, Pfahler proposed at the meeting of the Philadelphia Röntgen Society that radiologists should make a study of their blood, and asked for the co-operation in this matter of all those in America. The following conclusion could be drawn as the result of his examinations:

Blood pressure is generally rather low in radiologists but is not accompanied by definite symptoms.

Complete examination of the blood of 142 persons employed in the X-ray laboratories of the medical bureau of veterans in the United States had not shown any noticeable modification of the morphology of the cellular elements in the blood, nor even an appreciable modification in their number except very exceptionally in a few isolated cases (Matz, 1925).

Weindrach, of Odessa (1926), from an examination of the blood of 21 persons employed in X-ray laboratories, stated that, in cases where harm had been caused, eosinophilia is a common phenomenon connected perhaps with changes going on in the spleen; that there was a diminution in the number of the red cells and a corresponding fall in the haemoglobin.
During these last years the researches of experts have multiplied with the object of making clear the alterations in the blood which could be regarded as the expression of an occupational pathology of the haematopoietic organs of radiologists. But the results are unfortunately too divergent to be able at the present moment to draw conclusions. The results of the enquiries by Bertoletti, of Turin, on the state of the blood of Italian radiologists may be cited.

Apart from a common anisocytosis and a slight hypochromemia a frequent drop in the number of blood cells and in the number of red blood cells has been observed. On the other hand, among several old radiologists there is an obvious tendency to excessive production of cell elements.

The principal characteristics in the white blood cells are, in the great majority of cases, a dominant leucopenia which shows itself rapidly in the first years of exposure and increases with time. This leucopenia is essentially set up by a diminution of neutrophil leucocytes, while the basophil tend to disappear: the picture of the acidophils is, on the contrary, very variable. There is a general tendency to increase of the lymphocytes, often the passage from a relative to an absolute lymphocytosis, especially among some old workers. A real increase of the mononuclears takes place. The leucopenia associated with the absolute lymphocytosis can almost produce an inversion of the leucocytic count.

The changes in the histo-chemical picture of the blood of radiologists comprise two fundamental phases.

In the first, the rays do not damage the haematopoietic centres, but only the circulation. In the second, a real lesion may take place marked by the appearance of certain primordial pro-lymphocytic and monocytic forms. Further, attention should be drawn to the fact that radiologists who manipulate radioactive substances show a very definite tendency to impoverishment of the blood with marked diminutions in the number of the red blood cells. Caffaratti (1922) from an examination of the blood of 50 Italian radiologists detected anisocytosis and an advanced and persistent form of leucopenia, with retrogression after exposure to the rays had ceased.

Of the effect of X-rays on the sexual glands, it can be said that, although undeniable, its importance has perhaps been exaggerated from the practical point of view. As a matter of fact, the women who work in X-ray rooms only exceptionally show any interference with their periods or sterility, and as for the men frequently to X-rays (doctors, attendants, workmen), their potential coendui always remains unaffected, and it is rare to find azoospermia with sterility. The enquiry made by Bertoletti on this point brings out the fact that many Italian radiologists, after a long and tiring career, have numerous and quite robust children. Naujoks (Berlin) has also made a study of the fertility of radiologists' assistants, and in an enquiry covering 91 women 12 were said to be sterile as a result of X-ray work, while 9 out of a total of 125 children were reported as suffering from derangements of development and nervous troubles more or less imputable to the action of X-rays.

Finally, a general kind of malaise is found which is characterised in an early stage by nausea, vertigo, dyspnoea, tachy or bradycardia, etc. The sensitised organism reacts, even to small doses by typical anaphylactic shock (bradycardia, leucopenia, inversion of the leucocytic formula) or by an inversion of the form (hyperleucocytosis, lymphopenia, tachycardia).

The asthenia at times observed can sometimes be attributed to fatigue and perhaps also to remaining long in a badly ventilated room and to insufficient rest.

These modifications, as well as those of the skin, cannot be said to be on the increase, and were observed chiefly amongst the early specialists who had not proper means of protection or among those who did not use them in a proper way.

**Hygiene**

Knowledge of the dangers caused by X-rays and of the conditions favouring their injurious action suggests a whole series of measures of protection which, if scrupulously observed, possess real efficacy in safeguarding the health of radiologists.

From the technical point of view, the introduction of the anti-cathode — so characteristic at the surface of oblique rays — made by Röntgen himself, represents, apart from tubes made for special purposes, the only improvement in the construction of X-ray tubes. Coolidge introduced the incandescent cathode as a source of electrons in place of the hollow cathode, and gave to the new tube the form in which it is now known.

But among the defects and inconveniences of these types, there are certainly some that are sufficiently
serious, namely, the X-rays appear not only where they are wanted, but in every direction. This fact has been proved by its malign consequences on the health and life of radiologists.

Progress in technique has however succeeded in creating a type of self-protecting X-ray tube of a simple and strong form, which sends the rays forward in a single direction. The axis of the cylinder, and in this way assures, among other technical advantages, the radical protection of the operator.

The first fundamental principle concerns the tube, which should never function unless enclosed in a protective apparatus which is impermeable to the rays: that is why, whether for radioscopy, orthoscopy or trocoscopy, the tube must be contained in a box with walls covered with anti-X-ray conducting material, the opacity of which to the rays is equal to 2 mm. of lead, or 3 mm. of glass. The lead lining of the walls of the radiographic cabinet where the switches and manipulating handles are, and where the operator is absolutely obliged to put the tube in action, must be at least 2 mm. of lead, and should be provided with protected handles; even the manipulation of the diaphragm and of the movable box should be made by means of handles similarly covered with lead.

Further, the radiologist should never proceed to make a radiological examination without being provided with anti-X-ray conducting gloves, closing hermetically, and sufficiently long to cover a good part of the forearm. The gloves should be constructed of anti-X-ray conducting material, even on the palmar aspect, although flexibility will be diminished thereby. The hands should always be protected, especially on the dorsal aspect, by a protecting layer, the opacity of which should not be less than the equivalent of \( \frac{1}{2} \) mm. of lead. The use of aprons and goggles of anti-X-ray material should be the rule, and similarly for a long observation, use of movable opaque screens either at the side or below can create even greater protection by limiting the field of observation in a frame impenetrable to X-rays.

Though so many precautions may seem to be excessive, they are not really so for protection against such an insidious and inexorable enemy. On the other hand, all this protective apparatus can be so ingeniously arrayed as not to incommode in the slightest the practical work of examination. The radioscopic examination, however, should be as rapid as a careful observation will allow. When it is necessary not to carry the patient, for example, to examine the abdomen, to displace certain organs, to test sensitivity to pain, the bare hand should never alone be used, but in order to avoid the superposition of another shadow, the hand is replaced by Holzknecht's "distriminator" which is only a kind of wooden spoon with a handle, the convex part of which, applied over the abdomen carefully, will take the place of manual palpation.

When the radiologist has to give demonstrations to other colleagues or students unfamiliar with radioscopic work, he should never carry out while the tube is working, but describe the object that he wishes to show first without the current and then illuminate the screen for a few moments and only resume the demonstration when the current has again been broken.

For the work in the darkroom which supports the tube must always be in the form of a cup or box of anti-X-ray material of an opacity corresponding to 2 mm. of lead. The radiographic couch should always be a little distance away from the protected cabinet where the switches and manipulating handles are, and where the operator is absolutely obliged to go to put the tube in action. This should be in such a position that the anti-cathode can be turned to the side away from that of the cabinet. The thickness of the lead lining the walls of the radiographic cabinet should not be less than 2 mm.

If the cabinets are constructed of material other than lead, their uniformity should be periodically controlled to avoid cracks or more transparent zones which in the long run might represent some risk. Such control, easily effected with the fluorescent screen while the tube is working, might very well be extended to the whole of the protective material.

The Röntgen ray room is the place where the need for protection is greatest, especially when it is a question of deep therapy with apparatus of high potential kept in action for several hours, and producing radiations of very great frequency, and consequently particularly penetrating.

In this case, the operator working the apparatus should be in a room dif-
ferent from that in which the patient is. Naturally reliance should not be put on the dividing wall, especially if it is a question of a slight partition wall. On the other hand, a wall of a certain thickness does represent a very good means of protection. The wall separating the manipulating cabinet from the treatment room should be covered with a layer of lead of at least 3 mm. thickness. The tube, further, should be in a protecting envelope, the opacity of which should be equal to 3 mm. of lead.

According to Pfahler, complete protection against the rays is never entirely obtained; more and more elaborate protection is necessary for specialists using radium or X-rays of high voltage. A film carried in the pocket for two weeks will give a good indication whether or not there has been excessive exposure to the rays. If the film is clouded protection is insufficient.

If the hours of exposure to the rays are lessened, and ventilation and rest increased, the symptoms which have been described may be attenuated, and future troubles avoided.

In 1923, a substance made of rubber, industrial to X-rays, was placed on the market, the process of manufacture being kept secret. This substance resists a difference of potential of 2,500 volts and a thickness of 3 mm. is equivalent to 1 mm. of lead; with 5.3 mm. it equals 1.7 mm. lead.

A study of the strength of the rays emitted by the Coolidge tube across the different methods of protection thought out for eliminating any harmful effects, has led to the conclusion that the rays pass through all the defences (metal casing, leaden cabinet, brick wall treated with barytes, brick walls lined with sheet lead, etc.) but in each very infinitesimal quantity that, under ordinary conditions where the operator and persons living on the other side of the wall may be, no damage to the skin or viscera is likely to be feared.

All these precautions naturally should be taken in factories required for making Röntgen ray tubes while the vacuum is being created, so that the workman employed on the pumps is kept away from the tube in action in the furnace by the wall of this and by anti-X-ray conducting glass of an opacity equal to 3 mm. of lead. A thickness of 4 mm. at least should separate the tube from the workman when testing apparatus for generating current of high tension, especially in the case of transformers for deep therapy, where the test has to be carried on for several hours at a tension of about 200,000 volts.

But, as has already been said, it is not only the X-rays which threaten the radiologists in the line of their work; it is also the gases given off into the surrounding air when currents of high potential are produced or directed and where the Röntgen tubes are excited.

How should protection against the injurious gases be secured?

In the first place, precautions should be taken to reduce their production to a minimum, and secondly to eliminate them as rapidly as possible. Apparatus without commutators and revolving switches always produce much less injurious gas than those the action of which is bound up with the continual jumping of the spark between the revolving mill and the sectors.

This is why in apparatus for diagnostic purposes as well as of apparatus for deep therapy, mechanical commutators are eliminated as much as possible and replaced by thermo-ionic valves, as, for example, the excellent apparatus with condensers.

In any case it is advisable that the apparatus generating the current of high tension should be enclosed in a special place from which only lines at high tension can come along channels which isolate them. It is important that in the room for treatment the line should be as short as possible and enclosed in an aluminium or brass tube of sufficient size and having the ends terminating in bulbs so as to avoid escapes as much as possible. In the same way, the spinterometer, when it is not working, should be kept as far as possible from the sparking point; it should be in the form of a sphere rather than pointed.

All these precautions, even when adopted will not entirely prevent the production of toxic gases. It is, therefore, useful to have large rooms, well ventilated and provided with fans which constantly renew the air. As it is a question of heavy gases, suction should be applied low down. In winter heating by stoves rather than by radiators should be practised because the former method allows of renewal of the vitiated air.

The precautions which all members of the staff should take to avoid electrical discharges, or, at any rate, to minimise the consequences dangerous, are as follows:

To have flooring that is a bad conductor: waxed wood, linoleum, cork, rubber. Floors of earthenware tiles or concrete are dangerous, especially when they are wet.
The line of high tension current should be at a height of 3 metres from the ground at least; suspended wires should be avoided. The aerial network should be firmly fixed, tested from time to time, and fixed in such a way that if the wires break they will automatically be drawn up towards the ceiling.

All the metal parts of the generator at high tension-stands, tube holders, orthoscope, and trocoscope ought to be electrically earthed (preferably by connecting up with piping for drinking water).

The installation of the current at low tension should be furnished with fusible valves and apparatus of high tension with automatic safety circuit breakers ready to act in the unfortunate event of a short circuit, as, for example, by a high tension wire earthing itself through the human body.

The operator manipulating high tension wires when naturally no current is passing through them ought in any case only to touch one at a time; he ought never to have the two poles in his two hands at the same time. If, unfortunately the circuit is closed and a high tension current is passing along the wire, the danger to the operator is much less if he is only touching one simple wire than if the high tension circuit is formed across his body by contact with the two poles.

The personnel should be instructed as to the risks of electrocution and on the importance of practising artificial respiration for a long time; exclusion of persons suffering from skin diseases, or the sequelae of syphilitic infection, diabetes or disorders of endocrine origin, etc., should be enforced.

The Committee of Hygiene of the Netherlands has proposed (1926) draft regulations to protect technicians and others in the vicinity from the action of X-rays.

The project provides for State permits for the installation of X-ray laboratories, a diploma as a specialist, etc. The report analyses the different methods of proposed protection.

A series of resolutions of international importance was voted at the Congress of Radiologists of the Soviet Federation held in Moscow in 1924:

*The medical man in the cabinet for diagnosis by Röntgen rays should be protected, in addition to an apron, goggles and gloves, by a wall lined with lead plates of a thickness of 3 mm. In cabinets for treatment by X-rays employing apparatus up to 150 kilovolts, a cabinet for the protection of the personnel is indispensables. Apparatus of more than 150 kilovolts should be divided up into three portions — one for the generator, another for the patient and a third for the personnel. Radiologists should have a four-hour day and limit themselves to five days a week. The persons employed should have two months' holiday annually and should undergo periodic examination to determine their state of health."

**Legislation**

There are at present no legislative enactments as to measures of protection for radiologists against the dangerous consequences of the rays. But professional societies in the different countries have taken up the question of obtaining insurance against damage caused by X-rays. Notification of cancerous dermatitis and other lesions of the skin from X-rays is obligatory in the Netherlands and in Poland and compensation is granted in Austria, Belgium, Czechoslovakia, Finland, France, Germany, Great Britain, Mexico, New York State, Sweden and the U.S.S.R.

**Prof. F. Perussia**

(Milan.)
The raw materials used in the manufacture of rope are ordinary hemp, Manila hemp, Indian hemp, phormium, jute, coconut fibre, esparto grass, etc. For certain special work, rope made from straw is used. (For metal rope see article "Metallization").

The raw material for rope-making arrives at the factory in bales which, on opening and shaking, emit quantities of dust. Ropemaking may be said to be at the present time a mechanical industry, hand work being very rare. It suffices to mention that hand work comprises the spinning of the rope yarn and the "laying" of the rope or twisting of several strands of the rope yarn.

The work executed in mechanical ropemaking is very similar to that involved in the manufacture of hemp (see that article). After shaking, the bales are run through softening machines, in which they are moistened with an emulsion of oil and water preparatory to carding. This operation, which consists in pulling the flax through steel needles fixed on a board, raises much dust, though the fibres are oiled. The hemp which has been mechanically combed is spun on a frame provided with a funnel-shaped condenser to regulate the thickness of the strand fed to the fly spindle, which effects the twisting.

Cables are made by means of "laying" machines, which warp and twist the threads to form strands. Other machines twist several strands together to form the cable, while certain types of machines form the cables directly.

Fine string is almost always made by machine. The string passes through a bath of dressing or dye and is then wound into balls by machinery.

Old ropes, tarring or otherwise, are used for making oakum.

**Sources of Risk**

The dangers arise especially from dust, oils, tar and substances used in dressing and dying string. The risk of fire should also be mentioned.

Israelsohn, who made a calculation of the amount of dust present in a string factory at Orel (1927), found from 0.109 grm. per cubic metre to 0.453, according to the machines operat-
matter used are not infrequent, and tetanus has on occasions been caused by organisms present in the dust.

HYGIENE

Primitive methods of handwork in this industry are now for the most part replaced by the use of machinery, but dust production is in nowise diminished unless effective local exhaust is provided over the machines. Good ventilation is also essential and workers in this occupation should be chosen with a view to the elimination of those predisposed to tuberculosis, those with nasal obstruction, flatfoot and varicose veins.

For other data relative to hygiene and legislation, see the articles corresponding to the different vegetable fibres.

BIBLIOGRAPHY

Rubber or India-rubber Industry

French: Industrie du caoutchouc. — German: Gummi- or Kautschuk-Industrie. — Italian: Industria della gomma elastica or Industria della gomma. — Spanish: Caucho or Goma elastica.

CHEMICAL PROPERTIES

In 1736 Ch. de la Condamine sent from Quito to the Academy of Sciences at Paris some rolls of a liquid resinous mass known under the name of "caoutchouc".

Rubber is a natural product obtained by the coagulation of "latex" or "latex-milk" of certain species of trees very numerous in tropical latitudes, of which the principal are the Heveas (especially H. Brasiliensis Mill., Arg., of the family of Euphorbiaceae), the Castilloas, the genus Landophila and the majority of the laticiferous plants of the Asclepiadaceae.

The latex extracted from the rubber trees by means of tapping has the appearance of a white viscid liquid in which the rubber is in suspension in the state of fine globules. It varies in quantity from 10 to 40 per cent. (Heveas). Separation from the serum is effected in various ways, either by spontaneous coagulation, or by boiling, or dry by smoking or by skimming or more rapidly by the addition of certain chemical agents (principally acetic acid), or lastly by modern mechanical processes (although not widely in vogue) of filtration, centrifugalisation, crushing the ligneous parts, etc.

Rubber freshly cut is colourless, without smell, elastic, extensible, a bad conductor of heat and electricity, and has specific weight of 0.910-0.942. At 3-4° C. it becomes rigid (it freezes); heat swells and softens it, but its elasticity is only momentarily lost. It unites with itself completely; dissolves in hydriodic acid, carbon bisulphide, petrol benzine, and naphtha (which can absorb as much as 30 per cent. of their weight in rubber).

Rubber is now regarded as a hydrocarbon of the aromatic series belonging to the family of terpenes represented by the general formula C_{n}H_{2n}. Only slightly affected by dilute acids and alkalis, this non-saturated hydrocarbon can, under certain conditions, fix certain elements with strong affinities (chlorine, bromine, iodine, oxygen, sulphur). The combination with sulphur is the most interesting, because it is the starting point for its industrial use. (See below, Vulcanisation.)

Among the resinous gums used in this industry, either alone or combined with rubber, to the view of the similar uses to which they are put, gutta-percha and Balata may be mentioned. The former is contained in the latex of certain plants of the family of Sapotaceae (coming from Malacca, Sumatra, Borneo, etc.), while Balata is a latex of the Minusops Balata Gaert, and of the M. Globosa Gaert. of the family of Sapotaceae (from Guiana, Venezuela, Brazil, and the Antilles). Industrially, however, other substitutes are used (rubber waste which requires pulverisation and grinding after washing), recovery rubber (see below, Rubber recovery), and artificial rubber which is far removed from the real article. Artificial rubber is only a chemical combination of vegetable and mineral oils (linseed, colza, rape seed, Black Sea rape, cotton seed, etc.), with more or less sulphur added. Sometimes mineral oils are added to vegetable oils. Thus rubber is obtained by synthesis, starting from isoprene and especially isoprene (C_{5}H_{8}) and methylisoprene (C_{6}H_{10}) converted into synthetic rubber by polymerisation (by means of heat under pressure or of catalysts, or of metallic sodium and heat). (See also article "Naphthaline").

Although processes in the rubber industry may vary slightly in different countries, it is nevertheless possible to give a general description of these, because the differences are not so great as might be imagined. Like all other chemical industries, however, the rubber industry is constantly experimenting with new substances, the use of which is at one time adopted and at another abandoned.

In addition to the gum resins of the rubber substitutes, the industry uses quite a number of substances of which the most important will now be mentioned. These are mixed with the pure rubber in order to conform to special properties (increase in the density of the mixture, acceleration of the vulcanising process). Certain compounds are used to colour the mixture (plumbate of lead, or graphite, or humin, or zine sulphide, cinnabar, zin' white, white lead and other lead compounds —
especially in the manufacture of rubber shoes — and even arsenical colours); other agents used to dissolve the sulphur chloride, or the rubber are petrol, benzene, carbon bisulphide, acetone, dichloromethane, carbon, tetrachloride, etc.; others used in the charges, or batches, are sulphates (plaster, barites), carbonates (of lime and lead). Use is made, too, of silicates (talc, asbestos, kaolin, etc.), and of various mineral compounds such as chrome yellows and greens, etc.; these will be mentioned when describing the different processes.

**TECHNOLOGY**

Raw rubber usually contains impurities (water, resin, wooden debris, leaves, sand, earth, etc., with which the juice has been contaminated at the time of collection). These are got rid of by a preliminary treatment steeping in water at 40-50° C., sometimes alkali, or acidulated. The rubber is then broken up, being subjected to washing in cold water; then grinding takes place in such a manner that the pieces squeezed between the rollers are freed from the foreign bodies contained in the interior of their mass. The sheets of rubber after grinding are next dried and pass to steam-heated calender rolls; the rubber gets warm, softens, becomes plastic and takes on a compact consistency and homogeneous texture that had been lost during grinding. If the rubber is to serve for the manufacture of “fine sheet”, it is treated in a disintegrator or “devil” — a cylindrical apparatus in the interior of which revolves an iron drum with its surface studded (as is also the interior wall of the cylinder) with spikes.

The rubber obtained is subjected to stronger pressure in order to cool it and is then in the form of a compact parallelopiped (block) or cyllindroid, and is transferred thence to a cellar and kept at a low temperature for some time (freezing). At the proper time the block is sawn into “fine sheet” and the product, absolutely pure, is ready to be worked and undergo vulcanisation by heat or cold (see later).

Purified and prepared as described, the rubber can also be mixed with the vulcanising agent, the substitutes, the adjuvants, the batches and the necessary colours. This latter operation is done in different ways, either in the making up or the vulcanisation, according to the nature of the ultimate product required.

**Mixing.** — The masticated rubber (rarely frozen) is immediately subjected, together with the other substances, to compounding; measuring and weighing the different compounds can only be regarded as dangerous when it is a question of toxic compounds handled in absence of the necessary precautions. If the grinding, crushing or sieving of the required compounds (of lead, antimony, aluminium, iron, calcium, tin, and zinc) are done, all contamination of the atmosphere by dust must be prevented by the use of closed apparatus or locally applied exhaust ventilation.

In the case of volatile products, e.g. aniline, closed receptacles should be used. In an American enquiry (Ohio) in 1914, two cases of aniline poisoning were reported at this stage of the manufacture.

Among the chemical substances used to accelerate vulcanisation (litharge and less frequently basic sulphate of lead or white lead) are aniline, toluidine, piperidine, certain aldehydes such as aniline-formaldehyde, ammonialdehyde, certain aliphatic amines such as hexamethylenetetramine (ethyl diphenylguanidine, thiocarbanilide paraphenylenediamine (no longer used), diphenylguanidine and other substances more or less toxic (see the corresponding articles).

Generally speaking, the inclination in the trade is to suppress the use of the more toxic accelerators as, for example, paraphenylenediamine, thiocarbanilide, and even aniline.

**Compounding.** — This is done by kneading by means of smooth steam-heated rolls, which yield a very homogeneous mass ready for further treatment. For certain purposes, however, the rubber mass is softened by rolling out and calendering, in order to obtain very regular thin sheets. As the mixture is carried round the rolls, much of the dry powder falls off and is caught in a tray underneath the rollers, and the mixer has to sweep it into a pile, scoop it up with a shovel, and throw it back on the revolving machine. He cuts off the rubber sheet as it emerges from between the two cylinders and throws it back on the mixing mill until the powder is thoroughly incorporated with the rubber.

The dangers present are especially those arising from dust and fumes (principally aniline, as the other accelerators only give rise to minimum traces of vapour; the American enquiry already referred to found at this stage nines of lead, antimony, and aniline). Among 252 workers, 22 definite and 4 suspected cases of
lead-poisoning, and 3 of aniline-poisoning were reported. The danger was held to be serious in 13 out of 21 factories owing to failure of satisfactory removal of dust, and fumes, ignorance on the part of the workers, and insufficient welfare arrangements.

Good general ventilation and locally applied exhausts for certain of the mills (where toxic products are used) should be provided, although hoods in connection with the mills have been stated to render the work difficult.

Making up. — Rubber articles are made either supple or hardened in shapes determined by various processes which are included under one or other of the following operations: cutting out of a mould, pressing into cylindrical form, moulding. Flat pieces (washers, shoes, erasing rubber, etc.) are made by cutting the sheets as they come from the calander, or by assembling them on a mandrel at the time of vulcanisation. The parts to be joined up are also sometimes united by means of rubber solutions (see below, Rubber solvents) or by vulcanisation by heat.

Extruding serves to make hollow or flat articles by means of an Archimedean screw, an apparatus in the form of a horizontal cylinder in the interior of which a shaft provided with a helicoidal paddle causes the paste to move forward by forcing it against the front end and ejects it through a die plate fixed at that spot. The extruded material is then set in a mould. The parts to be vulcanised are inserted in the mould, and the mould is closed and heated by steam, or plate presses or moulds with heated walls. The apparatus takes the form and size suitable to the articles to be vulcanised.

For vulcanisation in dry air, there are presses with several plates, annular moulds with spaces communicating with one another; vulcanising pans for tubing, several dozens of yards in length, moulds like shells for pneumatic tyres, and even an autoclave press for rapid vulcanisation of tyre casings for motor cars. Vulcanisation for soles and corsets is done in a heated chamber (rubber shoes). Vulcanisation by diffusion does not require the mixing of the ingredients with rubber before sloping (cold cure). As soon as the object is ready, it is dipped in a vulcanising bath, which can be hot (melted sulphur at about 130° C.) or cold (solution of sulphur chloride in a solvent, such as benzene, carbon tetrachloride, carbon bisulphide, etc.). Combination between the sulphur and the rubber is effected on the surface, and the liquid passes to the interior by capillary attraction. The articles, freed from the layer of sulphur adhering to their surface, are then passed into a stove.

Shaped articles are also vulcanised by exposing them to the vapour of sulphur chloride.

The cold cure process, it should be noted, is now very little used, its utilisation being only in the proportion of 1 to 100 as compared with vulcanisation by heat.

The process of heat vulcanisation does not present very great dangers, particularly when in a well-managed factory. It is heavy, unpleasant work, if the articles are not conveyed mechanically and unless measures are taken for limiting the escape of steam and for keeping the temperature of the workroom low. It should be recalled that the decomposition of sulphur chloride by water gives off sulphur dioxide, yellow sulphide or antimony gives off hydrogen sulphide gas. Apart from the unpleasantness resulting therefrom, mention should be made of the dust (talc, etc.) and...
especially of the vapour of solvents used in the cold cure process (carbon bisulphide, benzene, petrol, carbon tetrachloride, etc.).

If the work of vulcanisation is done on any scale in small workshops (repair work or dry-cleaning) dangers may be sufficiently pronounced on account of bad general ventilation and especially from the use of the solvents without the necessary precautions. The surface to be repaired after preliminary rubbing and cleansing with a rubber solvent which on evaporating becomes viscous, is next coated with a liquid known under the name of “vulcanising acid”, which gives rise to the physicochemical changes necessary to enable the rubber to adhere perfectly under the application of strong pressure. The acid in question is only a mixture of benzene, carbon bisulphide and mono-chloride of sulphur (the last in the proportion of 2 : 1,000), sometimes only of benzene and petrol.

Stringent regulations have been passed for cold vulcanisation: dipping to be done in a closed apparatus (with downward exhaust ventilation of the fumes); a travelling belt to carry automatically under cover the objects dipped into a well-ventilated drying chamber. Carbon bisulphide should be replaced by benzene, and, better still, by carbon tetrachloride, dichloroethylene (see these articles), etc. The cold cure should always be done in a well-ventilated room with arrangements for the diminution, as far as possible, of the unpleasantness due to heat and humidity.

Rubber Solutions

Large quantities of rubber solution are used for making articles by the dipping process, coating and cementing. Coating solutions more or less thick are prepared by the use of rubber, either pure or mixed, and dissolved in petrol or benzene. For joining special articles rubber is mechanically prepared by balata or mixed with gutta-percha. Sometimes the solution is prepared by hand in open vessels; but in all well-managed factories it is mechanically prepared in a receptacle provided with localised exhaust ventilation. The solution is handed out to the workpeople in cans provided with a cover and aperture in the form of a valve to prevent evaporation. If the solution is to be sent out in tubes the filling is done mechanically. This operation requires a large number of workers who are all exposed to a degree of danger varying naturally with the precautions offered by the technical organisation.

The solution is used to fix or cement objects (shoes, pouches, sanitary goods, rubber clothing, bandages, toys, etc.); it is also largely used for making, by dipping, articles previously made with “fine sheet”; or it is sold as solution in tubes.

Danger. — Vitiation of the air by solution fumes, fire, and explosion.

Hygiene. — In making solutions only hermetically-closed apparatus should be used, provided with efficient exhaust ventilation; cans should have covers; ample cubic space per person with mechanical ventilation is essential. Hand labour should be replaced by machinery, although practically this offers certain difficulties.

Work with “Fine Sheet”

As has been said above, this serves for making a number of small, fine but flexible and elastic articles (baby feeding bottles, teats, nipples, finger-stalls, gloves, balloons, etc.). The articles are made by moulding or cutting and welding. Their vulcanisation takes place by dipping into a molten bath of sulphur or by the cold cure. These articles are prepared by a still simpler process (dipping) which consists in dipping celluloid or wooden shapes in a rubber solution, setting them to dry, then dipping again and again until the layer of rubber is thick enough. The operation is done in an apparatus completely closed and provided with exhaust ventilation. The dipping of the shapes is also mechanical as indeed are all subsequent operations.

Dangers. — Toxic vapour of the solvents (benzene, carbon bisulphide, etc.), unless exhaust ventilation is well adapted, or in absence of the necessary precautions.

Hygiene. — Downward exhaust ventilation should be installed and if the operation is not done mechanically the dipping troughs must be protected by a method analogous to that described later for spreading.

Manufacture of Spread Goods

Fabrics can be coated with rubber solution or woven with threads previously encased with rubber, or by the application of a thin layer of rubber. By the last-named method the cloth and then rubber sheeting is passed between the heated rollers of a calender which press the rubber into the fabric. The spreading of the
solution on the cloth is effected by a "spreader".

In principle, the spreading machines carry a drum on which the pieces to be impregnated are rolled. The cloth is drawn over the chests by a driven cylinder and receives, as it passes, the solution in a more or less fluid condition. This covers the cloth with a layer of uniform thickness by means of a spreading knife or "doctor" suspended so that it almost touches the outermost roll. The cloth is then drawn on to heated tables (100-120° C.) where the solution, penetrating into and attaching itself to the fibres of the cloth, solidifies on the evaporation of the solvent. During this passage evaporation is particularly active over the central tables of the machine and the quantity of vapour from the solvent depends naturally on the composition of the solutions used. In fact though the solution may contain 1 kg. of matter in 2 kg. of solvent, the pure solution is made on the contrary in 20-40 kg. of essence. The application of the solution on the cylinders may be done by hand by the worker who spreads it by means of a small wooden scraper, but the operation is generally effected mechanically (by dipping in a solution bath after which the cloth passes between spreading knives).

Danger. — Fumes of the solvent (especially benzene). Danger of fire and explosion.

Hygiene. — Locally applied exhaust ventilation to remove the toxic vapours facilitated by use of spreading machines provided with apparatus for recovery of the solvent. To effect the latter the cloth, after having passed the spreading knife, is carried into a passage way formed of two plates, the interior of which is heated by steam. This passage can be widened at will so as to assure more or less volatilisation as desired. The vapour is aspirated by a fan and passed into a refrigerator where it is condensed. Mechanical ventilation also can be applied along the sides or above the spreading table. In this case the hood with vertical duct to be effective should be prolonged along the sides by means of movable plates reaching as far as the level of the table.

While the removal of the vapours should be downwards across the floor, fresh air should be introduced from above and directed downwards by a plenum system.

Precautions must be taken against fire and explosion. Spreading machines should be earthed to remove from the cloth the static electricity with which it becomes charged during its passage through the cylinders.

In certain circumstances the belting, the pieces of cloth, the jets of liquid and even the workers themselves become charged with static electricity. A discharge may then take place between two bodies with a perceptible difference of potential, and such a discharge is likely to cause combustion, if it takes place in a mixture of air and combustible fumes.

According to Milne (1923) the problem consists in maintaining all bodies in the danger zone at the same temperature. The contents of the spreader, of the piping and the framework of the machine should be effectively earthed. A general system of damping the atmosphere up to about 40-45 per cent. should be instituted in order to deflect the charges of static electricity present prior to the passage of the product through the machine.

Each recipient and each jet or current of water or of vapour should be earthed at its source; the workers should wear shoes with metallic soles or nailed soles, etc. Precautions should be taken in regard to the transport and storage of the solutions in the spreading room.

The covering of the thread for weaving should be done in a separate room capable of being closed and organised in such a way that the process does not demand the continual presence of the workman.

Pneumatic Tyres

This branch comprises a whole series of operations which vary according as to whether it is an outer cover or an inner tube which is being manufactured. The latter is but an India-rubber tube fashioned by means of a mandril specially adapted for the purpose. The tube from the mandril is vulcanised in the curing pan and converted into a complete ring by turning up the ends on a special form and cementing the lips together with solution.

For the outer cover four or five strips of impregnated cloth covered

---

1 It is very important to know at any moment the concentration of benzene in the air of the spreading room. During the enquiry of Bridge and Price (1917), analysis showed that when seven spreading machines were at work there were 211 parts of benzene per 10,000 of air; behind eight spreading machines near the fan 163.5 per 10,000; between six spreading machines at a height of 30 cm. from the ground 3.7 per 10,000; at the same place 30 cm. from the ceiling 4.6 per 10,000. An increase in the renewal of the air of the room (from 25 to 67 per hour), replacing of benzene by xylol, and medical supervision rapidly improved the health of the workmen.
with solution are super-imposed one on the other to constitute the casing which is then completed by placing upon it the tread, which may be smooth or indented.

The casing of the outer cover, made as described, is taken from the metal core which has served for its manufacture and, in its place, an air chamber is introduced. The whole is placed in a mould consisting of two metal shells, the air chamber is blown up until it assumes the shape exactly, and vulcanisation takes place in the autoclave. Transport of moulds to different sections of the factory is done by means of an overhead railway with carriages carrying chains to which the moulds are hooked.

The work of polishing and buffing in the manufacture of pneumatic tyres to-day is very rare. Danger from dust raised in this operation only concerns, therefore, the few factories which still continue to do it. Similarly, lead salts are almost entirely dispensed with now in the making of pneumatic tyres.

Varnishing

The making of waterproof shoes deserves a special note. Once finished the shoes undergo drying followed by a coat of varnish made up of artificial black dissolved in petrol and turpentine which is applied on the golosh and even on the external sole. Vulcanisation takes place in a stove, heated by steam, the air of which is renewed at the end of each operation while fresh air is brought in by pipes passing through the lateral walls. Ventilating openings installed in the upper part allow the steam and toxic gases to escape.

Danger. — Vapour from solvents, fire, and explosion.

Hygiene. — As already described above.

Rubber Recovery

Extraction of the old rubber from the manufactured goods no longer in use is not an easy matter in view of the great diversity of composition of the manufactured rubber. There may be an excess of free sulphur, of mineral matter, or charges of metallic substances, etc., of which the rubber has to be freed by different methods, all, however, having a certain resemblance. The foreign matters are attacked by acids, alkalis, or neutral salt solutions. The recovery involves a long series of different operations according to the product handled. The processes followed may be mechanical (washing, grinding, sifting, etc.), or physical (heat, superheated steam solvents), or chemical (acids, sulphites, sulphides, etc.), upon all of which it would not be worth while to dilate as each factory applies methods of its own.

Danger. — Dust, fumes of the solvents, sulphur, hydrogen gas, etc. Reference is made in the literature of the subject to cases of anilism (Ramhosek, 1913), to lead poisoning, and to ill-effects from the "smother" and from heat.

Hygiene. — Prevention of dust, gases and irritating or toxic fumes by the use of closed apparatus and exhaust ventilation.

Dyeing

Rubber can be varnished with colours with or without a previous coating of size. The dye is also made to act on the mass by means of a bath of copper sulphide and ammonia or chloride of ammonium for black, sulphide of copper and ammonium chloride and chalk for green, etc. The mass can be mixed with colours such as cinnabar, white lead, yellow sulphide of antimony, etc.

Dangers and hygiene. — The dangers are those common to the varnish and lacquer industry. Decomposition of the yellow sulphide of antimony by acids gives off hydrogen sulphide.

Statistics

Austria. — In 1911 two fatal cases of benzene poisoning were reported and between 1914 and 1918, six cases of carbon bisulphide poisoning with mental symptoms were treated in the clinic for psychiatry in Vienna. The Factory Department drew attention to the risk of contamination from blowing sanitary articles with the mouth and urged replacement of this method by a pump.

Belgium. — In 1895 an enquiry by Gilbert brought to light 16 cases of illness from carbon bisulphide in the rubber industry, the symptoms being inco-ordination, delirium, psychical disturbance, paresis, etc. Application of preventive measures resulted in 1904 in very considerable improvement in the health of the workers. During the war, work ceased, but on its resumption, at the end of the war, cases again came to light. Enquiry by Vandenpladen (1920-1921) in a factory for toy balloons, etc., vulcanised by dipping in a solution of 1-2 per cent. sulphur chloride in carbon bisulphide, revealed the fact that 8 out of 6 examined had moderately severe symptoms of carbon bisulphide poisoning, while 11 mounters (fairly old workers)
were less affected (2 with some paresis, 6 with headache and digestive trouble); 16 out of 20 blowers (using compressed air) had previously been affected by carbon bisulphide and the majority of them at the time of the examination suffered from headache and vertigo; 6 had some degree of paresis.

Germany. — According to Laudenheimer, in the factories of Leipzig, employing about 728 workers, of whom 219 were employed in vulcanising, 31 cases of moderate poisoning and 19 cases of nervous diseases were treated by private medical men or in hospital between 1874 and 1908 — all attributable to carbon bisulphide. According to the same writer every workman who is exposed to the action of this substance inevitably runs a risk of more or less severe poisoning. In 1905 von Harmsen gave the result of an examination of 220 vulcanisers in 7 factories at Cologne, made in 1901. 112 of the workmen, i.e. 46.3 per cent., were ill, 18.6 with gastro-intestinal affections, 11.3 with pharyngeal catarrh, 6.5 with anaemia, and 0.9 with nervous affections. The data from the local sickness insurance society of Leipzig (1910) gave a very high morbidity rate to this category of workman. Thus, among 2,228 men there were 1,041 cases of sickness yearly with 20 deaths. The inspectors of factories have reported several especially among those employed in the spreading department. The Inspectorate consequently issued by the Secretary of State immediately issued instructions for ventilation and distributed leaflets and warning notices for the benefit of the workers and "petrol" was substituted for "benzene".

Italy. — An enquiry by Cicala (1921) covering the small repairing shops in Rome enabled him to say that a third of the workers employed (20) showed signs of benzene poisoning. Fatal and serious cases were reported in Milan among persons employed in waterproofing cloth (see article "Benzene").

Netherlands. — A fatal case of benzene poisoning was reported in 1916 in a spreading department. The Inspectorate immediately issued instructions for ventilation and distributed leaflets and warning notices for the benefit of the workers and "petrol" was substituted for "benzene".

United States. — A detailed health enquiry by Hayhurst in 1914, in Ohio, in factories employing 11,427 workers, of whom 1,942 were women, covered the conditions in all of the several processes. Effects from benzene were frequent; less than 1 per cent. were in contact with carbon bisulphide. The enquiry revealed 99 cases of poisoning of moderate severity from carbon tetrachloride. Cases of lead poisoning were also discovered in certain factories. The first of such cases reported in Great Britain. Between 1910 and 1921, 74 cases of lead poisoning were reported in the mixing process.

Pathology

Besides the local action of certain substances used in the rubber industry (carbon bisulphide, sulphide of antimony, accelerators, etc.), the general effects of the industry on the human organism should not be lost sight of, such as the condition of the atmosphere in regard to dust content, humidity and warmth, the human factor in relation to fatigue — from posture, speed of the machines, the carrying of heavy loads, etc. — and again in relation to poisonous materials (aniline, carbon, bisulphide, benzene, petrol, lead compounds, etc.).

While the various articles already deal separately with these different substances, certain details may be here noted. Thus, hexamethylenetetramine sets up an eruption resembling
measles with formation of pustules which have been attributed to its decomposition into formaldehyde and formic acid. Benzene is said also to set up a characteristic dermatitis occupying the interdigital spaces and accompanied by redness, itching, swelling and vesicles, while the rest of the hand remains intact. A more or less severe eczema has been attributed to the handling of certain substances which, during mixing, set up conjunctivitis. Poisoning by sulphur chloride is rare (see above, Vulcanisation). During the preparation of rubber substitutes from oil and sulphur, large quantities of hydrogen sulphide are given off which require careful removal. Lesions, set up by cinnabar, known under the name "rubber sickness" have been described as occurring among persons employed in making artificial teeth from gutta-percha. The German dentist Lazarus has described 20 cases of dental caries among his own staff, complicated at times by necrosis of the lower jaw, the cause of which was, however, not recognised. Wide use of talc can also cause respiratory affections (see article "Talc"). Gilbert, lastly, has described cases of deafness and diminution of the acuity of hearing among the workers exposed to very loud noise from the machines.

HYGIENE

In the rubber industry, and especially in the departments using solvents and solutions containing volatile compounds, stringent regulations for unhealthy and dangerous trades should be applied. Factories should not be in populous centres unless measures are taken to suppress the unpleasant smells. The buildings should be constructed of incombustible materials; and every precaution against fire and explosion must be taken (see articles "Benzene", "Petrol", and "Carbon Bisulphide"), and also against unnecessary noise; use of fuel giving rise to much smoke should also be limited. The floors should be impermeable and wood on walls and elsewhere should be cemented or plastered; fireplaces, hearths, lights, etc., should be disposed in such a manner as to prevent fire, and no one should be allowed to enter with naked lights; burning of debris, etc., should be prohibited; necessary precaution must be taken in drying; sand should be available for the workers to extinguish a fire on its first appearance. Special precautions are necessary in the storage of inflammable materials in the workrooms (only sufficient for the day's requirements to be kept in closed receptacles, etc.), and for the removal of waste; all escape of steam and excessive heat should be controlled as far as possible in order to maintain as reasonable a temperature and humidity rate as possible. Cubic space should be ample for each person (at least 30 cubic metres per person — the German Factory Act allows 20) with constant renewal of the air.

Processes giving off toxic vapours should be effected as far as possible in closed apparatus or at least in apparatus completely covered and kept under a negative pressure. A recovery installation for the spreading machine, besides lessening the temperature of the atmosphere, is pointed out by inspectors of factories to present considerable economic advantage from recovery of the toxic products by condensation. The workers should be protected against the risk of poisoning by the toxic products employed, especially for mixing. All noxious gases should be condensed and certain substances should be replaced by others less toxic (carbon bisulphide by petrol, carbon, aniline, etc., by other accelerators).

A mixture of 80 parts of lead compounded with 20 parts of pure rubber is now in use. This mixture is homogeneous, is sold in sheet form, and is ready for direct incorporation with the other ingredients on the rolls and offers the hygienic advantage of causing no toxic dust (Klein).

Workers should be warned of the dangers of the work. The residuary waters should be deodorised by chloride of lime, or some equally efficacious substance. Effluents which are not in a condition to be run directly into the sewer should be collected in tanks before their evacuation and should be passed through a metal grid to hold back particles in suspension. The usual precautions prescribed for persons employed in unhealthy industries should be observed. Bottle of soda in solution has been recommended for application to the uncovered parts of the body in the case of hexamethylenetetramine rash.

LEGISLATION

The Regulations issued in Germany (Order of 1 March 1900), in Prussia (20 February 1910), in France (20 January 1909, Ministerial Circular), in Great Britain (Special Rules of 1897; Regulations No. 721, 1922; and No. 329, 1922) relate only...
to processes involving contact with carbon bisulphide.

The recent British legislation governs vulcanisation and treatment of rubber involving the use of toxic volatile solvents, and compounding processes in which lead or lead compounds are used. The decrease in the number of cases of poisoning in spite of the greatly increased use of these substances is due to the enforcement of ventilation rules whereby the toxic vapours are drawn off by fans, and lead dusts are removed in a somewhat similar manner.

In 1922 Regulations requiring periodic medical inspection and locally applied exhaust ventilation wherever dry compounds of lead were used led to the use of "plastic rubber", that is, the incorporation of dry lead compounds in mother batches of rubber to the extent of, perhaps, 90 per cent., so that portions of the mother batch could be used instead of the dry compounds themselves. Where this method has been adopted, there being no lead dust generated, the occupier is absolved from the necessity of providing not only exhaust ventilation but also medical examination.

Netherlands. — The regulations enforced in the Netherlands for workshops in which poisonous fumes and dusts are liberated also apply to workshops where carbon bisulphide is utilised.

Argentine women are excluded from the manufacture of waterproof materials and from workrooms where carbon bisulphide and benzene are given off (rubber factories and manufacture of rubber articles).

France. — Women are excluded from workrooms where rubber solutions are made or applied after solution in essential oils and carbon bisulphide.

Young persons under 16 are excluded from vulcanising processes (with carbon bisulphide) in France, Canada, Germany, Great Britain; under 16 years in Belgium, Canada (Quebec), Spain (boys); boys under 15 years are excluded in Italy from vulcanisation by carbon bisulphide and chloride of sulphur, preparation of rubber solutions and their application; female young persons under 21 are excluded in Italy and Spain. This exclusion applies also to the coating with rubber solutions of articles to be made waterproof.

The special legislation cited above includes mechanical suction or use of machines and closed apparatus for the operations giving off toxic vapours; efficient general ventilation; reduction of hours to 5 per day with a pause after every 2 or 2½ hours of work; posting up of the Regulations; general welfare provisions.

In Germany and Great Britain periodic medical examination of workers (monthly) exposed to bisulphide of carbon and dry lead compounds is enforced.

For notification and compensation, see the articles on various toxic substances.

BIBLIOGRAPHY

Dr. A. Hamilton
(Boston, U.S.A.)
Salicylic Acid

Salicylic acid — symbol C₇H₆(OH)₃CO OH — forms white odourless needles with a sweetish taste. It melts at 155° C., volatilises at 200° C., and is but slightly soluble in water.

It is got by the action of carbonic gas, at a pressure of 5 kg., on dry sodium phenolate.

In industry it is used chiefly for the preparation of nitric colouring agents. (For symptoms, see articles “Phenols” and “Aniline”.)

Women are excluded from the manufacture of salicylic acid in Argentina and France (when manufactured from phenol), and boys under sixteen and women under twenty-one in Spain.

### Scavengers, Road Makers and Road Menders

This article deals not only with workers employed in towns in collecting household refuse, and street cleansing, but also with those engaged in tarring roads, in laying and repairing drains, making and repairing country roads (road-men), preparing and laying metal for surfacing roads, and emptying sewers and removing all kinds of liquid sewage.

The composition of the sewage and of the refuse collected varies according to latitude, climate and season; but that of liquid sewage depends on the varying nature of the source of the water used, whether from houses, or, more usually, from workshops or factories.

### Street Sweepers

Street sweepers are an important group of town scavengers.

The collection of street refuse represents a hygienic problem of great importance, which, however, has been simplified during the last thirty years by the changed conditions of the present day, as regards the composition of the street refuse, owing to the reduction, and even the disappearance, in some localities, of animal traction, as well as by the changes that have taken place in the construction and upkeep of street surfaces. Indeed, the composition of street waste varies from a multiplicity of causes, among which may be mentioned the geological formation of the ground, the products of local trade, and progress in urban hygiene.

Where removal of refuse is effected by means of a spade, for lack of modern machinery, and where the streets are inadequately watered, those employed must obviously inhale a dust-laden atmosphere, more or less charged with germs, many of which adhere to the particles of dust. Street sweepers working in towns where there is a lot of traffic, especially in streets crowded with people and animals, are exposed, if the local habits of cleanliness, or the individual habits of the population, are not all that can be desired, to the danger of inhaling numerous germs, which are decidedly more plentiful in the vicinity of hospitals and of buildings where certain kinds of organic animal and vegetable substances are treated, such as slaughter-houses, tanneries and silk spinning mills.

Reference to pathogenic microbes immediately suggests tubercle bacilli; but, generally, the virulence of these is lessened by being dried, and also by the sterilising action of the oxygen of the atmosphere and of the solar rays.

As a proof of the danger from microbes in street dust, it is only necessary to refer to an English enquiry, according to which there were fewer
cases of illness among children coming from those neighbourhoods where attention was directed to the surface and cleanliness of the streets, all the other hygienic and social conditions, such as housing, food and clothing, being, of course, similar.

An enquiry conducted by Allevi in 1914 dealt with 217 street sweepers of Milan, among whom he found the following troubles: flat-foot occurred in 64 cases with an occupational origin, due to the method of carrying on the work, to the daily duration of work, and the number of years of working experience. The candidates suffering from flat-foot adopt a posture which Annandale calls “attitude of rest”; it enables the subject to carry an overload with the foot in a position which encourages the development of flat-foot; in this position the lower limbs are set square, so that the foot is rotated externally and pronated. Gastric and intestinal disorders occurred 43 times. Conjunctivitis due to cold and dust was present in 18 cases. Respiratory diseases claimed 15 cases, and rheumatism 13 cases. Pulmonary tuberculosis is not common, or at any rate does not exceed the average found in other occupations. Allevi explains this fact by the bactericidal action of sunlight, and by work in the open air. Out of 1,000 street sweepers who were members of the Mutual Assistance Society, the morbidity rate was 48.8 at ages 15-34; 65.77 at ages 35-54; and 124.70 at ages 55-74, and the mortality rate 0.63 at ages 15-34; 2.41 at ages 35-54; and 10.56 at ages 55-74. The cases of pulmonary tuberculosis were, for the three age-groups as stated above and per 1,000, 6.74, 10.21 and 9.99; the mortality 1.90, 3.32 and 3.92 respectively.

SEWER-MEN

It is becoming increasingly usual in large towns to construct special tunnels in which are placed water pipes, gas pipes, and electric mains. In other towns the sewers themselves constitute large tunnels, easy to inspect and readily cleansed which are also spacious enough not only to fulfil their original purpose, but also to have space for special conduits for water, drinking water, and telephone cables, e.g. Paris.

These tunnels are sometimes very deep, 20 or 30 metres or more, and may be connected — especially for residuary water — to factories, the waste from which, invariably or under special conditions, gives off injurious emanations. Lack of light, damp, cold, gases and fumes constitute a health risk for persons whose lot it is to work in these tunnels.

Sewer-men are in contact with liquid detritus, abounding in organic matter, which readily putrefies and gives off large volumes of gas; it is the cause of the condition known under the name of “mephitism”. This form of poisoning is connected with the presence of gases which are sometimes only unpleasant, e.g. ammoniacal fumes; but which sometimes are genuinely toxic, through the action of a mixture of gases varying in composition, according to circumstances, but generally consisting of ammonia, ammonium sulphide, carbon dioxide, hydrocarbon, chlorine and sulphuretted hydrogen. The nature of the toxic gases and their concentration explain cases of poisoning which are gradual and imperceptible in development, as well as cases of sudden onset, unexpected and serious, which sometimes advance swiftly to a fatal termination (“sewer-men’s stroke”).

The inhalation of putrid gases, even in small quantities, but recurring frequently or from time to time, causes disorders of nutrition; weakens the organism; brings about changes in the composition of the blood, resulting in anaemia; and paves the way for infectious diseases. A large number of clinical observations and experimental enquiries have led to the recognition of a connection between mephitism and actual disease, more particularly between sewer gases and intestinal diseases, e.g. typhoid and cholera. It should be recalled that Marchionni, before the discovery of the Eberth bacillus, had affirmed that sewer gases were the direct cause of typhoid fever. In Italy, Di Mattei and Sette; in France, Brouardel and Chantemesse; in Germany, Eichorst; and in Australia, Badham and Purdy have reported cases of typhoid epidemics among sewer-men or in houses near sewers which had been opened in consequence of repairs or similar operations.

Among sewer-men, cases of jaundice have also been observed, caused by spirochetosis. And fatal cases of pulmonary spirochetosis (Heim de Balsac, Agasse-Lafont and Fell).

Experiments have proved that the inhalation of these gases diminishes the resistance of the body to infections, particularly as regards the typhoid bacillus, and the bacillus coli, even when the experimental infections were effected with weakened germs, or in very small quantities (Di Mattei, Alessi, Puntoni, Ronzani). Apart from
this in the case of sewer-men, it is essential to recall the possible danger of in contact with the typhoid bacillus, by direct contact with the sewer liquid.

In the case of the men who work in tunnels at the construction and maintenance of different conduits, instances of poisoning have been reported by gases and fumes of the most varied origin, which may penetrate into or become liberated inside the tunnels, such as carbon dioxide, sulphured hydrogen, chlorine, carbon monoxide, acetylene, hydrogen and arsonured hydrogen, methane, hydro-carbon or nitrous fumes.

Among these workers cases of pharyngitis, bronchitis, broncho-pneumonia and rheumatism occur; there are also cases, some of which are fatal, of poisoning by inflammations from the soil, and from coal gas; other cases known consist of cerebral congestion with slight paralysis (Cimaduomo, 1929).

The dangers being similar to those incurred in coal mines, a proposal has been made that safety lamps shall be used in order to detect the presence of inflammable gases, especially methane. An enquiry was carried out in 1925 by Katz, Metter and Bloomfield for the United States Bureau of Mines, in three towns, with the object of studying the gases present in these tunnels. The gases found were classified in three groups: toxic gases, asphyxiating gases, and explosive gases; although there were gases which may be grouped under two of these headings. Among the toxic gases they found ammonia, arising from freezing mixtures; benzol, coming from vehicles, garages and depots; carbon monoxide, a product of illuminating gas, products of combustion, and flue gas; petrol, from vehicles and depots; sulphured hydrogen from coal gas and sewer gas; and sulphur dioxide from the fusing of insulators. Among the asphyxiating gases they found carbon dioxide, a product of combustion and a sewer gas; nitrogen, of similar origin; and natural gases. Among the explosive gases were benzoës; carbon monoxide; ethane; petrol; hydrogen; and methane in natural gases and sewer gas. The gases identified in these tunnels most frequently arose from illuminating gas, natural and artificial.

Natural gases, used a good deal in the United States, are not as a rule toxic; but they only need a small quantity of artificial gas, with its content of carbon monoxide, added to make them dangerous.

Statistics

Two fatal cases of poisoning by sulphured hydrogen were reported in the U.S.S.R. by Litkens in 1927, who found, in sewers 0.31, 0.575 and 1.09 per thousand of toxic gas, according to where each sample was taken.

Data relating to sickness and mortality among the sewer-men of Paris were collected by Hein de Balzac, Agasse-Laforest and Feil in 1926. Their observations scarcely justify any decision as to establishing a connection between illness and occupation or not. Absence through sickness was twice as much in duration as absence through accidents, amounting, on an average, to four days a year per head. The principal causes of illness were chest troubles, digestive disturbances, rheumatism and cardiac pains. Four per cent. of accidents due to falling into water were reported; jaundice, 6 cases; conjunctivitis, 2; no rat bites occurred, but, strangely enough, cat and dog bites.

The death rate for the period 1900-1924 fell from 3.2 to 1.7 per cent.; invalidity at the end of the twenty-five years had risen from 1.1 to 6 per cent. The improvement in the mortality rate is attributed to the adoption of a working day of eight hours, to measures of individual cleanliness, with lavatories for washing and cloakrooms, since 1910, and to higher wages, which allowed a higher standard of life.

In a list of causes of death are found: 7 cases of chronic respiratory diseases, bronchitis and tuberculosis; 1 of tuberculosis of the vertebral column; 1 of asectis; 3 of external diseases; 3 accidents, and 3 not specified. Another list, for 1925-1925, gives, out of a total of 85 deaths, the following causes of death: 27 cases of pulmonary tuberculosis; 8 of respiratory diseases; 2 of poisoning by sulphured hydrogen from residuary water; and 2 accidents due to asphyxiation in the sewers. As regards invalidity in 1925, 3 cases of rheumatism were reported, 2 of chronic respiratory diseases, 1 of pulmonary tuberculosis, 1 of chronic gastritis, 1 nervous disorder, 7 accidents and 12 not specified. 1

In the U.S.S.R., Zatzepine in 1929 studied ocular diseases among well-sinkers of the Don. These men remove mud and slime from the bed of the Don by dredging. This writer found 385 cases of various ocular disorders among the 315 workers examined; 264 had conjunctivitis, which he attributed to the inadequacy of the artificial light provided and to dust. In practice the mud and slime taken out is spread on the dredgers and so is reduced to fine dust, which may be the cause of this ocular trouble. It should be added that the conditions of housekeeping on the barges on which these men live are not good, and ought to be improved.

Another enquiry, in 1927, was concerned with the conditions of work of men

1 See also the report published in 1938 by Etienne Martin (Lyons).
employed in repairing aqueducts at Moscow. This work is carried on largely in observation wells at a depth of from 3 to 3.5 metres, with a cubic space varying from 2.5 to 10 metres. In order to go down into these wells, the diameter of which only measures 70 cm., the men are obliged to remove their upper garments.

Analyses made from time to time of the air in some wells at the level at which the man was breathing gave the following results: carbon monoxide: 1.2 to 3.5 mg. per cub. metre of air; carbon dioxide: from 49.8 to 533 mg. The workmen often complained of headaches, giddiness, buzzing in the ears, stiffness, insomnia, and troubled vision.

**Navvies and Road-Men**

The construction and maintenance of roads are distinguished technically from each other as two separate processes, especially as regards country roads.

The ordinary process is called "macadam"; it may be done with or without rolling, or with rolling and superficial tarring; it consists in spreading such stones as broken flints or gravel on the level where the road is being constructed, either with or without foundations, and then covering the stones, in order to fill in all the empty spaces, with finer material to bind and hold them together. This material is composed of gravel, coarse sand and bitumen or asphalt. After tarring, a steam roller is used.

Roughly speaking, the various kinds of tar used for roads may be grouped as follows: tar for surface treatment; tar for internal treatment, and, in a mixture, as "tar macadam"; tar with anthracene oil, 50/50 and 60/40, is used for surface treatment; 65/35 and 70/30 for internal treatment.

Practically speaking there are many varieties, to which concrete and tar cement must be added.

Tar or special mixtures are also applied in liquid form to road surfaces by spraying machines. The products are melted in a little boiler by the roadside. When the tarring is of some depth, that is to say, when the mixture of stones, sand, and binding bituminous or asphaltic substances, is spread on the road and crushed down by a roller, the result is designated as "tar macadam", or macadam made with tar.

In towns, considerable use is also made of special blocks of wood, which, after being laid, are steeped and sprayed with asphaltic substances.

This brief summary of the two principal processes suffices for the present purpose.

Certain occupational etiological factors are common to the town labourers, who constitute the urban body of road workers, and to the country labourers or road-men; whereas other factors are peculiar to one or the other group.

All those who are employed in the transport of material for repairing the roads, and in the transport of rubbish, are designated by Pieraccini under the generic name of "para-stradini" (para-road-men). As in the case of very many other road workers, such as paviors, stone-breakers, masons and labourers, these men are exposed to the inhalation of hard mineral dust, and their work is very strenuous.

The operations connected with treating the surfaces with tar, bitumen or asphalt expose the workers to the inhalation of ammoniacal and, especially, sulphurous fumes from these various substances, as well as of dusts which arise from the material once it is dry and mixed with the dust of the road. The tar is always melted by the roadside, and it often happens that petrol and heavy oils are added to make the tar melt more easily. The worker is then exposed to irritation of the upper respiratory tracts and to conjunctivitis. This danger is repeated, on a less serious scale, during the work of spreading the hot tar or similar substances on the surface of the roads.

The dangers which may arise from tarring roads have long been a matter of discussion, the chief danger appearing to be that of pulmonary cancer. It must be acknowledged, however, that this opinion is not upheld in scientific circles, and that as recently as 1930 Lehmann expressed the view that tarred roads are not injurious, and that pulmonary cancer, which some people have tried to connect with tarred roads, is certainly not caused by the tar.

While refraining from forming any decision on this still obscure question, it will be sufficient to refer to it here and to express the hope that successive observations may make it possible in the near future to form a more definite opinion, based on convincing evidence.

When roads are constructed by excavation, or where they are shut in between houses, the air is thick with dust raised by vehicles; it is also laden with tar fumes, or even with such exhaust gases from motors as carbon monoxide, or lead due to the use of ethyl petrol. Much has been written on this subject, and several experts consider that it is quite possible that poisoning may be caused by exhaust.
gases from motors on the big arterial roads of towns where motor traffic is considerable.

The different noxious factors just referred to may also be found arising from work on country roads, but they are less frequent and only occur under certain well-defined circumstances, e.g. work along the side of conduits, open trenches, or liquid manure trenches, since closed sewers and pipe-lines are unusual in the country.

Men employed in supervising and maintaining great main roads represent a very extensive group of workers, as the road system is daily assuming increased importance in every country.

Road-men are compelled to work and live most of the year in an atmosphere laden with dust. This dust is raised into the air when roads are swept, and dust is shovelled up by the rapid transit of motors and lorries, and even by the wind, which, however, by dispersing the road dust, protects the road-men to a certain extent. The material upon which these men work is dusty during several months of the year; though, of course, it varies according to its geological nature, to the exposure, latitude, and altitude; it is dustier during cold and damp or semi-liquid during the other months.

All this work has to be carried on in the open air, in the country, on plains or on mountain sides; consequently the workers are exposed to every atmospheric vicissitude, from extreme heat to extreme cold.

Cold and damp are common causes of rheumatism; they affect the respiratory organs in particular, and accentuate the habitual inhalation of dust. Hence arises a high death-rate from acute and chronic forms of broncho-pneumonia.

For the work of breaking up pavements, compressed air tools are often used; for this reason there occurs an unusual incidence of the troubles due to these tools (see article "Pneumatic Tools"). For concrete workers on motor roads, see article "Cements".

**Statistics**

Statistical facts referring to the health of road-men on the system of highways are limited to those published by Pieraccini in 1928, which deal with road-men in the province of Florence, and cover a period of seven years, from 1918 to 1925. The average length of life was fifty-seven years, and the average length of service twenty-six years. It should be noted that the personnel concerned were engaged at between the ages of twenty and thirty years, after medical examination; thus they may be described as picked men. The death-rate was as high as 8.72 per cent.; pulmonary tuberculosis accounted for 38.8 per cent. of the deaths, and for 77.7 per cent. of all other acute and chronic respiratory affections. The statistics do not give any information as to other causes of death, such as rheumatism, sunstroke, or cold.

**Pathology**

Removing snow and ice with a broom or a shovel or with a pick is a dangerous, unhealthy and exhausting operation, for it is carried out at a low temperature, often accompanied by damp, and often hazardous, due to falls and slipping, while it favours eye troubles.

Road-men, obliged to go some distance over a frozen or snow-covered road for inspection or snow-sweeping, are exposed to the reflection of solar rays from the white surface, as well as to the action of road dust and wind; hence arises acute irritation of the eyelids and conjunctiva, with watering of the eyes and sometimes photophobia, sub-conjunctival ecchymoses and superficial ulcerations of the cornea. This "snow opthalmia," is observed, although rarely, among road-men; thus Oblath quotes an epidemic among the workers on the roads in the Caucasus, as described by Reich. Generally it is temporary and is easily cured. The experts even recognise that there may be an individual predisposition to this ocular lesion.

In summer, road-men are exposed, particularly in some countries, to heatstroke and sunstroke, and to the action of light rays. The prolonged action of sun glare, in a dry atmosphere, with reflection of heat from the surface of the road, or the heap of stones, when stone breaking, plays an important part, according to certain medical authorities, in the production of opacity of the lens.

Other medical men are more cautious in their statements; and others again consider that excessive strain and abundant perspiration may possibly be connected with this formation of cataract which, in their opinion, resembles the cataract found among workers who are exposed to radiant heat from furnaces.

Dust from the roads, in hot countries, mingles with sweat and cutaneous grease, and forms a layer irritating to the skin, without causing real dermatitis, but just erythema on the face and arms, due to solar rays. As has been previously remarked, cases of subacute or mild
ciliary blepharitis are also found. The movement of the eyelids cleans the surface of the eye and the tears remove the dust and pass it into the nasal ducts. It appears to be the irritating action of this dust on the lachrymal passages which encourages the development of dacrty-cystitis in the case of workers who are employed on dusty operations. However, mineral and insoluble dust from roads — for it is unusual for road dust to be mixed with dust that is soluble and exerting a chemical action — ends by irritating the conjunctiva and causing inflammatory and catarrhal affections, which follow a favourable course, if the workers give up the dusty occupation. In the case of workers habitually exposed to dust and wind, chronic blepharitis and conjunctivitis occur. Here also individual predisposition plays an important part (Oblath). Gallenga has observed cases of pterygium, even in the case of young workers; this illness is found more rarely among other groups of workers, and in higher social classes, and Landshere has considered it to be an occupational disease, confirming the opinion of Fuchs, who maintained that these conjunctival changes are due to the action of dust and inclement weather.

The continuous action of dust is responsible for little opaque patches and small incrustations on the cornea, which have affected the sight; dust blown into the eyes by wind and storm causes a permanent feeling of having a foreign body in the eye causing these workers to rub their eyes, and bathe them with water.

**Stone-Breakers**

When studying the conditions of road workers, the work done by stone-breakers deserves special attention. The breaking of stones and pebbles, ready for road-metal or for use in macadamising, is an operation carried on almost entirely by the roadside, during the various months of the year, according to country and season. Although stones nowadays are broken up mechanically, in crushing machines with rollers or jaws, the custom of breaking them by hand is still very common. The largest stones, weighing several pounds, are broken by means of an iron sledge-hammer from 4 to 5 kg. in weight, and then smashed with a smaller iron hammer of about a pound. Road engineers recommend the selection of large stones and pebbles, as smaller ones give a product of inferior quality.

The stone-breaker may work standing or in certain countries seated on a low seat, which not infrequently is placed on the heap of stones. The work is tiring, and demands the cooperation of the muscles of the trunk, and especially of the muscles of the upper limbs.

When it is remembered that stone-breaking is a dusty operation; that the stones lie in dust or mud; that dust is continually raised during the manipulation of the stones; that the road itself is very dusty; that the stone-breakers work by the side of the road during the months when dry debris exists in large amounts; that in the seated position the distance between the nose and mouth and the level of the road is about 3 ft.; that breathing is quick and deep, sometimes through the mouth rather than through the nose; consideration of all these factors justify the conclusion that stone-breakers must inhale and swallow large quantities of dust. This explains why dust is found in the faeces of these workers.

The palm of the hand, especially the palm of the more active hand, has a permanent exaggeration of the hollow, and the four fingers are partly flexed. In the case of aged stone-breakers, the limited extension of the hand is probably due to a retraction of the tendons, consequent upon prolonged and enforced flexion, in the course of work and continuous handling of hard bodies. This lesion has also been observed in other workers who have to use heavy and rough tools (Mori). The skin of their hands is coarse, wrinkled and thickened, and, in the horny palm of the right hand, ridges of skin that are even harder stand out along the metacarpophalangian line. In the left hand, the callosity is more uniform; and, in addition, the edge of the nails is worn from continuous contact with the rough surface of the stones which the man has to place under the hammer.

The specific accidents that injure the stone-breaker are crushings of fingers, and especially the ends of the fingers, which happen frequently. Another and more serious traumatic lesion, and one that is not rare, affects the various parts of the eye; it comprises lesions caused by splinters from the stones, which cause bruises or wounds, or become imbedded in the tissue. As a rule, medical aid is only invoked in the case of serious eye injuries. The stone-breakers of the province of Florence, about 150 in number, experience an annual average of 15 serious eye wounds.
entirely suppress fatigue for the workers, and to shorten the time taken in the operations. This work is often carried out far away from the road, which ensures an atmosphere free of dust for the workers.

Where mechanical means cannot be adopted, it is advisable for the stone-breakers to work at some distance away from the roadside, where they are away from dust; they can afterwards convey the stones to the various points on the road where work is in operation.

Stone-breakers should be provided with goggles to protect them from splinters and sun glare in the summer, as well as with thick fabric gloves to protect their hands.

It would be wise to regulate the working hours of these men, who generally work on piece rates, and to exclude children from this work.

In sewers and conduit tunnels, workmen should be provided with safety lamps for detecting the presence of toxic gas. These tunnels should also be ventilated, and the air maintained fit for the men to breathe. The tunnels can quite easily be made healthy by means of apparatus fixed in the road, which withdraws the foul air from the tunnels and introduces fresh air.

The French Ministry of Labour issued instructions to Prefects on 22 June 1925 referring to the establishment and permanent control of purifying septic tanks and similar contrivances, in accordance with a report laid before the Higher Council of Public Health, drawn up by a special committee (Calmette and Roland).

In Belgium, a committee of enquiry set up on 28 March 1927, on first aid and care in cases of asphyxiation during the laying down of gas pipes, made a special study of construction and earth works, as well as the sewer system, at which the workers are exposed to special health risks and sometimes to fatal asphyxiation.

In Bulgaria conjunctivitis caused by ammonia and sulphuretted hydrogen is compensated as an accident; in Mexico compensation is afforded for injury sustained by sewer-men, workers emptying and cleaning cesspools when such injury is due to carbon dioxide and sulphuretted hydrogen.

Prof. G. Pieraccini
(Florence).
Schoolteachers

The staff in schools, and teachers in particular, are liable to fall victims to certain diseases in regard to which prophylaxis and treatment are of capital importance with a view not only to protecting the occupational class in question, but also on account of the numerous children exposed to possible contagion.

Pathological manifestations met with amongst teachers are caused and sustained by various factors such as bad hygienic conditions under which the teacher is not infrequently called on to carry out his work; the sedentary life; the physical resistance of the individual and predisposing him to various diseases (nutritional disturbances, tuberculosis, nervous exhaustion, etc.).

**Statistics**

A very extensive study of morbidity amongst teachers is that of J. Y. Hart, which deals with the staffs of elementary schools in London for the fifteen-year period from 1904 to 1919. Expressed as a percentage based on the working days lost during the year, the incidence of the various diseases met with may be shown as follows:

This enquiry covered a total of about 14,000 individuals at the beginning, and 20,000 towards the end, in the proportion of 30 men to 50 unmarried and 30 married women.

Analysis of the morbidity statistics classified per annum, per age-group and per circumstances (marriage, post held, status, assistants, etc.) has led the investigator to conclude that sex plays a fairly important role in the pathology of teachers.

The average sickness rate for the male sex was 4.6 per cent. per annum, whilst that for unmarried women reached the figure of 8.2 per cent. and for married women, 9.3 per cent. These figures do not take into account absence connected with childbirth.

Age shows an influence on the duration of periods of sickness, especially in the case of the women. Amongst the men, the average duration, which was 4.3 days for the age-group 21-25 years, attained 9.2 days for the group 61-65 years. The corresponding figures for the unmarried women were 6.4 and 19.1, and for the married women, 11.1 and 19.6. For the men, the most healthy period was between thirty and forty years of age, morbidity falling to 2.8 days per annum, whilst for the married women it was between thirty-one and thirty-five, with a morbidity rate of 7.1 per annum. As regards the unmarried women, the morbidity increases yearly up to the age of fifty-five, where it attains 50.1 days per annum. After this period, it drops to 10.4, with a new increase between the ages of sixty-one and sixty-five.

The most frequent affections are those of the respiratory organs (bronchial tubes, throat and forms of influenza), constituting 43 per cent. of the total morbidity. Nervous and mental troubles take second place (16 per cent.), followed by gastric troubles (8 per cent.), forms of rheumatism (5.6 per cent.), infectious diseases (3.8 per cent.), debility and anaemia (3.7 per cent.).

About 88 per cent. of the absences were incurred by a small percentage of the persons under observation (21 per cent.), and the average duration of sickness was eight days. The absence record is not so heavy as would appear, by reason of the fact that 43 per cent. of the total absences were due to a restricted number of teachers, 3 per cent. only of whom were affected with illness having a duration upwards of fifty days. During the war, periods of absence on account of disease increased by 37 per cent.

Other English statistics drawn up by Fairfield affected 13,748 teachers under observation during a period of twelve economic circumstances, often resulting in overwork (necessity for supplementing the salary earned), insufficient nourishment — all causes capable of reducing the physical resistance of the individual and predisposing him to various diseases (nutritional disturbances, tuberculosis, nervous exhaustion, etc.).
years, and revealed the fact that the great majority of pathological troubles meet with amongst the women were of a nervous order (225), and came under the category of psychogenic syndromes (224). Leaving out of account cases of influenza (84), digestive disorders (86) are partially at least overshadowed by the incidence of affections of an oto-rhino- laryngological order (68). Finally, in order of importance, there come gynaecological forms of disease (66), circulatory affections (56), accidents (49), rheumatism (37), etc.

In Bulgaria, Petroff has furnished a report (1910) on the health of teachers, utilising data collected by the Medical Inspector, V. Georgief. The returns cover 8,306 teachers, 3,650 being women observed during a period of one year. The 675 medical certificates, 500 of which apply to women, showed the following distribution: infectious diseases, 157 (123 women); nervous, 72 (39 women); respiratory, 78 (51); circulatory, 23 (20); sense organs, 9 (5); digestion, 62 (44); genito-urinary system, 93 (72); skin, 11 (5); various, 17 (10). Childbirth and its sequela show the figure 183.

In Italy, E. Sorrentini has furnished very detailed data in regard to morbidity amongst teachers in elementary schools.

The enquiry covered 677 teachers, of whom 1,461 were women, classified according to age, as follows: 20-30 years, 152; 30-40 years, 253; 40-50 years, 226; 50-60 years, 132; 60-70 years, 33; above that age, 1; no age stated, 50.

According to this enquiry, respiratory affections occupied the foremost place, the most frequent clinical forms being recurring bronchitis, laryngitis and pharyngitis. Amongst the infectious diseases, intestinal affections predominated. Finally, nervous diseases due to a constant expenditure of nervous energy and diseases of the digestive system due to unhealthy nourishment and irregularly regulated digestion occupied the third and fourth place respectively.

The enquiry revealed the limited number of children in teachers' families. The figure 0.9 out of 100 families was below the average (4.26), and even below that for various adjacent professional classes. On the other hand cases of abortion were found in excess, the percentage being 18.28. Finally, there was revealed a considerable infant mortality, represented by 43.03 per cent., a figure which exceeds the rate met with amongst the poorest classes. Amongst the most frequent causes of infant mortality, after respiratory diseases came forms of acute infection, the contagion being facilitated by the parents. Diseases of a digestive order figure last on the list.

During the scholastic year 1921-1922, only 17 per cent. of teachers in Milan (354 out of 1,990) had no absence due to sickness, whilst for the year 1917-1918, 1,269 male and female teachers had 27,374 days of absence, and in 1921-1922, 1,626 had 29,444 days of absence. On an average, the men showed a rate of 12 absences, the unmarried women 19, and the married women 23.
portion of 15 per cent. of the deaths from all causes, pneumonia 5.6 per cent., other respiratory affections 1.7 per cent., cardiac affections 12.6 per cent., diseases of the respiratory system 4 per cent., etc.

For female teachers, the values were higher. There were found, for example, 38.7 per cent. due to pulmonary tuberculosis for the age-group 25-34 years, and 10.2 per cent. for the group 35-44 years. Cancer accounted for 4.8 per cent., in the group 25-34, 13.9 per cent. in the group 35-44, 22.2 per cent. in the group 45-54, and 16.2 per cent. in the group 55-64.

Amongst cases of sickness affecting 675 Bulgarian teachers (see above), the number of deaths only amounted to 34, due on 17 occasions to pulmonary tuberculosis (7 cases being women); on 2 occasions to typhoid (one woman); on 5 occasions to pneumonia (2 women); 2 occasions appendicitis (1 woman); 1 cancer; 1 general paralysis; 1 sclerosis of the liver; 2 circulatory diseases (both women), and on 5 occasions various diseases (3 women).

Italian statistics covering the decennial period from 1907 to 1916 show evidence of a fairly high mortality amongst teachers and professors in comparison with the general mortality. The male teaching staff comprised about 35,000 persons. The general mortality amounted to about 19 to 25 per thousand, as against 16.47 for males of fifteen years and over, respiratory diseases showed a figure of 3.42 (2.75 per 1,000), disease of the urinary system 1.06 (0.45), etc.

In 1917, the mortality for the same occupational group was 23.7 per thousand as against a general mortality of 16.87. It is believed, moreover, that mortality amongst female teachers is about one-third higher than that for male teachers. This higher mortality rate is the logical consequence of a higher morbidity rate.

According to the mortality statistics of the Registrar-General of England and Wales for 1901-1903, male teachers showed fairly favourable comparative mortality figures — a little less so for the age group 16-25 years. For the later age-groups, the mortality rates did not exceed the comparative mortality figures, except for appendicitis, diabetes and influenza.

While Italian statistics available would appear to prove that the data in regard to women reveal similar results, in Great Britain the mortality rate for female teachers was, in 1925, 0.55 as against 0.44 per cent. for male teachers (Fairfield).

PATHOLOGY

Pathology as it affects teachers is therefore characterised by particular frequent occurrence of disease forms, notably respiratory affections, nervous affections and infectious diseases.

Amongst respiratory affections, pulmonary tuberculosis occupies first place. Whilst in France Roblot (1925) only found 2.75 per cent. of confirmed tubercular cases amongst members of the French Association of Teachers, Leune found a higher figure (4 per cent.) amongst those of the Département of the Seine, and Nobécourt met with the figure 5.77 amongst pupils in the higher Normal schools.

Th. Altschul, of Prague, reported in 1913 the mortality from tuberculosis of 5.83 for men and 14.35 for women, whilst in Bohemia during eight months he found only a figure of 1.5 per thousand. Schmidt, of Düsseldorf, found tuberculosis to amount to 13.3 per cent. as a cause of retirement or of death amongst 172 teachers, 22 of whom were women. Other statistics, covering 2,790 deaths, showed 18.3 cases of tuberculosis per thousand.

The enquiry effected by Frederick Lorentz (1913) dealt with male members of the German Teachers' Fund, of Berlin and showed, for the period 1907 to 1912, 247 cases of tuberculosis in 2,167 deaths. The mortality rate was said to be, according to this enquiry, parallel to the social position of the teacher, and higher in the country than in the town, and higher also amongst teachers in primary schools than amongst those in higher schools.

As regards the age, death occurred more frequently amongst the group 25-30 years. The mortality curve attains its maximum at the age of twenty-eight, to drop again at the age of thirty-three, remount at thirty-four, and descend once again regularly, except for 2 points at forty-five to fifty years of age. Between twenty-five and thirty-five the number of deaths comprised about 50 per cent. of the total fatal cases.

According to statistics in the United States for 1909, pulmonary tuberculosis amongst teachers exceeded the average for the age-group 25-35 years, and likewise in Sweden.

Hubbert, Todds, Oldright, Lustig, and others have drawn attention to the high incidence of pulmonary tuberculosis and in particular of a special form of laryngitis amongst teachers. These authorities consider that laryngitis, due to exhaustion of the organs by abuse, may be considered more than any other disease, as the occupational malady of teachers. Contributory causes of this lesion are to be attributed to age, which brings about changes in the voice, to an individual nervous constitution, to under-nourishment and
— amongst men — to the abuse of alcohol and tobacco. There have similarly been blamed sudden changes of temperature favouring congestion of the larynx, and serving, as a starting point, for endemic affections of the organs of speech.

Rarely secondary to affections such as emphysema, asthma, adhesions of the pleura, vegetations, adenoids, hypertrophic rhinitis, laryngitis is the result of the vocal effort demanded of the teacher, who is obliged to teach in a functional disorder. As is known, over-crowded classrooms. Alterations of the vocal cords finally become transformed into extinction of the voice or transient hoarseness into chronic laryngitis, with the result that on the larynx — locus minoris resistentiae — certain affections are apt to settle — larynx, cancer, and especially tuberculosis.

It is evident that laryngeal affections, symptomatic of other disease forms, become aggravated by the continual exercise of the voice in the case of teachers. Diseases of the nervous system — functional nervous affections — are those which are most frequently met with amongst teachers, organic affections being more or less rare. Even where such exist, they possess no special character justifying their consideration as specific troubles connected with the occupation. As regards functional disorders, it is known that the troubles in question are psychic-genic syndromes, the origin of which is generally to be found in the moral atmosphere in which the teacher is called on to exercise his profession. Amongst the women, nervous troubles would not appear in direct relation to the menopause. In fact, there have been reported cases of neurosis and psycho-neurosis at twenty years of age (42 cases), at thirty (56 cases), between forty and forty-four (30 cases, one case of menopause), between forty-five and forty-nine years (53 cases, and 2 of menopause), between fifty and fifty-four (31 cases, and 6 of menopause), between fifty-five and fifty-nine (31 cases, and I of menopause). Amongst the troubles described as of a nervous character, the ones most frequently noticed are carbon monoxide poisoning, which occur with a fair amount of frequency when the heating system is defective. The same cause may engender predisposition to miscarriage (Agasse-Lafont).

Epidemic contagious diseases occurring with frequency among the scholastic population may also constitute a danger for the health of teachers. While, thanks to acquired immunity, risk of contagion, notably in the case of eruptive diseases of childhood, is reduced, infectious diseases are shown to be amongst the most frequent pathological troubles in certain statistical returns affecting teachers. On the other hand, the teacher may play the part of a carrier and, by his intermediary, communicate such diseases to other persons, notably members of his family.

Apart from the three categories of disease mentioned, there have been met with amongst teachers gastro-intestinal and cardiac troubles, to which attention has been drawn on account of the relatively important place which they occupy in statistical returns.

Hygiene

Amongst causes favouring disease amongst teachers a foremost place is due to the conditions in which they are called on to effect their work: indoor life in classrooms, sometimes in a very dusty and vitiated atmosphere, lack of cleanliness, and in particular overcrowded classes requiring a continuous effort of the vocal organs. Attempt should therefore be made to combat these defects, to create comfortable classrooms adequately furnished and suited to the requirements of modern scholastic hygiene. In order to combat the monotony of the sedentary life the schoolmaster should take an active part in the recreational pursuits of his scholars. Thereby he will improve his physical health and also his moral tone and be enabled to establish intimate relations with his pupils, becoming for them a great friend as well as a master.

In order to avoid the risk of infectious diseases a working uniform resembling the doctor's overall, should be worn during class hours and removed on leaving the school (Méry and Genevrier).

Once he has been attacked by disease the teacher should of course follow the requisite treatment. Particular attention should be accorded to tuberculosis, which constitutes a permanent risk for pupils. It has been proposed that teachers should be medically examined periodically in order to detect incipient cases and prevent infection at a stage when it is also important to commence treatment under the best conditions for its efficacy. Attention should be paid to hygiene in the classrooms, enlightening social organisation of the professional life of teachers, avoidance of harmful effort and over-strain, careful vocational guidance prior to the choice of the career,
SCHOOLTEACHERS

with contra-indication as to the profession for all those who are weakly.

In France, when a tubercular teacher is unable to continue his work and is obliged to follow a treatment which, if not very costly, at least demands material resources already severely strained by inactivity, there is granted long leave with full pay during three years, and half pay during two years, with renewal each half year (Even Act). It would appear, however, that the application of these measures has given rise to certain difficulties in the absence of means permitting detection not only of suspected cases but also of confirmed cases (Parisot and Viollette). In order to remedy this state of matters the French Congress of Hygiene (1921) passed a resolution to the effect that the presence of any tuberculosis, whether open or in process of evolution or latent, should entitle teachers to leave; that all male and female teachers and auxiliary staff should be annually subjected to specialised medical examination, generally at dispensary of social hygiene with the assistance of all means of diagnosis at present available; and in particular that those already attacked should be submitted to examination for as long a period and as repeatedly as necessary.

In Germany medical experts have drawn rise to certain difficulties in the presence of any tuberculosis, whether open or in process of evolution or latent, should entitle teachers to leave; that all male and female teachers and auxiliary staff should be annually subjected to specialised medical examination, generally at dispensary of social hygiene with the assistance of all means of diagnosis at present available; and in particular that those already attacked should be submitted to examination for as long a period and as repeatedly as necessary.

In Japan the prefectorial Governments allocate sums of money to teachers in primary schools who have to leave the service on account of contagious disease (tuberculosis, leprosy, etc.). A law (1914) and a Regulation issued by the Department of Public Instruction (1915) established the procedure to be followed in these cases. From 1916 to 1925 there has been indeed constant decrease of tuberculosis and of the assistance requiring to be granted to teachers suffering from this disease (693 persons were accorded assistance and 145,985 yen were paid in 1916; 381 received assistance and 84,034 yen were paid in 1925). As regards prophylaxis in relation to derangement of the vocal organs and affections of the larynx, hygienic precepts ought in general to be observed in regard to voice production: rest whenever strain or complications develop as regards the voice, regulating the lute of the voice, good articulation, rhythm of speech, posture (head well up, chest free, etc.), elimination of all factors imposing an undue great effort on the voice, a reduction of the number of pupils in the classes, good acoustics in the classrooms, exclusion of toxic factors such as tobacco, etc.

Systems of heating ought to be specially supervised. Teachers should be made aware of the danger of carbon monoxide poisoning and informed of the early symptoms in order to be in a position to detect these either amongst their pupils or in their own case (Agasse-Lafont).

The campaign against nervous derangements is highly important not only in regard to the protection of the patient's health but also as regards the moral and intellectual well-being of the scholars. Rigorous vocational guidance should be practised with a view to eliminating from Normal schools all subjects predisposed to affections of the nervous system, and particular attention should be paid to personal hygiene, physical as well as moral, and the teacher should fortify his mind with humanitarian and moral culture in order to prevent depression due to moral conflicts and unforeseen events liable to upset the equilibrium of the inexperienced teacher.

While in account of certain of the above conditions the teaching profession may be considered as a difficult career, it possesses the great advantage of long annual holidays. This period of rest should be utilised by the teacher with a view to developing his physical activity, and wherever possible he should profit by the opportunity for leading an open-air life (country), in practising sport which is not unduly strenuous, for instance walking, rowing, swimming, etc. He will thus achieve alternation of physical habits providing the best guarantee for conserving his health and combating pathological manifestations arising out of the professional life which he is obliged to lead, during periods of scholastic inactivity.

BIBLIOGRAPHY.

Scientific Management and the Human Factor

Just as the engineer studies the output of the machinery, endeavours to increase its productive power without injuring its lasting powers and endeavours to use it in the most economical way, so the physiologist, regarding man as a machine sui generis, tries to increase his output without tiring him out and having regard to the greatest economy in working. The object of industrial physiology is to organise work in greatest harmony with man's functional power.

The scientific aspect of human work has for long occupied man's thoughts. To go back only to the seventeenth century it may be recalled that Galileo (1644) had the curiosity to apply his studies on the principles of simple machines to the human frame. Towards the end of the same century, Sauveur, Philippe de la Hure and Amontons took up the study of the human machine, notably as to the relation of force and physical weight, and on the carrying of loads. La Hure it was who fixed on 65 kg. as the upper limit for the carrying of loads, although he would allow 75 kg. for loads carried on the shoulder or in walking along a level road. Amontons interested himself especially in the rapidity of the rhythm of work with the object of determining quantitatively the daily task of the worker. Vauban dealt rather with the question of supervision, which he regarded as a means of increasing production. In his ground-levelling operations he came to the conclusion that output stands in direct relation to the load carried by the workman and the distance he has to traverse. De Carus (1729) wrote a popular work entitled "Traité des forces mouvantes" for the use of workmen and of his contemporaries. Bélidor (1729) continued the work of Vauban; he expressed in the following words his own ideas as to length of hours and wages: "It is certain that ten hours a day for a man who has his own interests to consider is equal to fifteen in another who has his hours regulated for him. To push men further is to cause overstrain and to expose them to illness and fatigue."

The eighteenth century was the epoch of Lavoisier. It was further enriched by the researches of Coulomb (1736-1806) on the "Force of Man", in the course of which he discussed work in injurious trades, weight carrying, manipulation of windlasses, cranks, etc. Coulomb was aware of "the method of alternative short spells — of carrying loads with intervals of rest as being the best for the animal economy". It was he who first stated that output "varies with the skill, selection of the individual, and food", and took account of the factor of psychology in his investigations. He recommended that a good workman on piece work should be kept under observation, but at the same time, so as not to affect the immediate job in hand, should not know that he was being watched.

In the nineteenth century Dupin and Poncelet undertook a campaign in favour of the distribution of scientific and professional knowledge among workpeople. Finally the researches of Chauveau, Atwater, Moaso, de Saussure, Rubner, Zuntz, Dubois, Reymond, Loewy, Marey, Braune, Fischer, Demeny, Liesse, Claude Bernard, Humbert, Imbert, Jantier, Durig, Amas, Maggiora, Hertlitza, Atzler, Catcart, etc., are too near our own time for all not to be acquainted with their work. They relate mainly to laboratory research, the practical application of which up till now has not been very great. Economists have likewise devoted their attention to the problems of the scientific organisation of industry. Thus, Adam Smith interested himself in the division of work and gave consideration to the economy of effort and to the technical division of work. He was followed by Babbage and J. Stuart Mill in Great Britain, by J. B. Say, Garnier, and Clement in France, Walker in America, and by Von Hermann, Cohn, Brentano, and Abbé in Germany. Societies commenced to interest themselves in these problems,
thus it was that towards 1910 the German Society for Social Politics started an enquiry into the subject of vocational selection, the nature of the occupation, the importance of work in modern industry, etc.

The distinction between what is called scientific management and what is meant, on the other hand, by the physiological organisation of labour is of importance.

By scientific management is generally meant the method thought out and developed by the American engineer W. Taylor, the principal lines of which it is proposed to describe here.

"Taylorism" has not the same object in view as industrial physiology; increase in production is sought by the one and increase of human output by the other. These objects are not opposed to one another; the task of the science of the future and of industrial physiology, indeed, will be to co-ordinate them into a single system.

Scientific management is a very big thing including financial, technical and social questions. Industrial physiology on the other hand has a more limited field; it only takes up one side of the problem and supplies scientific management with information suitable to a general solution.

**THE BASIS OF TAYLORISM**

The problem set by Taylor is as follows: to find the conditions of work which will enable a workman to perform a maximum amount of work with a minimum of fatigue, that is, to apply to the machinery and the man the formidable economic law of how to obtain the maximum effect with the minimum effort. For this it is necessary:

(a) to alter the machinery — a technical expert would be useful here whose duty it would be to study the changes necessary in the plant, having always in mind technical progress;

(b) to select the workers — dismissal consequent of those who after a certain length of time are considered to be incapable of furnishing the prescribed output;

(c) to reduce the operation to its simplest terms — that is to say, split it up into the simple elements of which it consists, and, with the aid of a chronometer, choose the method which accomplishes it most rapidly in order to suppress all unnecessary useless movements;

(d) to instruct the workmen — when after long tests and theoretical calculations, the best technique for the job in question has been arrived at, it is taken as the standard to be taught to, and learnt by, all the workpeople;

(e) having clearly defined the job, to give incentives in the shape of prizes to those who deserve them; most (a special office has the task of fixing each time the prescribed daily output and the prize is awarded to those who attain it).

Such are the principal laws of Taylor's method. It would be hyperbolic to describe it as "scientific"; "rational" would be more exact.

This method, provided that it is linked up with wise collaboration on the part of the workers on the one hand and of the management on the other, does admit of the output of an industry being brought to its maximum.

**Physiological Criticism of Taylorism**

Taylor's system, looked at from an industrial point of view, certainly succeeds in increasing production, as has been empirically demonstrated by the industries that have adopted it. But looked at from a biological standpoint it would appear inadequate in many respects.

(a) **Rigidity of the Method**

If, theoretically, a perfect adaptation of man to his occupation and an extreme diversity of the means of work are admitted in practice, it is difficult to have an installation of machinery sufficiently varied and a sufficiency of manual labour to apply the system rigorously. Consequently a compromise has to be made in regard to the selection of workers unless a large number of men are to be dismissed. Many, indeed, are dismissed who with will, application and patience, in virtue of latent human energy, might become in time very capable workmen. This is why recourse is had to practical rather than to physiological and psychological tests. But a careful and stringent selection, it is evident, is needed both in the interests of industry and of the workman.

(b) **Automatism of the Workman**

By Taylor's system the workman is turned into a mechanical unit, which effects its work just like the running of a machine. That is to say, that the actions of the workman in the course of time become automatic, thanks to training and practice. This may appear to be advantageous from a biological point of view, because auto-
matic movements do not call for sustained attention or an effort of will, and therefore involve the minimum of energy, nor do they add nervous to muscular fatigue.

While however from the point of view of output, automatism may appear an advantage, morally it lowers the workman in his own eyes, so that he comes to regard himself as a mere machine. Further, the continuous and stereotyped repetition of fixed movements brings about hypertrophy of certain groups of muscles, and, in the case of the young whose development is not complete, deformities of the bones may even be produced.

(c) Mistaken Value of the Methods and of the Physiological Results

In the problem he set himself to work out, Taylor was preoccupied with the question of time. He looked upon man as a piece and tried to convert him into one, while the better course would be to adapt the machine to the man.

The human motor is governed by laws other than those of a machine, and the difference is in the phenomenon of fatigue. Taylor judged the degree of fatigue of the workman by the extent, greater or less, in output. But such an appreciation cannot have the value of a strictly objective experiment.

However clever the observer may be, he cannot gain such precise information as is furnished by a scientific examination. Evidently a clearly defined task can be carried through, up to a certain point, without overstrain, provided that the work to be performed is wisely planned and takes into account the physiological powers of the workman. But in order to judge whether a task is, or is not, within the physiological capacity, an examination of when and how the functions of the body become modified is of importance. It is a matter of common knowledge, however, that in the present stage of scientific progress an objective test of fatigue is by no means easy. To acquire this information several kinds of tests have been proposed. Taylorism must be completed by technical measures calculated to aid the workman in the accomplishment of his task; and just as the machine requires the care and attention of a technical expert, so the worker requires care and attention on the part of a physiologist who must supervise and study each case.

The mechanical side of Taylorsim, however, has undergone a change with time. While at the beginning its advocates were very anxious for the transformation and utilisation of industrial technique, so now the modern developments of "scientific management" are more and more preoccupied with the human factor. In the course of the last few years the study of industrial physiology and psychology have increased. Methods capable of preventing strikes and ensuring a constant co-operation between the different organisations of productive have been methodically worked out. These researches are to-day part of the scientific organisation of labour in America, and have the same object as the strict application of the principles of Taylor in the factory and workshop. The proof of their success is seen in the changed attitude of the workpeople, who recognise that the efforts made, with the object of increasing production, have become more and more humane, and that more attention is paid to the human side and to the health of the workers.

In Europe, in spite of the deceptive experiment made before the war, the necessity for considerable effort at reconstruction has started afresh the problem of the scientific organisation of labour. Employers and employed have declared they are at one, in principle, in recognising the value of truly scientific methods as alone capable of meeting the necessities of production, running parallel with the social needs of the working class consumer. The International Labour Office interpreted this general sentiment when it proposed, in 1920, to institute a service of industrial technique, the object of which would be to study internationally problems bearing on scientific management. This view took concrete form when, in conjunction with Messrs. Filene and Dennison, the Labour Office leased the International Management Institute.

At the present time a large number of scientific and technical experts expend their activities in the study of the problems of scientific management, and it can truly be said their aim and object are to safeguard the human side.

Foremost amongst the work effected by these experts should be mentioned the enquiries of Atzler, Biasi, Buyse, Ferrannini, Frois, Giese, Joteyko, Lahy, Langlois, Lipmann, Moede, Myers, Patrizi, Pioskowski, and the great Pleadian constellation of British investigators who work under the Industrial Fatigue Research Board of Great Britain, of which the Secretary is D. R. Wilson.

Next comes another class of investigator, the number of which con-
Rhythm of Machinery

In industry the workman is bound as to his own activity by the inexorable rhythm of machinery which it is often beyond his capacity to keep pace with. For instance, in the textile industry, the number of throws of the shuttle that a weaver can manage to make is from 75 to 80 a minute. At the present time a weaving machine can make 33,000 throws in ten hours. The most that the strongest and most intelligent workman can manage is from 18,000 to 20,000, and a woman 13,000 only. This example illustrates what a continuous effort a man must make to keep pace with a rhythm which is not physiological, is unduly rapid, and leaves out of account, moreover, the sterile functioning of machinery (Viale). This is still more evident in Lancashire, where a weaving machine can make more than 80,000 throws in ten hours with an ordinary output of about 80 per cent., so that the number of throws a workman has to attend to reaches 64,000.

In the organisation of the future, harmony must be sought between the machine and the worker; on the one hand, a psycho-physical, intelligent selection of workmen, and endeavour to transfer the phenomenon of fatigue to the functioning power of the machine. The speed of the machine undergoes no variation whatever be the hour of the day, while, in the case of the worker, fatigue goes on increasing, and a rhythm of work which may be suitable at the commencement becomes excessive at the end of the day. Theoretically it should be possible to slow down the machine in proportion to the lapse of time, following a curve which would correspond exactly with the degree of fatigue. This ought to be an extremely useful innovation in industry in the future, and should make allowance both for economy of the motive and of the human capacity. To load anyone up with work who is already fatigued involves expenditure of an amount of energy very much above the normal.

Rhythm of Work

Where on technical grounds the movement of the machinery cannot be altered, then a rhythm of work should be adopted which would not be likely to induce fatigue. The physiology of work has taught how important it is to have a break between two periods of work. With pauses suitably arranged the muscles seem to be inexhaustible. The labor of the fingers of the right hand, for example, loaded with 6 kg., if they contract only every ten seconds, show no signs of fatigue. The ideal rhythm may not be the same for all the muscle groups or for all operations: it must be determined for each particular case.

Monotony of Work

The monotony which characterises machine work has already been referred to. This exercises a double influence on the body and spirit of the

Physiological Principles of Scientific Management

Fatigue (excluding certain transformations of energy which are comprised in the cycle of the general principles of thermo-dynamics) is the prominent fact which distinguishes man from a machine in function. The physiology of fatigue has as its task to endeavour to overcome fatigue, which is the most striking feature in the technology of the human motor. Fatigue diminishes muscular power, weakens the power of attention, causes the movements to go more slowly, and increases the number of accidents, while at the same time raising the coefficient of loss in the working of the machinery.

Fatigue, accumulating in the system, is the cause of overstrain and interferes with nutrition. It modifies the growth of young persons, and, in women, predisposes to miscarriages and difficult labour.

Since there is no practical indicator of early fatigue, the necessity arises of organising manual labour so as to prevent fatigue and overstrain caused by the accumulation of fatigue.

Monotony of Work

The monotony which characterises machine work has already been referred to. This exercises a double influence on the body and spirit of the
workman. Cevidalli, for instance in regard to physical influences, has laid stress on the skeletal deformities and visceral changes, especially in the young. While recognising that uniformity is a necessary condition for a given task to be accomplished quickly with the minimum expenditure of energy, it should be remembered that if this activity is of a local nature then the organism works at a disadvantage and some compensatory action should follow. This compensation can best be obtained by means of physical exercises, sport of one kind or another, giving play to the muscles and joints that have been kept in a bad position or in a state of inertia.

The unfavourable effect of monotony on the psychic state of the worker is no less important. Constant repetition of the same movements has been found, in the end, to make the workman lose interest in his job, and he does his task entirely without, or with the minimum, attention and will (Buyse). The fact that workmen take on the job they are set to without much objection is not to be taken to mean that it suits their mentality; it is only the expression of necessity, of its money value, or, perhaps, of indolence (Donaggio). When it would appear, adapt themselves more readily to monotonous work than men. Workpeople welcome change and work with pleasure at a new job with the object of becoming good at it so as to secure greater output. But as soon as this output is reached without effort they lose interest again and the desire for a change makes itself felt (Donaggio).

To obviate this state of things the workman should be given the chance of employing his mind during his work. This, however, is only possible with his intellectual faculties. These he can acquire during his leisure time, and thus indirectly monotonous work raises the question of how the man can best employ his leisure. Donaggio presented a resolution with this in mind at the Italian National Congress of Medicine held in Venice in 1924, to the effect that, in order to combat the monotony of work, the question of the organisation of leisure should be looked upon as an important matter quite apart from the organisation of hygiene in the factory.

**Load Placed on the Muscles**

When it is not considered economical to slow down the rhythm of shifts of workmen, or to introduce pauses in their work, it would be well to lessen the load (weight of tools, piece work, etc.), in order to arrive at what physiologists call the final maximum weight, thanks to which the value of the contractions, muscular activity, and output, do not fall off, even although work is carried on for long hours.

Even Taylor recognised overstrain, in selecting for each workman the task proportional to his strength and capacity.

**Energy Requirement in Work**

By analysing the movements in carrying out a set task it is important to get the workman to dispense with all movements which do not assist in the accomplishment of his job and only constitute a useless expenditure of force.

The abolition of these so-called "parasitic" movements makes the act more rapid and enables a better output to be achieved; it is the object of Taylorism. But instead of Taylor's formula of "Find out the most rapid technique", from the physiological standpoint we should substitute the formula "Find out the technique which calls for the minimum amount of force". The two formulae cannot always be combined. Study of human energy producing power has already led physiologists to lay down certain rules of general application which it would be well to adapt to the technique of industrial operations.

Movement rhythm, its extent, the load on the muscles may vary while carrying out the same piece of work. Our body has been shown experimentally to consume less energy when it uses more movements in lifting a light weight, that is with a weight always the same the work can be done with frequent and short movements, or few and large, just as marching can be done with short but rapid steps, or with long and slow ones, or a staircase can be climbed step by step or two by two. In this case similarly the human machine consumes less force when the work is broken up and the movements are more frequent but shorter.

Moreover, in maintaining a constant rhythm a workman will effect his task more easily by wide movements with light loads and short movements with heavy weights. In every case strain is the thing to try and avoid. To sum up, the greater the number of muscles taking part in a piece of work, so as to distribute it, the more is the consumption of energy reduced. As a matter of fact, two-handed work is more economical than one-handed. Work done with the left hand (even in left-
handed individuals) involves greater expense to the organism than when it is done with the right. It is rational, therefore, to teach children to use the right hand in preference to the left.

The factor of environment seems to have a great influence on the amount of output. Work, for instance, at a high altitude is less economical than down below; work at a low temperature makes less demands than at a high one. On empirical grounds an increased ration is given to Alpine soldiers.

Other factors may influence work, such as light, ventilation, tobacco, alcohol, the emotions, etc. Up to the present these problems have been treated not from the point of view of energy-producing power, but from that of industrial hygiene, in taking account of the mechanical output which a workman under certain conditions can furnish. Really in the problem of human work no solution can be given which takes into account only the question of the energy-producing power.

Individual Factors

Man, however, is not merely a machine. He has also a soul. All human work has a psychological, individual aspect, of which it is important in the highest degree to take account in psychological organisation. Age, sex, and race have their importance, but it is not yet known if a given piece of work costs a woman or a child most or to what race the workers belong who can produce the highest output. Mention only is made of the result of certain ergographic tests tending to show that women seem to be more apt than men in preserving in work which does not call for big efforts. Thus, women are said to be better at repetitive work, men at work demanding more or less expenditure of energy. This is not the place to discuss these details, which have not as yet been sufficiently studied from the scientific point of view. (See article "Women's Work ".)

Hours

Legislation in every country has recognised the need for putting a limit on the number of hours worked in industry. Adoption of the eight-hour day is a wise measure. In the distribution of hours, however, sight should not be lost of the advantage of dividing the hours of work rather than demanding continuous labour. Indeed, as has been demonstrated by ergographic and chemical means, the last hours of continuous work, as well as overtime work, cost a great deal more than the first.

By reduction in the duration of work output is not diminished. This has been recognised, even on the employers' side. An employer has for instance stated that the hours of work in his factory at the commencement of the war were increased to fifty-three per week, and in the case of women was extremely surprised to find they lost on an average fourteen hours each per week. These fourteen hours of lost time brought the weekly hours of work down to thirty-nine for each worker. "That cannot go on", he said, "let them come an hour later each morning and let them go an hour earlier in the evening ". The week's work was then reduced by twelve hours. The employer then found that with a week of forty-one hours the time lost was on the average one hour per worker per week. They worked forty hours instead of thirty-nine as before; but he found further that during these forty hours (after deducting the lost time) there was a weekly increase in output amounting to 44 per cent. (Lord Leverhulme).

Stanley Kent laid stress on the fact that "the time lost by factory operatives makes on an average 10 per cent. of the day's work. The total sum of lost time varies with the length of the day's work and would seem to be dependent on fatigue ".

Workpeople react, moreover, against a system leading necessarily to exhaustion and a tradition of slowing down. As arranged, probably automatically, and as a kind of physiological "self protection " (Kent). In taking account of this state of things, the British Committee which was appointed during the war to study the question of industrial fatigue stated: "Without some conscious or unconscious slackening of effort indeed during working hours of improper length in the past, the output might have been even more unfavourable than we know it to have been for the hours of work consumed ".

Vernon, who studied the effect of the reduction in the number of hours worked daily on output in the case of different kinds of industrial operations, made interesting observations in studying the milling of the caps of shells by young persons where acceleration was technologically impossible. "Every reduction in the duration of work time required a strict time limit; nevertheless after reducing the weekly number of hours from 72$\frac{1}{4}$ to 54$\frac{3}{4}$ — a reduction of eighteen hours or 25 per cent. — the observer could show that the decrease in the total weekly output
was very small — it was only 3 per cent — and that consequently there was an hourly increase in output of 29 per cent. How could this be possible seeing that the rhythm of the operation proper could not be accelerated?

Vernon thinks the workers could only obtain this increase by feeding the machines more continuously during the whole middle of the day. They were running (quoted by Milhaud). This meant that before the daily reduction in hours an automatic slowing down existed to preserve the workers from undue fatigue.

Finally, as further evidence in favour of a reduction in the duration of work, there may be quoted here the conclusions drawn up by an official committee appointed by the Public Health Service of the United States where it is stated that the principal characteristic of the system of eight hours is the constant maintenance of output at the same level, and that the principal characteristic of the ten-hour day is the progressive diminution of output.

PHYSIOLOGY OF REST

The physiology of rest constitutes a principal part of industrial physiology. This fact has been recognised by physiologists and medical men and mention may usefully be made here of the principles which have been laid down on the subject by the Association of German Industrial Surgeons (Arbeitsgemeinschaft der deutschen Gewerbeärzte):

(1) All prolonged work — physical or physiological — ought to be broken by rest periods. If that is not done fatigue increases to excess, while the capacity for output diminishes considerably. The necessity for rest periods has been established by scientific experiment and practical experience.

(2) The rest periods ought to come during the period of work itself. It is physiologically wrong to do away with periods of rest during worktime on the ground that sufficient rest can be obtained after work is over. The right time for and length of the rest period depends on the nature and duration of the work. Further, other external factors often have to be borne in mind (train service, etc.).

(3) Normally output diminishes towards midday. The physiological curve of the daily activity shows a fall, thus indicating that that is the period for the longest break for rest and dinner. With this point of view it is necessary to fix on an effective break of at least an hour, provided that the workman has not to go a long distance from the works to the place where he has his meals. When the distance between the factory and the home is considerable the break should be proportionately increased. The same provision should be made in the case of persons employed on poisonous materials in order to allow them sufficient time for washing and changing their clothes.

A canteen should be provided close to the factory for workmen who live too far away for them to go home for meals. Brightness in the equipment of the canteen contributes to make it restful.

(4) Continuous work (as in England) without breaks has been the custom in large cities. But despite some apparent advantages the procedure has considerable disadvantages in the point of view of the physiology of work, which shows that this arrangement of the daily round is not a sound one. A preliminary essential condition for a long spell of work is a good nourishing breakfast before commencing work and a short break at midday for lunch, which should include at least one hot dish (tea or soup).

(5) In addition to the principal rest pause secondary pauses should be introduced. Some breathing or easying of this kind are required for certain kinds of work. Where this is not the case a short pause of from ten to fifteen minutes should be made in the forenoon and third afternoon. The best time for, and duration of, these short pauses depends on the special conditions of work. Very early start in the morning and long travelling before arrival at the factory, for instance, make a fairly long rest pause necessary early on in the morning. In some instances hours described as "short hours" (Kurzstunden) (fifty minutes' work and ten minutes' rest) are very useful.

(6) The custom recently adopted of reducing as much as possible, or doing away altogether with rest periods is contrary to all principles of industrial physiology and is exhausting for those who have to carry out the work. This is true for the healthy adult worker and still more so for the weak and the ailing, and for women and children.

(7) Where the principles of industrial physiology receive adequate consideration, working energy is maintained, total output is increased and possible employment is prolonged.

Neglect of these same principles leads to insufficient repair from the fatigue engendered by work, to early exhaustion, and to ill-considered utilisation of the most precious asset the workman possesses: his capacity for work.

The industrial surgeons of Germany consider it their duty to call attention to the importance of these principles of industrial physiology. But it is, moreover, the duty of the workpeople themselves and of their leaders to resist any unreasonable shortening or stoppage of their rest periods.

It is well known that the muscles ought to recover their strength and power in order to reach their maximum output. Thus, to restore the body it is necessary to rid it of the products of muscular
exchange (kino toxines, lactates, salts of potassium, etc. and supply the muscles with fresh energising materials (carbohydrates, fats, proteids).

The body loses its toxins when resting, especially if the place is well ventilated, because the oxygen burns up and destroys the waste products of work and helps in rebuilding the energising material in the muscles.

The disintoxication of the fatigued body can be secured by drinking fresh water, or better still bouillon or salt solution, rather than alcoholic beverages. Elimination of toxins should be facilitated by the circulatory and renal functions, and disturbance of the heat-regulating mechanism of the body, so frequent among workmen, should be avoided.

The second phase, which is that of recovery of the sources of muscular energy, is obtained not only by an adequate supply of fresh air, but also by sound feeding, in which should be combined carbohydrates (glucose being the most consumed substance while at work), fats, proteid substances and vitamines. Whether a vegetarian or mixed diet is best is not known.

The principles which have been briefly discussed here belong to the domain of industrial hygiene. They can bring man's output to its highest level without interfering with the harmony of the functions of the body.

Seamen (Pathology and Hygiene of)

Two classes of work are carried on on board ship, one of which has to do with the navigation and safety of the ship, effected by sailors and engineers, and the other with work similar to that carried on ashore, done by bakers, domestic servants, musicians, radio-telegraphists and the like.

The latter class in no way differs very appreciably from similar industries carried on ashore, but the former class, on the other hand, possesses special characteristics.

The crew entrusted with the nautical operations include the deck-hands and the engineers.

The deck-hands include the seamen properly so called, who carry on the work of navigation, cleaning, loading and unloading of the holds; the engineering staff are in charge of all the machinery and allied services, and include the engineers and firemen.

On board ship the division of work into specialised categories is carried to the extreme limit.

The work done by each class of the crew is different in nature and duration, in port as well as on the voyage. However, in ships with small crews both deck-hands and engineering staff may do work inappropriate to their grade.

Conditions of Work

The conditions of work of the crew are contingent, i.e. common to all the personnel, and intrinsic, varying according to the two groups.

The first comprise conditions of (a) place, (b) time, (c) duration, and (d) training.

(a) In port, a seaman's work is moderate and perfectly regularised by a time-table, just as in factories; night-work is limited to care of the ship, both internally and externally. When at sea, however, work is continuous, and is especially fatiguing in rough weather.

(b) A seaman must work whatever the weather, and when it is bad his work becomes arduous.

(c) The duration of work is fixed by the engagement contracts; in some countries it is eight hours a day divided into two parts of four hours each. The time-table cannot, however, be strictly observed, as in the case of
factory workers, for the state of the sea, the handling of the ship on entering and leaving port, and other circumstances make extra and heavy work inevitable. A sailor’s work has two disadvantages: discontinuity of sleep and the absence of any weekly rest during the voyage.

(d) Training is the best preventive against physical fatigue, and this explains why men who are not accustomed to life afloat, such as cadets and cabin-boys, waste a good deal of nervous energy and muscular strength, and experience far more fatigue than do seasoned sailors.

In examining intrinsic conditions it is found that the work allotted to the deck-hands is as follows:

(a) Navigation: concerned with steering, anchors, windlasses, masts and boats. All of these operations are characterised by being performed in the open air.

(b) Cleaning the various parts of the ship, including washing down the decks. — Tons of sea water are pumped over the upper decks every morning; the sailors generally paddle about with bare feet, and only occasionally wear rubber boots.

(c) The loading or unloading of the holds in ports. — This is done by some of the deck-hands, helped if necessary by the dockers in the ports.

(d) Painting. — Includes taking off an old coat and applying fresh varnish.

The engineering staff is engaged on the following processes:

(a) Control and supervision of the machinery. — The mechanical power on most steamships is obtained by burning coal or oil; electric power, obtained by transforming the thermic energy of Diesel motors, is now also used. The work of the engineering staff is not so fatiguing from a physical point of view; it is more mental than manual and calls particularly for alertness.

(b) Supervision of fires and boilers. — The furnaces for burning coal and oil are arranged in compartments, the capacity of which varies from 100 to 400 cubic metres. The ventilation required to maintain combustion is so great that it calls for a renewal of the air sixty times an hour. This necessity does not exist on ships with internal-combustion engines; in consequence, the ventilation in those cases is less active. The labour on coal-burning ships demands a great expenditure of physical energy, with a reduced consumption of mental force. On oil-burning ships, the oil is distributed to the furnaces by sprayers, thus eliminating the manual labour, and the necessary work is reduced to superintending the apparatus.

(c) Loading coal into the bunkers and moving it from the bunkers into the stoke-holds. — The firemen employed on these processes work in cramped positions, in places which are narrow, very hot, poorly ventilated and in an atmosphere charged with very fine dust. On large ships they have, in addition, to traverse some distance along very narrow openings carrying heavy loads.

(d) Loading oil on oil-burning ships. — The supply is carried out mechanically by motor-pumps, which draw the oil from reservoirs and pump it into the tanks on board.

(e) Examination and painting of double bottoms. — There are spaces arranged between the two bottoms of a ship, which usually remain empty or are used as cisterns for drinking water. Firemen have to visit these spaces from time to time for the purpose of drying and renewing the covering of the walls.

**Sources of Dangers**

Work in the open air is carried on whatever the weather, day and night, exposing the deck-hands to meteorological conditions and to the extreme fatigue associated with night-work.

The daily washing down of the decks, carried out with their feet in water, affords sailors, when they have become accustomed to it, an excellent means of hardening their bodies against rheumatism.

On the other hand, work in the bunkers exposes the men to the action of physical agents, like dust, to chemical changes in the air, and to such biological agents as pathogenic micro-organisms.

The dust is of a very varied nature. It reaches its maximum when such material as grain or coal is put into the holds pell-mell; but it is relatively slight when the material is delivered in sacks. The nature and solubility of the substances with which it comes in contact affect the action of the dust: it may act mechanically and locally on accessible mucous membranes and the skin, or chemically causing general poisoning.
The chemical composition of the air in the holds may, owing to reaction with the materials they contain, be affected by qualitative changes, i.e. by diminution in oxygen, due to absorption by such materials as coal, maize or resin, or by qualitative changes, due to gases and fumes given off by such materials as petrol or asphalt, by gases formed by combination with the elements of the air, giving rise to methane, carbon monoxide, etc., or by gases liberated by the processes of decomposition, in the case of undressed skins, guano or ferro-silicium.

The loading and unloading of materials affected by pathogenic agents or of bunkers where animals, such as rats and insects, have infested, are carriers which act as a source or as carriers of such infection render the crew liable to contract diseases transmissible by contagion and by inoculation. From this point of view, skins, bristles and rags may transmit anthrax or pyogenic infections, and horses may transmit glanders to the men who have to tend and clean them.

The work of chipping and scraping the sides of the ship painted with varnishes and colours may originate a considerable quantity of dust which is injurious when the covering materials contain lead compounds. The use of rapidly drying varnishes in poorly ventilated places may give rise to very poisonous emanations.

Manoeuvring machinery for raising the anchors or for controlling the steering may occasion injuries which become manifest during the voyage. The work of loading and unloading the holds in ports at times causes violent injuries.

The sources of danger for the engineering personnel lie in the physical state and chemical composition of the air.

When the engines are running, the air temperature in the principal engine-rooms is about 40° C. Humidity is also increased. In the secondary engine-rooms the air temperature often exceeds 45° and the moisture reaches saturation point. On the other hand, in the stoke-holds the temperature and humidity of the air are not so high as in the proximity of the engines. Hence a prolonged stay in these places — as well as the heat variations, great and rapid, when passing from overheated places into others less heated — throws a heavy strain on the mechanism of the body. Nocht found in f iremen working in stoke-holds temperatures (under the armpits) varying between 37.5° and 38° C.; but Nespor, under identical conditions, observed it to be in the neighbourhood of 38° C. and the pulse about 140. In the principal and secondary engine-rooms, Belli observed that the engineers stood temperature rising to 60°-70° C. without trouble, provided that the humidity of the air was not raised (see below, Pathology). In the engine-rooms on steamships the maximum quantity of carbon dioxide found by Belli was 0.70 per thousand; in the ordinary way it did not exceed 0.50.

Schwartz in 1929 reported the results of his health research made on board during a voyage round Africa. In the engine-room and the stoke-hold the hygienic conditions during navigation in the tropics were not good, even in first-class ships. While the work is not too hard, except in the case of urgent repairs, it requires, on the other hand, a heavy burden of responsibility from the men. In the stoke-hold the conditions are better, but the physical labour is much harder.

The ventilation in the boiler-rooms is so good that the air is perfectly pure beyond the immediate vicinity of the furnaces. On motor vessels, where the exhaust from Diesel motors is discharged outside, theoretically the air should not be liable to any change from the products of combustion.

Another cause leading to vitiation of the air of workplaces is dust on vessels using solid fuel. The taking on board of coal into the bunkers and moving it to the furnaces give rise to a great amount of dust which, on an average, reaches 2 grm. per cubic metre of air.

On ships burning oil small quantities of volatilised oil escape from the joints, the pipes and valves, and, being heavier than air, settle in the lowest parts of the places.

In the empty spaces of the double bottom, which are constantly kept closed, the oxygen is absorbed by the varnish with which the sides are covered as a protection against rust.

The supervision and handling of the engines, and associated services, may cause serious occupational injuries, which are common among firemen.

**Statistics**

According to some American statistics, provided by M. R. King, relating to the sailors of the Eastern Squadron treated in hospital in the ports of Manila, Philippine Islands, from October 1920 to February 1923, the classification of the various diseases was as follows:
In a report of the British Admiralty published in 1927, which gives the health statistics of the Navy for the year 1924, the morbidity and mortality rates for the year 1924, compared with those for the three preceding years 1921-1923, are as follows:

Disease is shown to have been a much more frequent cause of mortality among Lascars than among other members of crews, although it was the principal cause of death for all cases. About three-quarters of the deaths among Lascars were due to disease; of this rate, 20 per cent., were due to tuberculosis and 18 per cent., to pneumonia. Among seamen other than Lascars a little over half of the deaths were due to disease, the principal affections being tuberculosis (12 per cent.), pneumonia (10 per cent.) and cardiac affections (10 per cent.).

The principal causes of death from trauma and accidents were as follows (in percentages): suicides or supposed suicides, 13; falls into the water from quays and accidents ashore, 16; falls overboard and fatal accidents on board, 10; boats lost, 9; disappearances at sea, 9; falls down hatchways, etc., 8.

Deaths among crews of fishing boats as defined by Part IV of the Merchant Shipping Act, 1894, totalled 109. Of this number, 35 were due to shipwrecks, 50 to other accidents, including homicides and suicides, and 24 were due to diseases.

According to the calculations of the Registrar-General of England and Wales, the general mortality of seamen was found to be 76.8 per cent. in excess of that of all occupied and retired males. As regards tuberculosis, this excess is represented by 35.5 per cent.; for violent causes of death the general average is five times higher in the case of seamen. As regards the mortality for various other causes, high percentages have been recorded for infectious diseases: pneumonia, influenza and other respiratory affections, rheumatism, abscesses, wounds and other septic conditions.

The final invalidity of officers and seamen is ascribed to infectious diseases (tuberculosis, 166 times; primary syphilis, 6; secondary syphilis, 26; gonococcal infections and their sequelae, 253); to nervous and mental troubles (diseases of the spinal cord, 7; paralysis, 4; epilepsy, 35; neurasthenia, 58; other affections of the nervous system, 71; insanity, 31); to diseases of the special sense organs (eyes, 174; ears, 116); to diseases of the circulatory system (cardiac affections, 67; veins, 11); to diseases of the respiratory system (bronchitis, 12; asthma, 4; pulmonary fibrosis, 41; pleurisy, 3); to diseases of the digestive system (stomach, 15; intestines, 6; hernia, 35); to diseases of nutrition and metabolism (diabetes, 1); to diseases of the genital system, the locomotor apparatus, and of the skin and the cellular tissue (skin, 12); to diseases of the urinary system, neoplasms (4 cases), alcoholism (2 cases), and wounds.

In Germany, H. Ruge found that infectious diseases occupied the first place among the diseases of seamen: typhoid fever, typhus, dysentery, and, in the tropics, yellow fever and malaria.

These returns referred chiefiy to the times of the old voyages of discovery: At the present time the diseases of seamen in the German mercantile marine can be divided into four principal groups: those caused by exposure to cold, mechanical injuries, inflammation of connective tissue and venereal diseases. Under the diseases caused by exposure to cold are tonsillitis, laryngitis, bronchial catarrh, pleurisy, catarrh of the lungs, and injuries of the musculoskeletal system and articulations. The engineers, or rather the firemen, are the most affected. But mechanical injuries are more frequent and more dangerous on sailing ships, where the mortality has reached 39 per cent., whilst it is only 5 per cent. on steamships. Accidents in the engine-rooms are quite unusual. As regards division by categories, it is found that recruits are more affected than the old hands, and that accidents are more common on Monday and at the beginning of the week than towards the end; 55 per cent. of accidents occur during work.

Boils, which also cause incapacity of long duration, are generally situated on the arms, and occur more often among firemen than among seamen, and they reach their peak in summer, with a recrudescence in the autumn, when new hands are recruited.

In Italy the mortality among those drawing pensions for invalidity from the mercantile marine for 1914-1924 remained at a much lower rate than that of the civil population.

The various statistics, although fragmentary, give the impression that, of recent years, the hygienic conditions of the merchant service have become satisfactory in Italy.

This improvement, of which it is impossible to determine the exact extent, but which remains nevertheless established fact, is due, in part at least, to measures recently adopted on behalf of the merchant service.

The causes of the most widely spread diseases among Italian merchant seamen, as everywhere else, are venereal diseases (nearly 16 per cent., according to the Sickness Fund of Julian Venetia, 1926); venereal diseases (in 1924, 13 per cent.; in 1925,
Pathology

In an attempt to examine the health of seamen by reference to sickness returns supplied by the merchant services, it must be borne in mind that they are even less complete than those of mortality. In fact, the particulars are supplied only by shipping companies, trade unions or insurance institutes, and are not complete, dealing only with one group of persons and with the objects for which they have been prepared. Naval statistics are not of any more use, as service in the mercantile marine and in the Navy is not exactly homogeneous; the first includes men of all ages, from cabin-boys to old seamen, whilst the second is made up for the most part of men aged twenty to twenty-five years; the first group concerns a personnel collected haphazard, and the second men selectively, after a medical examination on engagement and in accordance with regulations. Nevertheless, the two groups are analogous as regards nautical work properly so called; in consequence, where the particulars for the merchant service are lacking, it is reasonable, on analogy, to examine the state of health of the crews of warships.

Infectious diseases are found to be the most common. According to the health returns of the British mercantile marine, given at the Oslo Conference, venereal diseases constituted 50 per cent. of all diseases. The statistics of the Julian Venetia Sickness Fund only showed 8.3 per cent.

Pulmonary tuberculosis is a serious scourge among crews, especially among the deck-hands. In France it is responsible for 9.50 per cent. of cases of sickness; in Germany 10.1.; in Italy, according to the statistics of the above-mentioned Fund, approximately 16 per cent. Nocht and other authors regard tuberculosis as an occupational disease of seamen.

Plague and yellow fever affect particularly the bunkermen, when there are plague-infested rats in the holds, or infected stegomyia mosquitoes.

Affectsions of the respiratory system, bronchitis and lobar pneumonia, and of the locomotor system, acute articular rheumatism, are common among cadets and cabin-boys, for their bodies are not yet accustomed to resisting the effects of cold. Experienced seamen, on the other hand, get accustomed to the condition and this increases their bodily resistance against the effects of cold.

The engineering personnel is less liable to the above-mentioned affec-
tions, in spite of oscillations of temperature of 30° C. and more, to which engineers are exposed during sudden moves from their workplaces to a fresher environment.

Pulmonary anthracositis is chronic among firemen who have worked as such for a long time, and is due to the penetration of coal dust into the respiratory tree.

Affections of the digestive system seem to have a particular frequency among seamen. According to statistics of the Seamen's Sickness Fund at Trieste the percentage of these affections is higher than that of venereal diseases, for in 1924 there were 480 (16.29 per cent.) compared with 328 (10.92 per cent.) for venereal diseases; in 1925, there were 483 (13.77 per cent.) compared with 349 (9.95 per cent.) for venereal diseases. The number of days of sickness was, in 1924, 15,712 for affections of the digestive system and 14,303 for venereal diseases; in 1925, 14,904 for the first, compared with 13,794 for the second. It should be noted that the cases are not always slight, for fatal cases were most common in all this group of diseases. Among the serious forms, there were noted, in 1926, 41 cases of gastric ulcer, diagnosed with certainty, and 50 cases of typhoid fever. The great frequency of digestive diseases among seamen is due to causes which can be easily removed. A better quantitative and qualitative calculation of the food ration, a judicious choice of the articles of food, better means of keeping food, especially in the tropics, as well as a stricter control of the cook's galleys, better victualling and distribution of food, should bring about a diminution in the sickness rates (Soldi). The engineering staff is the one, among the different categories, which is most easily affected by diseases of the digestive organs. One of the causes lies in the absorption of large quantities of water. A seaman may drink as much as 8 litres a day to make up for the loss occasioned by sweating.

Cases of heat cramps are fairly common on ships which voyage in the tropics, where they are regarded as heat stokes; fifty-six cases were observed during a single month (June 1926) on an American vessel, and forty-two cases were observed simultaneously on the French vessel "Bugeaud" in the Red Sea in 1900.

There is no doubt that, with the increasing use of oil fuel, heat cramp is becoming rarer and rarer. This interesting fact lies in the observation that it is not in the hot engine rooms that the onset of cramps occurs, but in the stokeholds (which are fresher and better ventilated) where the heavy work causes profuse sweating, and it is to this latter fact that the cases which occur are to be attributed rather than to the high temperature. The researches which have been undertaken have not led to any conclusive results, some authors attributing the cramps to localised dehydration of the tissues and the accumulation of the products of metabolism (Fisher), whilst others consider them as signs of auto-intoxication resembling the symptoms of severe fatigue (Winslow).

In 1928 P. Cazamian and E. E. Smith re-investigated the subject of heat cramp. The best description of the syndrome was by Pryor (1918): during or after exertion the cramps generally commence in the calves and spread to the other parts of the lower limbs and to the abdomen; the temperature may rise in certain cases; usually tetany is always found. A marked resemblance exists between these cramps and those of cholera, and Wilcox has described a type of choleriform heat stroke in Mesopotamia. Cazamian likens the cramp to the onset of tetany and attributes it to a diminution in the blood calcium ions in the blood in consequence of the sweating, and to an increase in the guanidine on account of the high surrounding temperature. According to Noel Paton, it is the ions of calcium which protect the nerve cells against attack by this substance, and Cazamian advises the administration of calcium chloride in doses of 60 grm. and more.

Investigations in Great Britain by Moss have done much to clarify the position. He ascribes the condition to an undue loss of salt in the sweat, after which plain water acts as an irritant to the thirsty tissues, and cramp results as a kind of water poisoning. If a little salt is added to the water, cramp is avoided; the men drink less of this water and are much more quickly refreshed.

Cases of sudden death may be due to tetany of the cardiac muscle, as has been observed experimentally on dogs exposed to high temperatures. After death there is found acute interstitial congestion of the lungs and swelling of the renal epithelium. Pryor recommends sugar as a preventative. In the British Navy, stokers drink oatmeal water with lemon juice and sugar.

According to Ehrengreund, the intensity of the vibrations of the ship play undoubtedly a large part in cases of sudden death on board ship. Ex-
tions of carbon dioxide, as insufficient ventilation, slow absorption of carbon dioxide, or the state of the sea. But according to this authority it is the intensity of the vibrations of the ship produced by the engines and the state of the sea, and rolling rather than pitching, which lead to cardiac or cerebral embolism, especially in individuals suffering from slight endocarditis, of which they are not aware, following rheumatic infection, which quite frequently occurs in seamen.

As regards the existence of an occupational anaemia among engineers and firemen, the haematological researches of Belli and Brancato show that an anaemia, properly so-called, does not exist, and that pallor of the face, the special symptom of this supposed condition, depends on a simple oligochromaemia which appears, only to disappear as soon as the subject leaves the place of work.

Examination of the blood of firemen working in a temperature of 48°-51° C. on board an Italian ship enabled Brancato to observe a gradual diminution of leucocytes during work in the stokehold. At the same time there was an increase of the lymphocytes and a diminution of the polymorphous leucocytes. Return to the normal was observed thirty hours after the cessation of work. During the first hours of sleep there was an increase in the polymorphous leucocytes. Brancato found, in addition, a diminution of the bactericidal property of the blood up to as much as 30 per cent. during work and immediately after.

Affections of the skin and subcutaneous tissue are common among the engineering personnel on board coal-burning ships, in consequence of the irritation and the small injuries constantly caused by coal dust.

Conditions caused by cold, such as numbness and frost-bite, affect chiefly men working in the open air.

Occupational poisonings are rare on ships, except amongst those who have to do with the transport of naphtha oil. Cases of lead poisoning or poisoning by turpentine, alcohol or benzene are observed exceptionally among men employed on painting.

On the other hand, cases of asphyxia are not uncommon among the men who descend into the holds or double bottom when the air is bad.

Violent lesions are common and serious on account of the numerous and complicated machinery on board. The greatest number of accidents are met with among the engineering personnel, and especially those who are serving as apprentices and have not become accustomed to the work.

**Hygiene**

Every kind of work may cause definite affections or definite occupational injuries; hence preventive measures should be adopted against the respective injury.

The best way of mitigating the unfavourable conditions for deck-hands working in the open air is to fit them out to face these. When the weather is severe it is desirable to provide hot drinks for the men on duty, and an extra meal, as well clothing, sea boots, woolen gloves and sou'westers.

All the well-known preventive measures should be taken against danger from dust during the operations of loading and unloading: prevention of the formation of dust by using means adapted to the kind of material, such as sacks and packing-cases; purification of the air by means of exhaust ventilators and methods for collecting the dust; protection of the workmen in the case of toxic material by means which will prevent it from penetrating into the nose, eyes and mouth, such as goggles and respirators. Wherever possible, manual work should be replaced by automatic machinery.

The prevention of casualties from vitiated air requires the application of suitable measures during the construction of the ship and during the loading and unloading of cargoes, in order to protect the workmen.

Before unloading, it is desirable to use in the holds a special system of ventilation to effect a complete change of air.

The specialisation of cargo boats, which has already been adopted for meat, fruit and oil, should be further extended, especially for cargoes which ferment easily or become decomposed.

Liquids which may give off gases and poisonous fumes must be stored in receptacles which maintain a stable position.

It should be ascertained that at the start of work the air of the holds is not irrepressible; men should descend with safety belts, under the supervision of an experienced and responsible man, and, if necessary, they should be supplied with breathing apparatus.

The prophylaxis against infectious spread by loading consists in putting the cargo in suitable holds and in the
organisation of the operations of loading and unloading. Goods capable of conveying infectious germs, or of affording shelter and food for rats should be placed in the hold in such a manner as to prevent the dispersion and transport of live animals. These operations should be done by daylight, so as to prevent mosquitoes entering the holds; rat-traps should be placed at the openings to prevent rodents having access to the holds and the ropes should be furnished with protective discs to prevent the passage of rats.

The prevention of occupational poisonings on board ship does not differ at all from that indicated for promoting industrial hygiene in general.

Means for improving the conditions of health of the engineering personnel are in the first place within the domain of the shipbuilder, and consist in lessening radiation from sources of heat by means of screens and by the use of covering media which are bad conductors; in lowering the temperature of the air; in the construction of rooms at a temperature between 25° and 30° C. in which the men may wash and change their working clothes for their ordinary clothes, and in the provision of douche baths for the cleanliness of the skin.

Masks to prevent the inhalation of coal dust are not generally appreciated by the men, who also refuse to use coloured goggles for protecting the eyes against dust and heat-rays from furnace fires.

Accidents from machinery are prevented by means of safety apparatus of a general kind or special for each machine; but an essential factor is the attention and skill of the personnel.

In life in the Navies every act is minutely disciplined. Hygienic factors are, in consequence, dealt with in regulations and contracts which fix the engagement, the quarters, food and clothing.

In all the merchant services, the crews are engaged by a simple labour contract. The shipowners engage the crews by judging their apparent capacity for work. The institution of a medical examination before engagement, which is necessary to decide on the physical fitness of candidates, as is done for ships of war, was proposed at the International Conference at Oslo (1926) and it is very desirable that it may be realised.

The elimination of men who have lost the capacity for work takes place by natural selection, men who are not in a state to resist the fatiguing life of the sea themselves seeking less arduous work. It is considered that it would be desirable to provide a system similar to that obtaining in the Army and Navy for dealing with cases for discharge and eventual transference to the half-pay list, in order to exclude from the crew those who are no longer fit for the work.

Accommodation. — In Great Britain the Merchant Shipping Act, 1894, provided for 72 cub. ft. of air space and an area of 12 ft. for every seaman or apprentice on board; these were increased in 1906 for ships of new construction and of a tonnage above 300 tons to 120 cub. ft. of air at least, and an area of 15 sq. ft. According to instructions published in 1913, cooking galleys, whatever their position, must not be considered as spaces intended for the crew, and any space reserved for the use of seamen should not contain cargo or provisions of any kind which are not the property of the crew and used by them during the voyage. As regards the height of the spaces occupied by seamen, the same instructions lay down that there must be at least 6 ft. between the flooring and the lower part of the beams.

In the majority of ships, the quarters for the crew are situated at the fore end, but there are also cabins on the sides of the ship and in the centre, on the aft deck; on board British ships of recent construction there is accommodation for the crew in the poop. The forecastle is generally composed of upper and lower quarters; the lower are under the main deck and reached by a ladder or stairs. It is very difficult to maintain healthy conditions there. Hence the Board of Trade has drawn the attention of shipowners and shipbuilders to the necessity of seriously considering accommodating the crew in cabins on deck. In new ships, hawse holes and cables must not be placed in the cabins for the crew and, when metal cables passing from an upper deck traverse a space they should be adequately protected from one deck to another. As regards lighting, the minimum obligation for necessary light is such that, in a new and freshly painted ship, it is possible to read the print of an ordinary newspaper in any part of a cabin, even if a third of the light is reduced. These conditions are not always carried out, especially in the case of quarters where the diameter of the port holes is limited, so as not to diminish the strength of the ship, and whether it is necessary to protect the glass in the port holes on account of the anchor. As regards ventilation, no definite strict rule can be set up as to the
system to be adopted. But every place used by the crew must be provided with at least two ventilators, one serving for the admission of air and the other for the exit of vitiated air. On all ships intended to voyage in the tropics, an opening, which allows the introduction of a wind-sail of at least 18 in. diameter, ought to be fixed in the deck above every space reserved for seamen, engineers and firemen. Efforts are made to obtain natural ventilation, but the results are seldom satisfactory, and even when suitable means and apparatus are provided their use is often neglected.

Every place occupied by seamen should, in addition, as far as possible, be well isolated and protected against any emanation likely to come from the cargo or the bilge water. The installation of metal bunks is recommended; they should be so placed that it is possible to enter them conveniently from the side. For each quarter of the crew the stove must be constructed so that it does not emit fumes or gases of combustion; cooking stoves should be forbidden in sleeping quarters.

The number of water closets should be in the proportion of one for 10 men up to 100; for any number above that the water closets should be increased at the rate of 4 per cent. Sufficient washing accommodation should be provided on board. Lavatories and bathrooms are necessary, especially for engineers and firemen, but the provision of water for them often presents a difficulty which has to be considered.

The sanitary condition of ships can be estimated from a report of 1918 relating to ships inspected in the port of London: in 1,496 of the ships inspected, the quarters for the crew have to be heated, the stove must be constructed so that it does not emit fumes or gases of combustion; cooking stoves should be forbidden in sleeping quarters. The number of water closets should be increased in the proportion of one for 10 men up to 100; for any number above that, the water closets should be increased at the rate of 4 per cent. Sufficient washing accommodation should be provided on board. Lavatories and bathrooms are necessary, especially for engineers and firemen, but the provision of water for them often presents a difficulty which has to be considered.

The sanitary condition of ships can be estimated from a report of 1918 relating to ships inspected in the port of London: in 1,496 of the ships inspected, the quarters for the crew have to be heated, the stove must be constructed so that it does not emit fumes or gases of combustion; cooking stoves should be forbidden in sleeping quarters. The number of water closets should be increased in the proportion of one for 10 men up to 100; for any number above that, the water closets should be increased at the rate of 4 per cent. Sufficient washing accommodation should be provided on board. Lavatories and bathrooms are necessary, especially for engineers and firemen, but the provision of water for them often presents a difficulty which has to be considered.

Among these rules is one which lays down that the food must be inspected before a voyage, and that the water tanks must be emptied completely, cleaned and filled with fresh water. In many ships a serious defect is the absence of a suitable place for storing the food in a satisfactory manner. According to the instructions published in 1913, on every ship making short voyages and on which the crew themselves provide their food, store cupboards must be provided, situated as far as possible from the sleeping quarters. On a declaration that these cupboards are for the use of the crew, they may be measured and their cubic capacity added to the space reserved for the crew and deducted from the tonnage (Buchanan).

Medical attendance. — A seaman who contracts a disease or suffers from a disease during a voyage (it is sufficient that the disease is contracted during the voyage and not necessarily in the course of the man's duties) is cared for gratuitously, and receives his full wages.

The Oslo conference discussed the question of a medical service by wireless for ships not carrying a doctor. A special committee for the welfare of sailors, which has its headquarters at Paris, is working on the problem, which has already been solved in the case of several countries.

In Norway it is proposed to make compulsory the provision of an ordinary sick bay on board every ship over 200 tons which has a crew of twelve men or more; in Australia some measures of this kind are recommended for ships of more than 1,000 tons which are ordinarily at sea more than twenty-four hours without putting into port.

The crews of merchant vessels are subjected to prophylactic measures against venereal diseases in the ports of those States which have adopted

Clothing. — According to ordinary contracts, clothes are supplied by the shipowners, usually at the rate of two suits a year, of the kind always worn by seamen.

Feeding. — The allowance of food, the time for meals, as well as the weight and quality of the various kinds of food, are fixed. The allowance satisfies the requirements of health conditions in general, and, from the point of view of alcoholic drinks in particular, may be regarded as more than sufficient (Belli).

In Great Britain, the Board of Trade has issued detailed rules for the inspection of food and water on board ships. Among these rules is one which lays down that the food must be inspected before a voyage, and that the water tanks must be emptied completely, cleaned and filled with fresh water. In many ships a serious defect is the absence of a suitable place for storing the food in a satisfactory manner. According to the instructions published in 1913, on every ship making short voyages and on which the crew themselves provide their food, store cupboards must be provided, situated as far as possible from the sleeping quarters. On a declaration that these cupboards are for the use of the crew, they may be measured and their cubic capacity added to the space reserved for the crew and deducted from the tonnage (Buchanan).
the Brussels International Agreement of 1 December 1924. In most of these States seamen are subjected by law to Jennerian vaccination, and, in case of necessity, to vaccination against typhoid, cholera and plague.

In some countries, Italy for example, during the stay of ships in ports infected by malaria, the seamen are entitled to a free issue of quinine as a prophylactic measure.

**LEGISLATION**

Numerous laws regulate the work on merchant vessels in various countries which provide, in engagement contracts, insurance against accidents and diseases (tuberculosis included), medical attention on board and ashore, and social assistance to seamen’s families.

The question of assistance to the crews of merchant vessels was brought forward for the first time in 1913 at the International Conference of Antwerp, but only tentatively. After the world war, owing to the foundation of the International Labour Office at Geneva, these questions passed definitely into the international domain.

The International Labour Conference at its Session of 1920 at Genoa adopted several Draft Conventions for the protection of seamen: employment agencies for seamen (19 ratifications up to 1 April 1932); unemployment indemnity for shipwrecked seamen (17 ratifications); and age at which children may be employed at sea (32 ratifications). In 1921, at Geneva, the Conference adopted two Draft Conventions concerning respectively the minimum age for trimmers and stockers (23 ratifications) and the compulsory medical examination of young persons employed at sea (23 ratifications). The Conference of 1926 adopted a Draft Convention concerning seamen’s articles of agreement (13 ratifications) and another concerning repatriation of seamen (12 ratifications). A Draft Recommendation which was passed in 1926 deals with inspection of the conditions of work of seamen.

In view of the prevention and treatment of venereal diseases among seamen, the 1930 Session of the Conference invited the League of Nations and the International Labour Office to take steps, first, to facilitate prevention and treatment in the principal ports and to get venereal diseases classified with those diseases for which medicines and care are provided gratuitously to sailors, and, secondly, to diffuse suitable information on this subject among seamen and to provide recreation for them ashore. In order to realise this programme the International Labour Office has requested all the Governments of maritime countries, the members of the International Labour Organisation, as well as national and international organisations of ship-owners and seamen, to supply information on measures already taken or planned in the various countries.

The first result of this action was the publication in 1926 by the International Labour Office of a study entitled *Protection of the Health of Seamen against Venereal Disease*. Next, at its 1929 Session, the International Labour Conference reserved the question of the welfare of seamen, opening for discussion, among other matters, the question of the improvement of the conditions in ports and the protection of seamen in case of illness, including the treatment of injuries on board. The discussion of these questions was provisional, owing to the system of double reading adopted by the Conference. However, the results obtained were positive in the sense that the Conference decided that the two questions should be entered on the agenda of one of the next Sessions.

The questions relating to the hygiene and health of the seamen have, in addition, occupied the attention of the General Council of the League of the Red Cross Societies, which during its third session in 1926 recommended a series of measures on these lines:

(a) educational propaganda on board ships by posters, pamphlets and other means;

(b) improvement of existing, or publication of new, popular health handbooks for the use of seamen;

(c) the setting up of Red Cross stations with dispensaries in order to provide the necessary treatment for seamen; and

(d) the elaboration of plans for supplying medicine chests fitted with up-to-date drugs and material.

In 1926 the Norwegian Red Cross and the League of Red Cross Societies called a conference at Oslo which examined various aspects of hygiene in the merchant services and appointed a permanent committee for the welfare of seamen. In October 1929 the second conference on hygiene and welfare in the merchant services took place at Geneva, during which welfare in the ports in general and on board were considered, and also tuberculosis and the campaign against venereal diseases.

The International Union to Combat Venereal Disease also devoted part of its activity to the study of the prophylaxis of venereal diseases in ports, and the general secretary of the Union expounded, in an international report presented at the second conference on the hygiene and welfare of merchant seamen, the general principles of the campaign against venereal disease, and their application to maritime conditions. The creation and maintenance, in the principal ports, of venereal treatment centres open to all merchant seamen or to boatmen, without distinction of nationality, with a view to giving to these workers the necessary

---

facilities for the treatment of venereal diseases, was the object of an international agreement signed at Brussels on 1 December 1926.

The fumigation of ships by means of hydrogen cyanide, hydrocyanic acid, or sulphur dioxide and trioxide was the object of an enquiry by the International Office of Public Hygiene at Paris, as well as of a series of memoranda on the part of various competent Ministries of different countries (for example, Great Britain). In most of the regulations dealing with the merchant services are found standards of visual acuity, hearing and colour vision for candidates for pilot's work (see study published by the International Labour Office in 1929 entitled Colour Vision Tests 1).

The laws and regulations concerning the engagement, discharge, repatriation and discipline of seamen have been collected and published by the Office 2.

In many countries persons employed in maritime navigation or in fishing are covered by the general legislation dealing with accidents, and in others they come under special regulations. The principle of compensation for occupational risk has been thus extended to maritime navigation, notably in Argentina, Belgium, France, Germany, Italy, Norway, Rumania and Spain. As regards occupational diseases, Germany provides compensation for exotic diseases, typhus and scurvy, when they affect seamen; Latvia, epidemic and tropical diseases, scurvy and beri-beri; and Yugoslavia, beri-beri.

BIBLIOGRAPHY

Literature on the subject is very abundant. See the quarterly publication of the International Labour Office: Bibliography of Industrial Hygiene.

Selenium

Selenium (symbol Se) is a metallicloid rare in nature, where it is found in a free state or accompanied by selenites of sulphur, cadmium or vanadium, in crocidolite as well as in certain pyrites, molybdenite and volcanic lava. Finally, it is found in anode muds in electrolytic refineries, copper refineries or in those of lead chambers in sulphuric acid factories when selenium-bearing ores are utilised.

Berzelius encountered for the first time (1817) selenium in the mud from lead chambers. This element becomes volatilised with sulphur dioxide, and on arrival in the chambers it is deposited in part together with the other products. It may also pass into the sulphuric acid of the Glover tower. Berzelius extracted it by washing the muds and treating them with a concentrated solution of potassium cyanide. After filtration, he effected precipitation of the selenium with hydrochloric acid, which he oxidised with nitric acid. By means of evaporation he obtained oxide of solid selenium, which he purified by sublimating it. The oxide was reduced to metallic selenium by an aqueous solution of sulphur dioxide.

In chimneys of foundries for smelting selenium-bearing ores it is possible to find dust containing up to 9 per cent. of selenium. In an American factory the ore is ground and washed in a lye solution; dissolved selenic acid is precipitated as a sulphate by means of sulphur dioxide. The sulphate is then dried, ground, pulverised and sometimes melted, though melting is not necessary.

According to certain authorities, there exist only three forms of selenium at an ordinary temperature: vitreous red selenium, obtained by precipitation; the crystalline red variety which melts at 144° C. and solidifies by becoming transformed into the third type; the metallic selenium which melts at 219° C.

Selenium melts at 217° C. (the red crystals form at 170-180° C.) and boils at 665° C. In the air it burns with a bluish-red flame, giving off SeO2, and having an odour of putrefying radishes.

By utilisation of the property which it possesses, constituting it a better conductor of electricity the more strongly it is lit up, the crystalline selenium is used in the construction of telephonic apparatus with luminous rays (seleno-radiophones, photophones), or telephotographic apparatus, and also for alarm apparatus (electric eye) and in photometry, etc.

Vitreous selenium and soda selenite are also employed in the glass and pottery industries for giving a rose and red coloration, and selenium for removing the greenish colour from white glass.
Whilst metallic selenium does not appear to be toxic, the majority of its compounds are said to exercise a harmful action to which the attention of those affected requires to be drawn. These substances can be readily detected in the system, since they give to the breath and perspiration an odour of garlic, in consequence of their transformation in the body into dimethyl selenium.

The methyl and allylic compounds which enter into the composition of products for removal of stains, to reinforce the action of benzine, possess powerful toxic properties characterised by a nervous symptomatology of chronic evolution (Zangger).

Wohl and Berzélius have referred to the toxic action of seleniuretted hydrogen, having suffered from the effects thereof during extraction of the element. Berzélius relates having been the victim of accidents of this kind as the result of the effect of a single gaseous bubble no larger than a pea. According to Eulenberg, animals are on the other hand killed rapidly by this minimum quantity.

Rabuteau (1867) has engaged in a study of the physiological action of *selenates* of soda and potassium which are said to cause vomiting and diarrhoea and to impart a garlic odour, which he attributes to seleniuretted hydrogen.

According to Chabrie and Lapicque (1889) and Modica, selenium dioxide (or selenious dioxide, *SeO₂*) and selenic acid are highly toxic and their action is said to be analogous to that of arsenic (Lewin). According to Robert this action is said to recall on the contrary that of sulphur.

Seleniuretted hydrogen (hydroselenic acid, *H₂Se*), a gas smelling of putrefying radishes, exerts an action on the skin and respiratory passages: irritation of the mucous membranes, pain, loss of the sense of smell, etc.

The first experimental research in regard to the toxicity of these products was that of Japha (Halle thesis, 1842) who tested the effects of the product on himself and discovered that it gave rise to phenomena similar to those caused by arsenic (emaciation, diarrhoea, etc.).

Czapek and Weil (1893) have, on the other hand, effected experiments with sodium selenide, the toxic action of which is more rapid and more intense than that of the selenate. This compound acts like sodium arsenide and provokes excitement, dyspnoea, and finally loss of reflexes, convulsions and death.

Like the foregoing authorities, Mead and Gies (1902) have revealed the fact that symptoms caused by selenium are similar to those due to tellurium (see that article). It must however be recalled that the former does not have the effect of suspending perspiration as the second does and that selenium is eliminated more rapidly from the system than tellurium.

In 1909 the study of Gadamer led to the conclusion that the toxic action of selenium is analogous to that of arsenic and that seleniuretted hydrogen is highly irritant when inhaled and may even cause pulmonary oedema in animals.

Amongst the other compounds, *seleneous acid* (*H₂SeO₃*) is, according to Gadamer, highly toxic, for it causes lowering of the blood pressure, vomiting, diarrhoea, paralysis of the central nervous system, convulsions and death.

*Selenic acid* (*H₂SeO₄*) is said to exert an action less intense than the above compound.

A. Hamilton relates that in 1917, when visiting a large American copper foundry, she collected information relative to several cases of poisoning by selenium. The symptoms in question were bronchial irritation and digestive derangements noted amongst workers engaged in crushing selenium-bearing ores. The selenium was eliminated by precipitation in the form of sulphate, but the melting process was considered the most dangerous operation for the workers (dust, fumes). The workers attacked complained also of pains in the abdomen, in the lumbar region, vomiting and colds with sore throat and fever. The garlic odour of the breath lasted for a long time even after work had been given up. These phenomena were, however, not common.

It should be recalled further that in the course of massive poisoning due to beer containing selenic acid (Great Britain, 1901) other symptoms were noted, such as paresthesia, erythromelalgia and melanosis (arsenic?).

Selenium and its compounds are not found on any list of *compensation*. Nevertheless injuries due to these substances may receive compensation in those countries which possess a very general formula, e.g. U.S.S.R., etc. (see article "Occupational Diseases: Definition and Compensation").

***
Seleniuretted Hydrogen

Seleniuretted hydrogen (symbol $\text{H}_2\text{Se}$) is a colourless gas, analogous to sulphuretted hydrogen, which is soluble in water. When burnt, it yields selenium, and precipitates various metallic solutions.

It is very toxic, according to Babu-teau, reducing the haemoglobin in the blood, to which it gives a deep red colour. The gas is eliminated by a current of oxygen, and a broad band of absorption between D and E in the spectrum takes the place of the band of oxyhaemoglobin.

Inhalation produces painful sensations of pricking on the nasal mucous membrane (attributable to the decomposition of the gas with deposit of selenium), then repeated sneezing efforts, which become tiring. The sense of smell is affected and may disappear for some days. Subsequently, too, there is headache and cough.

Statistics of poisoning relate solely to occurrences in the laboratory, such as those described at Göttingen. Berzélius, who studied seleniuretted hydrogen, is said to have suffered from the effects of the gas.

The processes of dosage and research are similar to those for sulphuretted hydrogen.

Shale Oil Industry

A well-defined group of skin lesions has been found to be associated with the processes of distillation and refining of mineral oils. These conditions have been the subject of careful observation in the Scottish shale oil industry for a number of years, and much work has been done with the object of lessening their frequency and severity. Any consideration of the pathological conditions due to employment must necessarily be accompanied by a short description of the processes of distillation and refining of oils, as some of these are more directly associated with pathological conditions than others.

Process

Oil shale, which exists in practically unlimited quantities below the lower coal strata in the west and Mid Lothian Districts of Scotland, is got by mining in a similar way to that in which coal is obtained. After being broken into small pieces in powerful breaking machines, it is fed into large vertical retorts which are heated partly by waste gases got from the distillation of shale, the temperature being maintained at approximately $1,900^\circ$ F. in the lower portion and $900^\circ$ F. in the upper portion of the retort. The oil gases are distilled from the shale in the upper portion, while the nitrogen of the shale is given off at the higher temperature, and in combination with steam passed through the bottom of the retort; part of this nitrogen forms ammonia gas. Another part of the nitrogen combines to form organic compounds (organic bases) known as amines, viz. pyrrol and series and pyridin and series. The gases are drawn into condensers where they condense into ammonia liquor and liquid oil, which by their different specific gravities separate and are drawn off into different tanks. The ammoniacal bases — amines — condense along with the liquid oil and are contained in the oil as organic nitrogen compounds known as the pyrrol and pyridin series. The incondensable gases are used for heating the retorts.

After the gases have been distilled from the shale, the refuse, known as spent shale, is discharged from the bottom of the retort into a hutch (wagon) underneath and conveyed to a waste heap. The ammonia liquor is distilled and the gases are treated with sulphuric acid, forming sulphate of ammonia, which need not be considered further as far as this article is concerned.

The condensed oil is known as crude oil. This is delivered into tanks which feed by gravitation into boilers (still) where the lightest fractions of oil, ultimately forming naphtha and burning oil, are distilled and condensed. The oil now left is distilled in dry gas, leaving a solid residue in the still, known as coke, which being rich in carbon forms a valuable fuel.

The gases from the heavier oils condense and form “crude distillate”. This crude distillate is run into tanks in which it is first mixed with sulphuric acid and then with caustic soda, removing the tarry contents of the crude oil; the nitrogenous compounds are at this stage eliminated by the sulphuric acid, passing off with the acid tar. At this stage, therefore, both tars and nitrogenous compounds are eliminated from the crude distillate. The acid is recovered and goes back for further use in the process; the tar is used as fuel. The acid is used for combining with ammonia gases to form sulphate of...
ammonia. The heavy oil left is now technically known as "green oil". This is re-distilled; the distillate is cooled by anhydrous ammonia, forming a pasty mixture of oil and crystals of paraffin frozen out of the oily solution. This mixture is pumped through filter presses. Up to this point workmen never come into intimate contact with oils, tar or other chemical substances, these being confined to the vessels in which the processes are carried out. By means of filter presses some of the oil is separated, leaving semi-solid cakes of paraffin, known as "paraffin scale". Filter presses consist of long iron frames about 3½ ft. high, with numerous iron plates arranged vertically, with coarse canvas filter cloth between each, through which the oil is filtered from the scale, the oil running off and the scale being retained between the iron plates. Workmen pull the plates apart at intervals and separate the scale from the filter cloths with scrapers. The scale drops into conveyers to be carried off for further treatment.

Fig. 112 and 113 show working attitudes of the men, and it will be noticed that the arms and hands are in more or less intimate contact with the oily scale.

The scale is now taken to the hydraulic press department, where it is packed into cloths laid on trays, the scale being shovelled into cloths and levelled with the hands and forearms. This process is more responsible for pathological conditions than any others.

The trays are then placed in hydraulic presses, vertical frames about 8 ft. high, with numerous shelves, and as the higher shelves are being filled, the workmen's arms are held above their heads and oil trickles down the forearms.

The legs and feet also get wet with oil. The departments in which the scale is filtered and put into hydraulic presses are known as the "crude paraffin departments or green sheds". After the oil is expressed by hydraulic power the trays are emptied, and the hardened wax left in filter cloths on trays is sent to the refining sheds ("sweating sheds"), where the last of the oil is sweated out by steam heat. The expressed oil is known as "blue oil". During the whole process in green sheds the workmen are daily in intimate contact with crude paraffin and oil, accounting for all of the pathological conditions met with among paraffin workers.

After exposure to steam heat in sweating sheds, the paraffin is now refined, and after a final purification with charcoal or other substance, is fit for commercial use. The oil separated in filter presses and hydraulic presses goes through the same processes, being re-treated with acids and soda, cooled and again filtered and pressed as before. The subsequent treatment of the oil, dividing it into the various grades of lubricating oil, etc., need not be considered here, as in no other stage of the entire process other than those already described are work-
men affected with any of the typical papular, pustular or erythematous lesions.

A diagram of the entire process of manufacture of sulphate of ammonia, mineral oils and paraffin wax from oil shale is given on page 832.

**PATHOLOGY**

**Occupational Dermatoses**

The skin lesions due to contact with oily paraffin in a crude or semi-refined state may be described as conforming to the following types, of which one only, or several, may be found on the same individual:

1. Occupation comedones.
2. Folliculitis and peri-folliculitis.
3. Dermatitis pustulare.
4. Dermatitis papulare (Erythema papulare).
5. Erythema simplex.
6. Dermatitis erythematosa (Erythrodernia).

These, which include all forms of occupational eruptions met with in the
Scottish shale oil industry, will be briefly described under their various heads.

(1) Occupation Comedones

These occur in parts exposed to contact with paraffin products, especially over flexures of elbows, posterior aspects of elbows, upper aspects of shoulder joints, and occasionally over knees. Their origin is purely mechanical, being due to obstruction of sebaceous ducts with semi-solid paraffin substances. They are larger than comedones met with under ordinary conditions, more closely packed together and confined to circumscribed areas, being most prevalent on the anterior aspects of body and limbs. They are easily expressed. There is little tendency to acne formation, as the materials obstructing the ducts are sterile. After they have persisted for lengthened periods, some tendency to acne may be seen. On ceasing work among paraffin substances, they
readily disappear if regularly expressed, and do not develop further, but are apt to recur on resuming similar employment.

(2) Folliculitis and Peri-Folliculitis

This is one of the most prevalent forms of skin lesion occurring among paraffin workers. It consists of destruction of the hairs and hair follicles as the result of a mild inflammatory reaction set up by mineral oils. The follicles become somewhat dilated and filled with epithelial debris and dirt, so that they appear as closely grouped clusters of black points, corresponding to hair follicles, over the parts affected. Occasionally a slight peri-folliculitis occurs, in which the inflammatory condition extends to the surrounding skin, which becomes slightly raised above the level of the rest of the skin tissue, and ultimately becomes hardened and thickened. The most common sites are the backs of fingers and hands, and to a less degree the forearms and legs round the ankles, and dorsal aspects of toes and feet, especially on the line of the extensor tendons of toes. There is never any tendency to sloughing or suppuration; the condition persists as described indefinitely. The appearance of dryness of hands, with clusters of black points on backs of fingers, is typical among paraffin workers.

(3) Dermatitis Pustulare

This is not a prevalent condition. Two types have been noted:

(A) One in which the condition is characterised by the appearance of numerous small pustules over the anterior aspect of body and limbs, and

(B) One in which the pustular eruption is due to the breaking down of the typical papule which is the most common form of occupational eruption.

(A) Primary pustular dermatitis. — A widely distributed pustular dermatitis occasionally occurs among youths beginning work in the paraffin departments. The pustules are small, each being surrounded by a slight inflammatory areola, and are mostly found on the anterior aspect of limbs and trunk. The channel of entrance of the irritant appears to be by the hair follicles, as generally a hair is found in the centre of each pustule. This type readily disappears on removing the individual from this particular form of work. The tops of pustules get dry and are shed as crusts, without further return.

(B) Papulo-pustules. — These occur on the sites of papules, the pus for-
ing at apical part of papule. These as a rule are not numerous and are usually seen in conjunction with a papular eruption. They are due to the breaking down of a papule from strepto- or staphylo-coccal infection, or to the separation of a small necrotic area from the centre of the papule, after which the papulo-pustule disappears.

(4) Dermatitis Papulare (Erythema Papulare)

This is by far the most common form of lesion met with among paraffin workers, approximately between 40 and 50 per cent. of the men being affected, the majority of these having only a few papules. These papules are known in the trade as "paraffin plukes", and are typical of an occupational eruption both in history and distribution. Papular dermatitis consists of an eruption of small rounded elevations of a purplish colour, varying in size from that of a small pepper corn to that of a small pea. They are solid, superficial, rounded in shape and contain no fluid. Frequently there is a minute central depression, from which a tiny core can be expressed or removed, and which corresponds to a necrosed hair follicle or sebaceous duct. Workmen affected try to pick out this core, after which the papule heals. The entrance of irritant is by the sebaceous ducts, but frequently the hair follicles are involved, in which case a hair occupies the central position in a papule. There is as a rule no inflammatory areola round a papule; there is never itching or irritation; they do not coalesce and as a rule heal spontaneously.

It has been frequently noted during the routine examinations that the sites of papules vary from time to time, some healing and others developing in different situations. Papules may be present in two's or three's or in larger numbers till there may be a diffuse eruption, but the majority of those affected show a few papules only. The distribution of the papular eruption is typical. In the great majority of cases it is confined to the forearms, being most pronounced over the ulnar aspects, though it is also prevalent over anterior and posterior aspects of forearms, round wrists and on backs of hands. Less frequently a few papules are seen on shoulders, legs and dorsal aspects of feet. They are frequently seen behind elbows. The palms of hands and soles of feet are never affected.

The earliest appearance of papules is seen in about twelve days after beginning work in paraffin sheds. They disappear a few days after ceasing work in that department. In old-standing cases, the papules, instead of heal-
ing, develop a warty hardness, forming scaly warts, gradually becoming harder and more indurated. These warty papules tend to persist indefinitely. In the most chronic types these warty papules may increase in size, with the formation of a central necrotic area, which may slough and separate, being followed by the healing and disappearance of wart, with scar formation. At a still more advanced stage the warty papule breaks down and forms an epitheliomatous ulcer.

(5) Erythema Simplex

This consists of a mild hyperaemia, in which the redness is distributed generally over parts affected. The first appearance is a slight blush, followed by a greater degree of redness which at first disappears on pressure, reappearing on withdrawal of pressure. This hyperaemia is practically always limited to forearms, and is associated with a dryness of the skin. Later the erythema becomes purplish and remains on pressure, with permanent pigmentation of skin. This condition may persist for years without alteration. The affected parts become scaly, and usually show a shiny appearance. This type of lesion usually exists alone without the presence of any other form of eruption.

(6) Dermatitis Erythemalosa (Erythrodermia)

This is essentially a dermatitis of a sub-acute or chronic type, due to prolonged action of oily paraffin on the tissues of skin. It represents a further extension of an erythema, in which the congestion gradually merges into a chronic inflammation of the various layers of the epidermis and cutis vera, followed by induration and, in the most advanced stages, by partial or complete destruction of small areas of skin in the affected parts. In the first stage the lesion consists of dull red patches distributed irregularly over the anterior aspects of forearms, either linear or roughly circular in shape. These are slightly raised above the surface of the skin, are dry and somewhat scaly. As the condition becomes more chronic, larger areas are involved, the whole of the forearms being affected. Pigmentation is usually seen in conjunction with this condition. This erythematous stage may persist for long periods, or healing may take place, the redness disappearing, and being replaced by induration of the superficial layers of the skin, with a permanent scaliness. Frequently the dermatitis progresses so that the deeper layers are affected, and, as the inflammation becomes more chronic, scars appear, white in colour, varying in depth according to the depth of the
inflammatory changes. There is a more or less constant tendency to the formation of small warts, usually oval or circular in shape, raised above the level of surrounding skin. These warts are dry and scaly. In advanced cases the whole surface of the forearms appears indurated, hard and thickened, giving a leathery appearance — sometimes called shagreen skin. The scaly warts are typical of old standing dermatitis, and go on proliferating long after cessation of working with paraffin materials. Once this stage has been reached, the hyperplasias go on, sometimes large warts being seen. These warts may still continue to proliferate and grow larger, ultimately breaking down and forming epitheliomata. Chronic dermatitis usually co-exists with old standing papular dermatitis, in which the papules are of the indurated type, hard and warty. Thus, in an advanced stage, the forearms show pigmented patches, white areas of scar formation, scaly or horny warts, and indurated papules, any one of which at any time may take on features of malignancy, depending entirely on “the personal factor”. The distribution of this type of dermatitis is confined to the lower halves of arms, the forearms, and to a lesser extent, the feet.

(7) Epithelioma (Paraffin Workers' Cancer)

Epitheliomata as seen among the paraffin workers of the Scottish shale oil industry occur only in those about or over middle life who have been so employed for twelve years or more. They usually arise from warts due to a chronic dermatitis or from indurated papules, both already described, and therefore may co-exist with an advanced dermatitis, in which wartiness is a predominant feature, or with numerous papules of a simple nature, of indurated type. The usual appearance is that of a gradually growing epithelioma, in the midst of an indurated dermatitis, with a number of warts or indurated papules, only one of which has become malignant. It is not uncommon for workmen to have several different growths at various times, but there are never two malignant growths at one time on the same individual. The warts or papules have been as a rule present for a number of years in a benign form, until the epithelial covering begins to proliferate more rapidly, with increasing growth of the primary lesion, gradually assuming the features of a malignant condition. These epitheliomata have been seen most frequently among those who have been paraffin workers for from twelve to thirty years.

Epitheliomata also occur among retortmen, stillmen, and labourers in oil works, quite distinct from the group of paraffin workers. These men do not
come into such intimate contact with oils and crude paraffins in their work, and so do not suffer from any of the papular or inflammatory lesions which occur among the paraffin workers. On these workmen an epithelioma arises as a reddish pea-shaped nodule, in which the typical cell nests are present practically from the onset. There is epithelial proliferation accompanied by the degenerative changes associated with an epitheliomatous growth. The scrotum is most commonly the site of such lesions, possibly due to the difficulty of ensuring cleanliness of this region.

Of all cases of paraffin workers epithelioma recorded in connection with the Scottish shale oil industry over the last twenty-eight years, the incidence was found to be 0.5 per cent. per annum among the paraffin workers proper, and 0.1 per cent. among the other oil workers. Among the paraffin workers, 63 per cent. of the occurrences were on arms, forearms and hands, 20 per cent. on face and legs, and 17 per cent. on scrotum, while among the oil workers the proportions were reversed, viz. 58 per cent. on scrotum, and 25 per cent. on hands, arms and forearms. These figures show that among oil works labourers the tendency is for epitheliomata to occur more frequently on scrotum, while among paraffin workers proper the tendency is for hands and forearms to be more frequently affected.

The important aetiological factors in production of epitheliomata are age, length of service, and idiosyncrasy or predisposition. Seventy-five per cent. of the total number of epitheliomata have been contracted over fifty years.
of age; 80 per cent. have occurred after fifteen years of service. Approximately half of the paraffin workers have some form of dermatitis, yet all are equally exposed to contact with oils, and of those affected only a very small proportion develop malignant conditions.

**Hygiene**

During recent years a great deal has been done for the protection of workmen in the paraffin departments of this industry, by means of baths, medical examinations, and protective applications. In all the works where refining of oil and separation of paraffin wax is carried out, baths are provided for the workmen. A description of one such building will suffice to give an idea of the provision made. The bathroom is a large airy, well-lit room, about 55 ft. long, 15 ft. broad, and 12 ft. high, adjoining the paraffin sheds. It is lined internally by glazed tiles, and is heated to a comfortable heat by hot air pipes. At one end are four hand basins fitted with hot and cold water; above each is a metal container filled with neutral liquid soap. At the other end of the room is a large steep bath, with clothes wringer attached for washing socks and clothing. On one side are five upright spray baths, lined with glazed tiles and fitted with hot and cold sprays, each having in addition a deep foot bath. On each side of a spray bath is a cubicle for one man to be getting ready while another is washing. On the fourth side, along wall and across floor are arranged forty lockers, fitted
with pegs for clothes, shelves for boots, wires for towels, the lockers being heated by hot air pipes passing through the bottoms. Seats are provided beside the lockers. Each workman is provided with a weekly supply of soap and towels for his own use. The baths are kept spotlessly clean by attendants. On ceasing work, the men bath daily, and put on their outdoor clothes. They wash their socks and hang all their working clothes in lockers to be dried and ready for use next day. The workmen are all supplied with heavy canvas aprons to keep the clothes as dry as possible. Before working, each man smears his hands and arms with commercial castor oil, which has been found to withstand the solvent action of paraffin better than anything else. A large jar of this is kept handy, and occupational and otherwise. Charts are used for recording conditions noted, for permanent record and for comparison with former records. The results of the examinations are very satisfactory, as conditions which might prove serious are got at the earliest period. During the last ten years, twenty small epitheliomata have been discovered and removed without recurrence. In no other way would it be possible to ensure correspondingly good results. The conditions of the men, as noted at each examination, are divided into several groups, as follow:

Group 1: those free from occupational eruption;
Group 2: those having a few papules or slight erythema only;
Group 3: those having a slight degree of any form of eruption and limited in extent;
Group 4: those with extensive eruptions of any type;
Group 5: those showing any condition approaching malignancy.

For permanently recording conditions found at each examination, different coloured crayons are used for each condition, so that the chart relative to each man shows clearly his condition. For those men who have been occupied for long periods in paraffin sheds, these charts form a valuable three-monthly record as to their progress; the same also applies to those recently employed, or who have been paraffin workers for shorter periods. In the cases of new employees, if after beginning work they

Fig. 128. — Steep basins.
are found to be extensively affected with papular dermatitis, and if this does not gradually improve substantially after a few examinations, these men are removed from that particular occupation, as being unsuited for it. In this way a selective process is continually going on, so that at the present time the personnel of the paraffin sheds is composed of: (a) a proportion of old employees who have been workers there for many years, and (b) a larger proportion of younger men who have been selected as showing little predisposition towards eruptions due to contact with paraffin. The whole cost of this inspection is borne by the employers, who help in every way in furthering the complete scheme as being in the best interests of the workmen.

LEGISLATION

In Great Britain section 73 of the Factory and Workshops Act, 1901, requires notification of all cases of epitheliomatous ulceration due to mineral oil and paraffin to the certifying factory surgeon for the district.

By order of the Secretary of State (Statutory Rules and Orders, No. 1775, 28 November 1929), the provisions of section 73 of the Factory and Workshops Act, 1901, were made applicable to epitheliomatous ulceration due to mineral oil and paraffin. This came into force 1 January 1920, thus making this condition a "scheduled trade's disease" from that date.

Shoddy
(Mungo)

French: Laine régénérée, laine renaissance artificielle. — German: Kunstwolle. — Italian: Lana meccanica, rigenerata, artificiale; — Spanish: Lana mecanica, recopuesta.

Several qualities of this product are known. Shoddy is made by unravelling waste from combed wools and merinos, etc.; mungo made by picking to pieces rags and fulled cloth (these two types of material are subjected to slight "gassing" in the factories); alpaca wool made from rags of mixed materials — not pure wool (the wool is separated by means of chemical processes: carbonising by hydrochloric or sulphuric acid or chlorides; this is followed by drying at a rather high temperature (from 65-130° C.) and heating to eliminate the carbonised matter)

Amongst apprentices and those new to the trade there has been noted in the rag-cutting workrooms and those in which the wool is freed from vegetable matter the occurrence of an affection designated "shoddy fever" and cutaneous lesions and lesions of the mucous membrane caused by the acids.

See also article "Rags".

The legislative measures issued in regard to rag picking are superfluous where rags are damped, washed and freed from grease before handling.

For hygiene and legislation, see article "Rags". For vegetable wool, see article "Kapok".

---

Silicon

French and German: Silicium. — Italian and Spanish: Silicio.

Silicon (symbol Si) is one of the most abundant elements in nature. Combined with oxygen, it forms silica (silicic dioxide, SiO₂). It enters into the composition of quartz, the amethyst, the agate, the opal, and numerous kinds of sand. In the state of silica it constitutes the principal constituent of the most important rocks. It was prepared in a pre-amorphous state by Berzelius (1823) by heating felsicarbonate of potassium with metallic potassium.

At the present time it is prepared in considerable quantities by reducing quartz with wood charcoal in an electric furnace, with the addition of CaO and MnO. The crude silicon obtained is purified by hydrochloric and hydrofluoric acid, and the final product contains 90 to 91 per cent. of Si.

It is also prepared by heating silicon fluoride with metallic sodium and by bringing to red heat powdered quartz in the presence of powdered magnesium. There is often found in crude iron from blast furnaces, free silicon derived from the reduction of silica by carbon.

Amorphous silicon is only soluble in hydrofluoric acid (with liberation of hydrogen) or in alkaloids. It is a bad conductor of electricity, and burns with liberation of SiO₂ when heated in the air. Crystallised silicon is a good conductor of electricity, of a hardness exceeding that of glass, does not dissolve in any single acid, but only in a mixture of nitric and hydrofluoric acid.

It does not become oxidised even when brought to red heat in an oxygen atmosphere. By boiling it in a solution of caustic soda, it dissolves, giving off hydrogen and silicate of soda. It melts at 1,439° C. Amorphous silicon heated to a high temperature acts like crystallised silicon; burned in an atmosphere of chlorine, it forms silicon chloride (SiCl₄). It enters into combination with iron at an ordinary temperature; at a high temperature it combines with nitrogen, and in an electric furnace with various metals for the formation of silicides.

From experiments of Glaser and Roll (1926) on silicon rendered free from silica, it has been shown that there exist stable modifications characterised by certain physical properties (thermic analysis and caloric dilatation). From the fact that silicon enters into the composition of iron, cast iron and other metallic preparations ("duralumin", "silumin" and "alpax"), the experiments of Glaser and Roll encourage the expectation of the preparation of materials of construction of a stable form.

The principal silicon combinations are:

Silicon hydrogen (SiH₄), a colourless gas with a disagreeable odour, subject to spontaneous ignition; silicon tetra-chloride (SiCl₄), used as a war gas, causes, during decomposition, caustic burning of the ocular and respiratory mucous membrane; bromide and iodide of silicon (SiBr₃ and SiI₃), silicon fluoride (SiF₄): colourless smoking gas with a piquant smell and harmful to the respiratory system and to vegetation. Mass poisonings due to this gas have been reported by Egli in a chemical factory; fluorsilic acid (SiF₄) — see
article "Hydrofluoric Acid"); silicon carbide (SiCl), a product commonly known as "carborundum". Carborundum is prepared in the electric furnace at a temperature slightly below 2,200°C. Raw materials utilised are silicious sand (34 per cent.), coke (at least 90 per cent.) carbon (35 per cent.), sawdust (7 per cent.), sea salt (2 per cent.).

According to Willis, silicon carbide dusts exercise no effect whatsoever on susceptibility to tubercular infection of the lung amongst animals which have been treated by injecting subcutaneously virulent virulent bacilli; calcium suicide (SiCa₂) used for reducing and desulphurising metals; iron suicide (see article "Ferro silicon"); dioxide of silicon (SiO₂) abounds in nature in the form of crystallised quartz in hexagonal pyramids, generally without cleavage. It serves in the manufacture of laboratory apparatus made of quartz, in the manufacture of quartz glass, and, in powdered form, in the preparation of cleaning powders, of paints, and in foundries, etc.

Manufacture of silicon glass has undergone special development recently as a result of progress made in the use of the electric furnace. Silicon glass, also known as molten quartz, contains 99.5 to 99.8 per cent. of silicon. It is obtained from pure silicon sand by melting in an electric furnace in the presence of carbon electrodes. During this operation there occurs liberation of silicon and carbon monoxide at about 1,400°C, whilst at a temperature of 1,600°C, the silicon liberated is in a state of fumes, and burns above the furnace, giving white silicon smoke. At this temperature silicon fumes may be freely disseminated and become condensed.

Quartz rocks, which serve in the preparation of silica, are subjected to grinding in grinding mills. The industry is a fairly restricted one. Middleton (1930) has reported a fatal case of silicosis with tuberculosis affecting a worker engaged in these mills in the north-west of England.

There should, in conclusion, be mentioned oxide of silicon (SiO), silicate acid (SiO₂H₄), silicon disulphide (SiS₂) and silicon nitride (Si₃N₄).

Silica has been found amongst the numerous constituents of the human system by Schmidt, in 1909, in normal urine.

Research by Spica on the action of soluble silica injected into rabbits would appear to have proved the existence of a harmful effect. Kunkel (1901) denies any toxic action from silicic dioxide, whilst Lewin (1903), as likewise Erben and V. Jacksch, attribute to silicon the presence of chronic catarrh of the mucous membrane of the respiratory passages, the occurrence of chalciosis, and other pulmonary lesions, upon which tuberculosis readily supervenes amongst workers in the granite industry, emery industry and amongst stone cutters.

At the present moment numerous research agents have demonstrated in a conclusive fashion the harmful action of silica on workers exposed to inhalation of dust from this product (see article "Tuberculosis and Silicosis").

Mazzi and Sgai (1913) found punctate basophilia in the blood of workers engaged in the glass industry. Having succeeded in eliminating the possibility of the action of lead compounds, the two authors were led to the conclusion that the harmful agent in question was silica, which opinion was corroborated by evidence of a slight increase in the silica content of the urine. Subsequent to laboratory research, these authors arrived at the conclusion that sodium silicate should be considered as a blood poison, fairly potent in the case of rabbits. Pure silica (silicious earth) constitutes an anaemia-producing agent less violent than sodium silicate. Pure amorphous silica given in very large doses causes serious anaemia in the case of rabbits, with, however, more retarded appearance of the symptoms (about twenty days) than in the case of impure silica. Silicon tetrachloride appears as an anaemia-producing agent, and its capacity for destruction of the red cells is fairly considerable.

Mazzi and Sgai have completed their experimental research by investigations conducted amongst masons and former glass workers. They found in the blood of these men alterations similar to those observed in animals (more marked anisocytosis, chlorotic red cells in a fairly considerable number, slight increase of chromatophile red cells, whilst four-fifths of the cases showed basophile red cells: increase of lymphocytes and slight diminution of the number of red cells and of the total haemoglobin). In the urine the silica content was increased in four-fifths of the cases. This increase was in proportion to the number of years of working experience and to the presence of punctate basophilia in the blood. Mazzi and Sgai have con-
cluded that silicon, and especially the silicates, diminish the organic resistance of workers to disease, and weaken their means of defence. The damage in question consists of cellular lesions of the tissues, and especially alteration of the blood with destruction of the red cells. There is a state of chronic poisoning having the appearance of toxic anaemia with basophilic granulation, accompanied by some polychromatophile cells, a certain degree of leucolymphocytosis and diminution below 1 of the haemoglobin count.

***

Silk

In the year 2698 B.C., Si-Ling-Chi, the wife of the emperor Hoang-Ti, invented the art of breeding silk-worms, and of reeling the cocoons in order to obtain the silk thread. Unreeled silk has been used by the Chinese from the most remote time for the manufacture of musical strings and fishing lines.

Since the introduction of silk-worms into Europe by two monks belonging to the Order of St. Basil in A.D. 551, the manufacture of silk has given rise to an industry which, still at the present time, comprises one of the chief sources of wealth in the countries which have encouraged its development. This industry includes two phases: (1) breeding the silk-worm, and (2) spinning the silk.

The silk-worm (Bombyx mori) can adapt itself to the most varied conditions of climate and soil; but it is chiefly the countries with a temperate climate where the thermometer does not fall below 20° C. during the breeding time which are best adapted for sericulture. One of the results of cultivating the silk-worm is that it has lost a good deal of its natural resistance; so that it is necessary to ensure the most careful hygienic conditions during its short larval period: rational incubation of the eggs or seed, and keeping the surroundings hygienic the raising ground. There are special firms nowadays which only concern themselves with the preparation of the eggs. After having selected the cocoons which are to be allowed to turn into worms, the breeder carefully supervises the placing of the insects and the laying of the eggs. On an average 100-125 moths are needed to obtain about 30 grm. of eggs; in a mass of this weight there are from 45,000 to 55,000 eggs. These are examined under the microscope, which permits the elimination of sterile and infected products, and ensures the selection of only good quality and healthy eggs. They are then preserved in closed boxes placed in cellars or refrigerators, in order to avoid sudden variations of temperature. The hatching of the eggs takes place in peasants' houses, or in silk-worm nurseries in Provence. A mechanical incubator is often used in order to hatch the eggs at a convenient moment, carefully related with the development of the mulberry tree, the leaves of which form the silk-worms' food.

The silk-worm (magnan) lives for forty days, during which time the temperature and the degree of humidity must be most carefully watched, as well as the feeding, the bedding and the skin casting of the silk-worm. At the end of this period it looks for some point of support upon which to hang its cocoon; therefore the next thing is to provide the silk-worm with little branches of wood arranged slantwise.

At the end of about a week all the cocoons are formed. The produce of the nurseries is collected by the establishments where the reeling takes place; here the chrysalis is killed in stoves by means of a current of air heated to 50-91° C. In certain cases the hot air is replaced by steam under pressure. For some time past chloropicrine has been used, the quantity being 1 grm. per kilogram of cocoons. When the cocoons are spread out on screens in the fresh air all smell of chloropicrine passes off. This process does no harm to the silky covering, interfering neither with the colour nor the quality of the newly formed cocoons, nor does it affect the spinning.

After being killed, the cocoons are reeled. This operation is preceded by soaking the cocoons in a round deep basin in water heated nearly to boiling point (the scalding process) and by beating, the object of which is cleaning, i.e. the removal of the superficial silky covering of an imperfect texture, from which is derived the silk thread called floss. The reeling of the thread is carried out in reeling basins, containing water at a temperature of about 60° C., a special apparatus being used composed of a shank which curves backward and forks at the upper end, and of a reeling frame. The woman worker passes in and out of the branches which are at the end of the branches of each shank, windable threads from
two or more cocoons; the movement of the reeler sweeps off the silk from the cocoons, which are fastened to the reeler by their free end. Silk thus obtained is called raw or crude. When the gum which covers it is removed, the silk is said to be scalded or scoured.

Before being woven, the silk thread goes through various spinning processes, which include: reeling the hanks; the transfer of the silk on to bobbins; twisting, which is applied separately to each thread coming from the bobbins; doubling two threads of raw silk already either twisted separ-
ately or not; twisting applied to the double thread; a fresh reeling on to bobbins; and the formation, by a fresh twisting, of threads arising from the collection of two or more threads of raw silk.

The hanks derived from drawing the threads from the cocoons are first of all sprinkled with soapy water in vats, where they are left for twenty-four hours to make them supple and elastic. All the operations take place in workshops where the temperature varies from 20 to 25° C. and the relative humidity from 60 to 80 per cent.

After this the silk is sent away to be woven. It can be dyed before or after being woven.

The lustre is imparted to silk when it has reached the stage of being a soft and uniform fabric. After being calendared and brushed, the silk acquires a shining surface by being treated with a solution of formic acid at 90 per cent. and a solution of celluloid, nitrocellulose and viscose or acetocellulose. The formic acid makes the silk swell out and become gelatinous. After being washed and stretched, it is treated with celluloid in a solution of 25 per cent. in alcohol at 94 per cent.

The solution is applied by brush, and evenly distributed by means of two rollers. The drying process follows.

When acetocellulose is used, it is in solution with phosphate of triphenyl (used to prevent fire) and triacetine as an adhesive, with the addition of such volatile solvents as alcohol and tetrachloride of carbon.

For bleaching silk, sulphur dioxide is used in an aqueous solution or in solution with bi-sulphite of soda. After elimination of the gum, the silk may be exposed in a room to fumes from burning sulphur. If the bi-sul-
phite is used, the silk is passed into vats containing the solution. But hydrosulphite of soda may also be used, followed by a wash bath and bath of hydrochloric acid or of oxygenated water, which must be hot, followed by an acid bath and a neutralisation bath. The method of using peroxide of soda and sulphuric acid is the least costly.

The silk-worm gut used in surgery and for fishing is obtained by taking the silk-worms which are ready to spin their cocoon and immersing them in vinegar. In Spain vigorous silk-worms are selected, and are prevented from climbing to the twigs of wood to hang their cocoon there; they are killed by being plunged into nitric acid solution or vinegar. Skilled women workers open the dead silk-worms and draw out the two serigenous glands, situated one on each side of the digestive tube. The silk-worm gut, after being carefully dried, is then washed in alkaline water. For surgical use the silk-worm gut has the two imperfect ends removed and is sterilised.

From climbing to the twigs of wood to hang their cocoon there; they are killed by being plunged into nitric acid solution or vinegar. Skilled women workers open the dead silk-worms and draw out the two serigenous glands, situated one on each side of the digestive tube. The silk-worm gut, after being carefully dried, is then washed in alkaline water. For surgical use the silk-worm gut has the two imperfect ends removed and is sterilised.

STATISTICS

There are few up-to-date statistics available relating to the health of women employed in raising silk-worms. Among spinners the general morbidity is not very high. Celli found a percentage of 13 among 206 women workers at one filature, amongst whom the various kinds of morbidity were represented by: general illnesses, 2.4 per cent.; respiratory diseases, 15.0 per cent.; nervous diseases, 0.5 per cent. In the course of a detailed enquiry made by Carozzi in 1910, 193 spinners who were medically examined were found to be suffering from (percentages): general illnesses (including anaemia), 6.33; respiratory diseases, 4.66; digestive diseases, 4.66; nervous diseases, 0.33; diseases of the genital organs, 0.66; infectious diseases (especially typhoid fever), 15.33; eye disease, 0.99; and other diseases, 2.97. The high incidence of typhoid fever was not connected with the occupation; it was the reflection of an epidemic that was raging in the district.

PATHOLOGY

There is no record in the available literature of any particular illness among the women employed in raising silk-worms which can be directly attributed to the occupation, except possibly asthmatic attacks of an anaphylactic character, due to the scaly dust produced by the fluttering of the moths' wings when they are mating.

Disorders which can be classed as
occupational have, however, been noted among spinners, apart from respiratory disease, anaemia, or, in certain cases, conjunctivitis, which are found to affect all categories of workers obliged to work in warm and damp surroundings. Investigations made by Correnti in 1912 only served to reveal the existence of disorders of the blood characteristic of anaemia and chlorosis, which he attributed particularly to physical exhaustion, to work in hot, damp and close surroundings, and to bad feeding. Women employed at the reeling basins complained, especially in the past, of menstrual trouble due to the uncomfortable positions they work in, and to the effect on the abdominal organs of the heat of the stoves on which the water for the basins is heated. Troubles connected with the sensibility of the hands were reported by Crocco in 1910; but nothing definite was noted, and further investigation on the subject is desirable (Carozzi). But more often deterioration of the skin of the hands, which has the appearance of being macerated and is erythematous, may be found. This condition is especially found on the right side; but it cannot be considered as characteristic of the occupation (Carozzi).

The silk workers' dermatosis or "basin disease" (mal des bassines), described by Potton in 1853, which was regarded as of serious importance in days gone by, has almost disappeared at the present time. Carozzi states that out of 300 women workers examined, he only came across 9 cases of ulcerations about the nails (3 per cent.) and 3 cases of phlegmon (1 per cent.). J. H. Fabre, who discovered the irritating character of, and isolated a special virus from, the body and excrement of the bombix, did not in any way connect the existence of this poison with "basin disease". He showed that the troubles attributed by the Provençal silk-worm raisers to poison from the silk-worm, i.e. red and swollen eyelids, attacks of violent itching, with exfoliations of the epithelium of the forearm, were caused by the dust of the dried excrement of the silk-worms, and by contact of dirty hands with the face. F. Heim in 1904 and Pautrier, referring to Potton's research work, have described two kinds of dermatosis: (i) "silk-worm disease", due in the silk-worm rearing houses, to contact of human skin with excrement from the silk-worms, and (ii) "basin disease", possibly of similar etiology, which appears in the form of ordinary lesions due to macerations in the hot water of the basins, and as specific lesions. In the opinion of these experts, the

![Fig. 128. — One of the earliest filatures in Lombardy.](image)
hypothesis of a parasitic acarus cannot be accepted, for the irritant property is to be found in the normal healthy chrysalis. By rubbing chrysalis powder mixed into an ointment on the skin, the dermatitis has been experimentally reproduced. The lesion is said to be aseptic if protected from any secondary infection, and thus only the first of the three stages of the malady results.

The high temperature of the water in the basins, the mechanical action of the silk thread and the chemical action of the various substances, such as gum, grit and wax, which are in the cocoons when scalded, also contribute their part in the pathogeny of this lesion. But the importance of personal cleanliness must not be overlooked, nor, primarily, individual predisposition. In the most serious cases the dermatitis is the starting-point for other infections, the origin of which must be looked for outside the occupation, e.g. in domestic work. The reelers suffer from lesions on the hands which come and go, and are very variable, such as small ulcers that are round and crateriform, caused by the friction of the bottom of the basin during the beating of the cocoons; a small callosity on the right index due to erosion by the silk thread; callosities on the palm of the right hand, due to the pressure arising from the "escoubette" a small circular broom used for beating the cocoons as they float in the basins (Carozzi). Warts are often observed. In their writings Goldberg (1926) and Vedroff (1927) confirm the existence of these various cutaneous affections among the reelers of cocoons.

Neither are there any up-to-date data on the pathology of the weavers of silk. Birwitzky (1927) examined 400 women employed in throwing silk, and found some comparatively mild forms of catarrh of the respiratory tract, due to rhinitis and laryngitis. He also reported undefined disturbances, which he connected with the noise and vibration of the workshops he visited where the reeling and throwing of the silk took place.

Fig. 129. A modern filature in Italy.

The "shuttle kissing" found among cotton spinners is unknown among silk workers (Elton).

In an article written for the Industrial Fatigue Research Board (1922) on the subject of the psychological and physiological qualifications needed for weaving, Elton comes to the conclusion that a weaver should possess good sight, power of observation, skill in the use of both hands, a sensitive touch, and endurance when standing.

For weighting silk, lead is often used and also tin in the form of the phosphate, which takes the place of tetra-chloride of tin. Lead is fixed on to the silk as the oxide or phosphate or a
combination of the two. But it is a fact that in practice other salts of lead are used, such as the acetate, which is cheaper.

Finally, it is essential to recall the fact that lead may be extracted from the silk by the solvents used in dry-cleaning processes.

In 1912 Teleky drew attention to the risk of lead poisoning incurred by workers and persons who use silk from the weighting and the dyeing of the silk when such salts of lead are used as the acetate. From 100 kg. of silk, up to 4-5 kg. of waste were obtained, containing as much as 42 per cent. of acetate of lead.

Unfortunately, it has not been possible to consult several Chinese and Japanese contributions on the subject of the hygiene and pathology of women employed in the silk industry of those countries.

Cases of eczema caused by wearing silk under-garments have been attributed by S. J. Taub (1930) to a protein in the silk capable of causing non-specific asthmatic reactions. It is essential that fresh investigations should be made on this point.

Atmosphere is inadequate, there will obviously be a considerable condensation of steam, with the formation of a thick mist. In summer all that is necessary is good airing or natural ventilation; but in winter the difficulties become great, because it is necessary to introduce large quantities of warm, dry air into the building. The floor of a filature must be made of good material, fairly thick and warm, but not entirely impermeable. Drains covered with a grating must be provided for waste water. It is a good thing to have adequate space under the roof. If the building has a

Hygiene

In places where silk-worms are raised, the strictest cleanliness must be enforced, and hygienic measures must be taken to ward off disease from the silk-worms and to protect the women workers from unhealthy conditions of work.

The premises of a filature, where spinning is carried on, must be of dimensions in proportion to the importance of its plant. This refers chiefly to its floor space and height. For, if the building is too high and if the heating of the upper layers of the

Fig. 130. — A modern filature in Japan.
glass roof, there should be sliding panes which can be opened. It is better to avoid placing a cocoon filature on the ground floor; it is advisable to have it on the first floor, with the plant for producing heat and power on the floor beneath.

Avoid all great radiation of heat, and also the formation and unchecked discharge of steam into the air.

The rational and effective solution of the problem of doing away with steam is to limit its diffusion into the surrounding air; so it is necessary to catch it at its source, discharge it outside, and replace air saturated with humidity by dry, warm air. Of course, with water which is kept constantly at boiling point. After this preparation the cocoons pass into other basins, called reeling basins, filled with water at a temperature of about 60° C.

In some filatures the same basins have to serve as accessory and as reeling basins, so that all these preliminary operations take place in the same vessels, only, of course, the temperature of the water has to be lowered for the reeling.

In order to prevent the discharge of steam, filatures having separate accessory basins provide closed-in exhaust hoods, through which there are openings for introducing or removing the

Fig. 131. — Another modern filature in Japan.

the changing and the warming of the air must be regulated in order to keep the surrounding temperature from becoming too high. It is also quite a good thing to keep the interior of the building under slight positive pressure or at a pressure that is equal to that of the outside in order to prevent the formation of cold currents by air coming in from without.

As has been seen, reeling is necessarily preceded by the preparatory work of scalding, beating and cleaning. For these operations the cocoons are emptied into a special basin filled cocoons. This exhaust system allows for the evacuation of the steam.

When the work is not thus divided, the problem is more difficult. Some employers have recourse to reeling basins fitted with apparatus for evacuation. The arrangement consists of a double basin with an exhaust cover. This double basin consists of a round basin, which rests on the basin bench and contains water heated by means of a steam pipe going to the bottom of the basin. A ring-shaped cover fits exactly over the round basin and rests on the basin bench. An interior basin

51
called a "bassinette", round-shaped and widening out at its upper part, rests on the cover; its bottom and sides are pierced with holes, through which the water from the round basin enters. The upper part of the bassinette, which is widened out and crown-shaped, is pierced with two rows of holes, through which the steam escapes, only to be sucked up by an exhaust column adapted for each basin and opening into a collector surmounted in the centre by a main upcast chimney for evacuation.

Thermometers and psychrometers should be provided, in order to control the temperature, which should be maintained at about 23° C. (dry), while the humidity should not exceed 70-80 per cent.

The water in the steam-heated basins should be renewed frequently; used chrysalids should be removed; and the accumulation of waste liable to putrefy, or of fetid water, should be forbidden.

Water that has been used for scalding and washing should be emptied into a drain, without giving it a chance to decompose; it must never be emptied on to the roads, nor used for watering the land. The chrysalids and the solid waste from the manufacture must be removed daily, where possible, and in any case very frequently, and should be taken to the open country and buried deep, or else taken to special factories to be changed into manure.

These conditions must also be insisted on in the treatment of floss from the cocoons, i.e. in dealing with the residue obtained during the reeling operation, as well as with cocoons which have been pierced, and constitute the material used in the manufacture of flock silk and certain other stuffs.

After having been freed by maceration from the gumming substance with which they are impregnated, these residues are dried, beaten, combed, carded and finally spun. The residuary water from these manufactures is extremely liable to ferment.

Maceration of the skin in the early stage may be prevented by smearing the hands and fore-arms with a hydrofuge paste.

Whereas the problem of natural lighting is generally simple, because the buildings more often than not have a double row of windows or a glazed roof, much consideration, on the other hand, must be given to the placing
of lights for artificial illumination. It is advisable to see that the lights are placed alternately on the two series of basins, so as to cross and integrate the illumination on the working posts adequately. The use of 1/4-watt lamps of 400-600 candle power is to be recommended; for it is of value from the double point of view of hygiene and industrial economy. On account of the high degree of humidity, a well-insulated electric system must be provided. The workers' ordinary clothes must not be worn in the spinning mill. Cloakrooms, properly warmed in winter, should be provided. Working clothes must be made of flannel. A sufficient number of lavatories should be provided supplied with hot and cold water; and also privies which do not expose the workers to sudden changes in temperature.

When Asiatic countries become industrialised, the transformation of little workshops in isolated villages into factories takes place under varied conditions of hygiene. The provision at filatures of factory dormitories, in China for instance, is an example of progress. The special committee of the Japanese Association for Social Legislation, when studying in 1927 the protection of women working in silk filatures in Japan, put forward a resolution demanding the reduction of the working day to eleven hours, improvement of the sanitary conditions in factories and dormitories, and the strict application of medical examination, with notification of diseases.

**Legislation**

Boys under sixteen and women under twenty-one are excluded in Spain from reeling cocoons; in France young men under eighteen; in Italy boys under fifteen and women under twenty-one are excluded from opening and heating the residue from the silk where adequate exhaust ventilation for dust removal is not provided.

There is no special legislation for the silk industry, but in Japan reeler's dermatitis is compensated.

**Silos (Work in)**

From the time of the construction of the first silo in 1875, their use has become more and more widespread, with the result that conditions of work in them are of ever-increasing importance.

The former type of warehouse consisted of silos hollowed out in the form of a ditch, a system which presented grave danger from the accumulation of heavy gases. The modern type comprises a construction above the level of the ground, generally in wood, masonry, reinforced concrete or metal, provided with a roof and furnished with doors at the sides. During the filling of the silos with products to be stored, which are driven back by a current of compressed air, the workers are sometimes engaged in heaping up the goods which arrive by way of the piping. Metallic silos are erected on concrete foundations and comprise a central part
or tower and accessory parts; the roof, the storing pipe or blower and the small discharge turret or aperture. The degree of airtightness required for protection against acids of fermentation is provided by the use of cement inserted between the sheets of metal. An anti-rust paint is applied to the outside or it is subjected to a metal spray. In the inside, a paint with an asphalt basis or an enamel with a bakelite basis is used.

In large silos, especially in ports, modern technical methods involve the use of mechanical apparatus for transport and loading of the products. In very large plant, facilities exist for withdrawal of dust by exhaust from the goods (wheat, meal, etc.) and their transmission to the storing chambers.

In the flour-milling industry, storing in sacks is increasing in use. Here storing is also effected mechanically and automatically, and the silos are constructed in such a way as to prevent heating and the liberation of disagreeable smells.

**Sources of Risk**

Two sources of risk are involved by this work: inhalation of dust and asphyxiation by carbon dioxide liberated as the product of intramolecular alteration of the vegetable products. As regards the first danger, research has been engaged in by Tedeschi and Abbo in Italy.

Experimental research conducted with a view to acquiring knowledge of the various germs contained in these dusts (exposure of guinea-pigs to dust from silos and to artificial dusts mixed with bacilli of active tuberculosis) have revealed the fact that the anatomical-pathological lesions caused by the dust from silos chiefly affects the upper parts of the respiratory tree, the pulmonary tissue remaining almost intact. Nevertheless there has been noted a chronic hyperplastic inflammatory process of the interstitial tissue. The anatomical lesions caused by inhalation of the dust containing tubercular bacilli did not differ to a remarkable extent from those caused by natural dusts. It was concluded, therefore, that dusts coming from silos only favoured to a limited extent the development of pathogenic microbes.

Asphyxia due to carbon dioxide represents a further risk for workers in silos. A number of agricultural periodicals have drawn attention to this danger, which has likewise been reported as constituting a risk for workers occupied in the holds of ships transporting grain, and also for workers employed in peat trenches.

The composition of the air at the time of filling the silos is exactly similar to that of the normal atmosphere, but as soon as the forage is introduced the free oxygen in the air consumed by the fermentations is replaced almost volume for volume by carbon dioxide. An analysis of the air even during the first twenty-four hours often shows complete disappearance of free oxygen. The nitrogen concentration generally remains unaltered. Increase in the initial temperature noted in the silo is due to the intramolecular respiration of the vegetable cells increased by the respiratory surfaces of the cut plants. The liberation of harmful gases increases during a period of two days when the carbon dioxide produced becomes mixed with the residual nitrogen of the atmosphere. The carbon dioxide given off is a product of the life-process of the vegetable cell and not of a fermentative action due to micro-organisms developed subsequent to storing in the silos (Hayhurst and Scott). Carbon dioxide also acts as a preserving agent in the silo, and loss of it would be prejudicial to the merchandise. In general the mould only attains the surface of the silo. The carbon dioxide rate of development in a silo filled with green corn may attain 75 per cent. of the total gas present, the greater part of the remainder of the gases being constituted by the nitrogen of the atmosphere.

An analysis of a sample of gas from a silo gave the following figures:

<table>
<thead>
<tr>
<th>Gas</th>
<th>1st analysis (percentage)</th>
<th>2nd analysis (percentage)</th>
</tr>
</thead>
<tbody>
<tr>
<td>Carbon dioxide</td>
<td>38.0</td>
<td>38.3</td>
</tr>
<tr>
<td>Oxygen</td>
<td>13.5</td>
<td>14.0</td>
</tr>
<tr>
<td>Nitrogen</td>
<td>48.5</td>
<td>57.7</td>
</tr>
</tbody>
</table>

No reaction led to detection of carbon monoxide, ammonia, hydrocyanic acid or methane.

Workers who enter silos containing coal dust are also exposed to a danger of poisoning.

**Pathology**

Examination of a certain number of workers working under the above conditions has revealed frequent incidence of injury to the respiratory apparatus, notably bronchial affections and processes of broncho-pulmonary-sclerosis. Amongst workers employed in subterranean chambers there has been noted general weakness, anaemia, loss of weight and muscular strength, signs of incipient broncho-alveolitis with de-
finite sclerotic foci. Nevertheless, examination of the sputa was negative as regards the Koch bacillus. It must be remembered that these workers live under specially adverse conditions (unhealthy dwellings, etc.) which are far from being adequate and are distinctly unfavourable from the health point of view.

Hayhurst and Scott reported for the first time four fatal cases which occurred at Athens, Ohio. It is possible that accidents of this kind may have already occurred, their origin being probably attributed to other causes. The cases reported occurred under the following circumstances: by means of a ladder placed against the outside of a metal silo, four workers opened a door which was at a height of about 3.50 metres and entered the silo by jumping to the bottom, which was at a height of about 2 metres below the level of the door. Five minutes later two other workers climbed the ladder, and stated that the first four workers were lying dead on the ground. By entering the silo by a lower door it was possible to remove the asphyxiated men, who were completely cyanosed and had ceased to breathe. In the case of three, some cardiac movement seemed to remain. Efforts at artificial respiration and restoration of life were without success. In a few minutes all four were dead. Apart from accentuated cyanosis of the lungs, the mucous membrane, the trachea and the bronchial tubes, congestion of the liver and kidneys, congestion of the capillaries of the brain and intestines, no other important lesions were found. The heart and blood vessels showed no injury.

The silo had been filled with green corn from a recent harvest, the temperature in the interior was about 3.77°C above that of the exterior atmosphere. A guinea-pig, a rabbit and a dog exposed successively lost consciousness after a period of respectively 30 and 60 seconds and 23 minutes. The guinea-pig died in 10 minutes, the rabbit in 42 minutes. The dog, withdrawn after a period of 33 minutes, regained consciousness after 6 minutes and was completely restored without artificial respiration. A member of the enquiry who put his head into the silo at the level of the corn suffered a pricking and burning sensation in the nose and smelt an odour recalling that of alcohol. Another member of the enquiry found similar fumes at the level of the lower part just above the corn and experienced irritation of the mucous membrane of the throat for a period of 15 to 20 minutes. Experience proved that toleration was rapidly acquired as regards this type of disagreeable effect, with the result that often the workers exposed do not even notice it.

Workers in silos may be exposed to injuries to the skin and mucous membrane, especially the eyes, caused by grain and parasites present therein. (See articles "Agricultural Labourers" and "Flour Mills").

**HYGIENE**

Danger from asphyxiation in silos is considerable and exceeds that encountered in other occupational groups such as cellarmen, vineyard workers, brewery and distillery workers, manufacturers of yeast and vinegar. Thoroughgoing measures of precaution are in consequence indicated. Doors placed immediately over the level of the products stored in the silos should be left open or provided with hinges allowing of automatic functioning in accordance with the settling of the products stored. Suppression of roofing has been advised, which would have for effect the provision of draughts for favouring the removal of the gas. Nevertheless, the best means of prevention consists in the utilisation of a candle or lantern prior to entering the silo. Extinction of the light provides information as to dangerous diminution of the atmospheric oxygen.

Where explosion is feared, experiment may be made by lowering a mouse or small bird.

In case of accident, artificial respiration should be applied as quickly as possible and oxygen administered for inhalation. The incidence of a fairly high proportion of respiratory affections amongst workers in silos, and, on the other hand, the unfavourable action exerted by dust from silos on the health point to the need for prophylactic measures such as medical examination of the workers prior to engagement and periodical medical examination thereafter, with a view to the timely detection of signs of incipient respiratory disease.

***
Silver

Properties

Silver is a very white metal, fairly soft, and when polished is beautifully bright. Its symbol is Ag.; its atomic weight, 107.88; specific gravity, 10.5; melting point, 960° C.; and boiling point, 1555° C. (with the escape of blue vapour). Molten silver absorbs twenty-two times its volume of oxygen, and at the moment of solidification there is a sudden evolution of this gas which causes the metal to spurt in a characteristic way (the rocketting or "rochage" of silver).

It does not oxidise in contact with air, but becomes blackened in the presence of very slight traces of sulphured hydrogen, owing to the formation of sulphide of silver. It dissolves in cold nitric acid, becoming nitrate of silver, accompanied by an escape of nitrogen dioxide. Silver is very slightly attacked when cold by other acids, and not at all by alkalis.

The soluble salts of silver are precipitated from solution as the white chloride of silver by the addition of hydrochloric acid or chlorides — the reaction characteristic of silver.

Production

Mines. — The richest silver mines are in Australia and Mexico; there are also important mines in the United States, Bolivia, Peru, Chile, Saxony, Norway, France, and Silesia.

The ores worked are very various: native silver, argyrose (sulphide of silver), argyrythrose or red silver (double sulphide of antimony and silver), proustite (double sulphide of arsenic and silver), polybasite (sulphide of copper, silver and antimony), etc., which are properly described as ores, for they are treated for the silver itself. There are also numerous accessory minerals such as pyrites and argentiferous galena, which supply silver in addition to the metal for which they are treated (see articles "Copper", "Lead" and "Zinc").

The processes used for the ores, properly so called, vary much, according to the richness of the ore and the resources of the country. They may nevertheless be grouped as follows: (a) treatment by lead or materials containing lead; (b) treatment by mercury or the amalgam process; (c) treatment by the wet method.

(a) The ore mixed with lead or litharge, galena, red lead, or waste products from desilverising works is heated to 500° C. in a cauldron or kettle (four à manche). The dress which forms on the surface of the liquid is skimmed off. In this way working lead is obtained which is desilverised by ordinary methods (see article "Lead").

(b) The amalgam process is always carried out in the American mines by the cold process, as fuel is scarce. The ore is broken by hand into small pieces of 2 to 3 centimetres, riddled whilst dry and pulverised between granite grindstones with water. The product thus obtained is spread upon a paved floor (the patio) where it is mixed with common salt, the whole being incorporated by being trodden out by mules. Some days later "magistral", i.e. roasted copper pyrites, is added and then mercury. Chloride of silver is first formed and thereafter the amalgam. At the end of fifty days the mud is washed away by a flow of water; the amalgam is collected, filtered and distilled. The addition of hyposulphite greatly hastens the reaction, which then only lasts four days.

Amalgaamation by heat is employed mostly in Europe. The process called "val process" (aux tonneaux) is employed in Saxony. The ore when crushed, ground and roasted with common salt forms chloride of silver, whilst any arsenic and antimony present in the ore volatilise. The mass is ground and passed into revolving vats with water, iron and mercury. The amalgam collects at the lower part. Any excess of mercury is separated by filtering through chamois leather. The process is also carried out in coppers or pans in which the roasted ore is heated with common salt, water and mercury. During every operation the mass is actively stirred. Then the amalgam of silver is distilled, usually in a vacuum.

(c) The Augustin process (Freyberg) transforms by roasting the sulphide of silver into sulphate; a second roasting with common salt gives chloride of silver. The mass is then washed with a concentrated solution of common salt, which dissolves the chloride of silver. The metal is precipitated from its soluble state by copper, which is regenerated by iron.

It is also possible to proceed by dissolving the sulphate of silver directly and precipitating by copper.

The process of Patera-Russell used in California is only a variant of the preceding process. Chloride of silver, obtained by roasting, is dissolved in a solution of hyposulphite of sodium and then precipitated by sulphide of calcium and common salt. The hyposulphite of soda is regenerated with the formation
of sulphide of silver, which is filtered, dried, and roasted with lead. The argentiferous lead is then cupelled.

In Mexico, the cyanide process tends to replace the mercury process for extracting silver from poor quality ores. In this process the ore is treated by a solution of cyanide of sodium, kept in movement by aerial agitation. A soluble double cyanide of sodium and silver is formed from which the silver is separated by precipitation by passing the solution over zinc filings. The silver is collected in filter-presses, washed, and melted with borax and carbonate of soda.

In order to obtain fine silver, raw silver obtained by one of the processes referred to above should be again refined, either by cupellation (see article "Lead") or by electrolysis of a nitric solution of silver nitrate. The anodes are raw silver and the cathodes leaves of pure silver. Various devices are provided for detaching the crystals of silver which keep forming and are liable to cause short-circuiting.

**Use**

Pure silver is only employed for making crucibles and pans, used in the chemical industry for the preparation of alkalisi. An alloy of copper and silver is always used for the manufacture of jewellery, plate, coins, and other articles. "White metals" are alloys of silver, copper, nickel and zinc.

Among the salts of silver it is sufficient to mention the bromide and the nitrate, which are the most used in industrial processes. They are used not only in pharmacy, but also in the preparation of photographic plates and printing paper, and in silvering (see article "Electroplating"). The silvering of mirrors is carried out by heating a soluble silver salt with a reducing agent: the metallic silver is then precipitated on the glass. Silvering by heat is now very little used.

A very unhealthy employment is that of black engraving or Tula work; a preliminary incision made by machinery upon the surface of silver articles is filled with a powdered and melted mixture of copper, lead, sulphur and silver. Any excess of the black mass of Tula material is removed by glass paper, whilst the small quantity of sulphide of lead formed during the process is partly oxidised into a soluble compound of lead. The silver is blackened by the help of arsenic, by plunging into a bath formed of arsenious acid, sulphate of iron, concentrated sulphuric acid and fine zinc filings.

Arseniuretted hydrogen is then liberated; whilst in other baths a liberation of cyanogen may occur.

The making of silver leaf, which is generally done by hand (see article "Gold"), and the making of silver nitrate pencils by evaporating a solution of silver nitrate, are both injurious. The crystals obtained are crushed, sifted and melted into moulds in the form of pencils.

**Sources of Poisoning**

The occupational risks of workmen employed in the metallurgy of silver are represented not only by inhalation and contact with the metal, but also by inhalation of vapours of lead, mercury, arsenic, and tellurium, as well as by such poisonous gases as carbon monoxide, compounds of cyanogen, and arsine.

Miners and metallurgists are also exposed to the action of mineral dust containing the products above mentioned (lead, arsenic, tellurium, etc.). Further, it is necessary to take into account the risks arising from changes of temperature (sickness due to cold).

**Toxic Action**

The dust of metallic silver or its salts, once absorbed, reach the circulatory system and become changed into albuminate of silver, which is deposited in the tissues; it is still a matter of discussion to-day whether the absorption takes place through the digestive or respiratory systems, or by way of the skin. The state of the digestive apparatus may sometimes render it difficult to eliminate the silver absorbed. Nitrate of silver changes in the stomach into the chloride, and probably also partly into albuminates, which are eliminated by the stools or absorbed by the intestine.

When once the compound of silver arrives in the tissues, it is precipitated in the metallic state and becomes fixed in the tissues in a form which cannot be eliminated. This takes place either by the action of light, e.g., the skin of the hands, of the face and of visible mucous membranes, or by reduction, by means of sulphuretted hydrogen, in other tissues.

**Statistics**

Cases of industrial argyrisms are quite rare and cases of generalised argyrisms are still rarer. Though Pauluzzini noticed a particular coloration of the skin among silver workers.
Koelsch collected in 1912 a certain number of cases of occupational argyrysm, among which he mentioned those which came under his personal observation among working women who cut silver leaves and arranged them in books. Other cases have been reported among working women employed in preparing pencils of silver nitrate.

There may be recalled here a case of Jung's (1909) with grey coloration of the conjunctiva; three cases cited by Reuss (1897) among photographers who presented a localised staining of the carunculae iridum; five cases mentioned by Noble, as well as the case reported by W. Jones (1907), refer to persons employed in the extraction of the metal by the cyanide process.

Teleky (1914) recalls the two further cases of Schubert and Lewin in making silver nitrate pencils, and mentions cases reported by himself among workers who made silver nitrate pencils, and among the workers in the Isergebirge district where heads made of silvered glass are manufactured, at Goblonz and Morchenstein. The making of glass heads of gold, silver, or changing colour, gave employment to about 2,000 workers for the most part at home. This work was carried on as far back as 1796. The silvering of the beads was obtained by employing an alloy of lead and tin. In 1894 Ledetsch had already drawn attention to the existence of forty to fifty cases of argyrysm among workers, but it was only in 1910 that an enquiry was held by Teleky, which revealed about ten cases of which only five were of recent origin.

The cavity of the blown bead is filled with a solution of silver nitrate (1 per cent.) containing a little caustic potash and common salt. After clarification lactose is added to accelerate the reduction of the silver. Before 1910 this solution was introduced into the bead by the mouth, but a section of workers even then employed a small india-rubber tube for this purpose; to-day the process is invariably effected mechanically.

Besides the cases reported by the industrial clinic at Milan, must finally be mentioned the very recent cases of Subai (1922, Germany), of Adamson (1924, Great Britain), and of Maranon (1924, France).

**SYMPTOMS**

The deposit of silver causes a special blue coloration (blue men) which may be localised or general.

Blue spots appear upon the face, the carunculae iridum, the buccal mucous membrane, and especially upon the hands (the left by preference) of workers with silver, either the metal or its salts. The facts that the upper parts of the body are most affected (probably because they are less protected against the action of light than the lower parts), and that the buccal cavity presents a very intense coloration, are characteristic.

The existence of a line on the gums is a good deal disputed. Teleky, for example, does not admit it, at least in the form which has been described by Lionville. Other experts hold that at the beginning a small grey line is formed which may also occur on the free borders of the eyelids and around the nails. This line, noticed among persons who have been following a treatment with a base of silver, has not however been observed among workers.

Similarly various opinions are held upon the general troubles caused by silver. While A. Schmidt speaks of toxic catarrh of the digestive tract, R. von Jaksch states he has never observed any interference with the digestive functions, or dyspepsia, and considers that if these troubles do exist, that they ought to be ascribed to other co-existing toxic influences. In the cases of silver poisoning reported by Agasse-Lafont among photographers, examination of the blood has established an unusual number of mononuclear cells.

Spots of silver salt upon the skin are easily recognised because they are not removed by sulphuric or hydrochloric acids.

**DEMONSTRATION**

Silver may be detected without difficulty in the urine. Mayencon and Bergeret propose the following process: soak in the urine a little cylinder of zinc or of magnesium around which is wrapped a thread of platinum. The silver is deposited little by little upon the platinum. This line is made visible by plunging it for some seconds into an atmosphere of chlorine or of nitric acid vapour. The thread of platinum is then rubbed upon white paper moistened with ammonia. The deposit of silver appears black if the paper be then moistened with a solution of sulphuretted hydrogen.

**LEGISLATION**

In Argentina women are excluded from polishing precious metals (silver, gold). In France young men up to eighteen years of age are excluded from the refining of gold and silver by acids in workshops where fumes escape and acids are manipulated. In Italy boys under fifteen years and women under twenty-one years are excluded from refining precious metals.

In Spain boys below sixteen years, and women below twenty-one years are excluded only from places where fumes escape or where acids are handled. See also articles "Lead", "Mercury", "Arsenic", etc.

Special measures are insisted upon particularly in lead foundries which also
Skin Diseases

Skin diseases constitute at the present time an important chapter in occupational pathology, ranging from light erythema to epilimbioma and including a whole series of intermediate injuries, at times designated by the expression "Dermatosis traumaticus". Where the eruption assumes the form of a dermatitis, folliculitis, ulceration, or cancer, such a term is quite suitable so long as the causative agent is added. Where the causative agent is uncertain, it is essential to qualify the word "dermatosis" by the addition of the words "occupational", "industrial", "extrinsic", "traumatic", or "exogenous". The lesion will then be differentiated from an analogous cutaneous disease similar in type but of internal unexplained or unknown (i.e. idiopathic) origin. Characterised by accidental occurrence, in general of a persistent or recurring nature, occupational dermatoses are of considerable importance from the social and hygienic aspect. With the exception of cancer they do not endanger life, but they may nevertheless gravely affect health, giving rise to long periods of incapacity for work.

Certain of these cutaneous lesions were already referred to by Galien, Paracelsus and Agricola (sixteenth century), but it was Ramazzini (1700) who was the first to enumerate in a precise and systematic fashion the principal forms of occupational dermatosis affecting bakers, millers, fruit peelers, laundry workers, shoemakers, tailors, horsemen, sailors, etc., thus bringing to light the importance of certain etiological factors. Nevertheless, it was not before the end of the eighteenth century that general attention in the medical world was directed to these forms of dermatosis (Pott, Willan, Bate-man, Thackrah, in Great Britain; Alibert in France; Cazenave, Schiedel, Halfort in Germany, etc.), and thereafter, more especially since the end of the nineteenth century, and particularly during and since the war as a result of the development of the manufacture and use of chemical products, increasing attention has been bestowed on this problem. Thanks to the numerous studies existing at the present time, forms of occupational dermatoses are better understood than formerly, and it may be anticipated that they will become, in all probability, a diminishing factor of occupational risk, since their causes are generally evident or readily discerned. Recognition of these and the recent development of pathogenic theory have facilitated the application in the case of cutaneous affections of adequate methods of prevention which are at times simple and straightforward.

Etiology — Pathogenesis

Occupational dermatoses depend on the action of irritant agents (causative factor), as well as on reactions peculiar to the skin (accessory factor).

Irritant Agents

Accidents occur when the intensity of the irritation exceeds the limits of resistance of the skin, or when the stimulation lasts over an unduly long period. The duration of the action, the close contact, certain mechanical factors, the nature and solubility of the stimulant, etc., constitute several special factors which must all be taken into consideration. The various reactions of the skin to a given product may at times depend on varying composition or presentation of the product (its origin, method of production, etc.). In the majority of cases a product must produce a direct action on the skin various products must produce a direct action on the horny layer (burning, maceration, dissolving) or a destructive or colloidial chemical action on the protoplasm of the cells of this layer. Certain toxic substances, however, pass intact through the horny layer (tar derivatives, etheral oil, iodiform, orthoform, resorcin, pyrogallic acid, naphthol, naphthalene, aniline, and azo colouring compounds, certain vegetable substances, quinine, chrysarobin, etc.).

It is impossible, on account of their multiplicity and diversity, to provide a systematic and rational classification, not only of all the physical, chemical and biological agents likely to cause occupational dermatosis, but also of the trades and processes in which these sources of danger are encoun-
tered, and equally impossible to enumerate the operations involved.

Attempts to do so have, however, been made, and reference to these will be limited to the classification made by Prosser-White and based on the physical, chemical or biological affinities of the causes of morbid conditions:

1. **Mechanical or physical agents:** Cuts, pricks, abrasions, friction, pressure, crushing, tearing. Mass effects such as the action of solids, liquids or fumes, either in molecular form or in subdivision.

2. **Detergents:** The action of which consists in a washing of the skin, generally with softening or solution of the horny layer (maceration): hot water, soap, light alkalies (soda, turpentine and its substitutes); all substances which emulsify skin lipoids increase the irritant action of other chemicals: cotton seed oil, olive oil, alcohol, phenylene bases, aniline and many aromatic hydrocarbons which dissolve the skin cholesterol and enable the former to penetrate.

3. **Desiccators and anhydrides:** Hydroscopic bodies, sulphurous, sulphuric, nitric and phosphoric dioxides. These products absorb water and generate heat in forming their respective strong acids: potash, soda and strong alkalies; ammonium nitrate, caustic lime, calcium chloride, calcium nitrate, hypochlorites including the hypochlorides; nitric and sulphuric acids.

4. **Hydrolysers:** These unite with one or more molecules of water to form separate compounds, usually more simple: chlorides of organic compounds (for example dichlorehyl sulphide, which in the presence of water liberates chlorine ions to form hydrochloric gas), borocain (splits into boric acid and cocaine), ammonium nitrate (splits into nitric acid and ammonium), phosgen (splits into hydrochloric acid and carbon monoxide). Hydrolysis causes liberation of energy which stimulates the sensitive nerve endings, and the consequent reflex brings about dilatation of the blood vessels, capable of developing into erythema, swelling, phlyctenules and necrosis (W. E. Dixon).

5. **Protein precipitants:** These are all irritants: all the heavy metal salts (Cuschny), formaldehyde, most acids (tannic acid, picric phenic acid, etc.).

6. **Oxidisers:** Nitrates in the presence of acids, chlorine and its compounds in the presence of water, free iodine and its preparations, the hypochlorites including "bleaching powder", ferric chloride, peroxide of hydrogen, chlorate, potassium, nitrate of potassium, nitric and sulphuric acid under certain conditions, pure potash and soda, ozone, persulphate of soda.

7. **Reducers:** splitting water with liberation of hydrogen: These agents in weak solutions are often keratogenic (kerato-plastic) stimulating cornification; in strong concentration they act as keratolytics: tar, pyrogalol, most free and all finely divided colloid metals, formalin, paraphenylenediamine, phenol, resorcin, sulphur dioxide, hydrosulphites and sulphides, carbon monoxide, arsenious oxide (combines with oxygen to form arsenic acid), bismuth: and meta-phenylendiamine, phenyl in the presence of oxidising agents.

8. **Free acids in salts or forming toxic nitro derivatives:** Nitro-hydro carbon derivatives, trinitrotoluene, dinitrobenzene, tetryl, picric acid.

9. **Keratogenic and neoplastic agents:** Arsenic, certain distillations of bituminous coal, petroleum and shale oils, aniline, certain radiations.

10. **Biologic agents:** Effect of vegetable and animal agents on the skin and tissues (micro-organisms, parasites).

11. **Sensitizers:** Favoring constitutionally changes of the skin and bringing about a more intense or violent reaction in response to a further application of the former agent:

   (a) **Anaphylactoid agents** (Hanzlick): chemical products: haematoporphyrin, aspirin, benzene molecule in 606, iodine, mercury, phenylhydrazine.

   (b) **Anaphylactic agents** (Richet) set up antigenic reactions; vegetable proteins (legumes, cereals, flour, pollen); or animal proteins (milk, eggs, feathers, scales, flesh).

The various products met with in industry exercise mostly a mixed action and there is a certain difficulty in determining at what point chemical action ceases and physical action commences, etc. Nevertheless, it is the chemical action which is predominant in inducing the outbreak of forms of occupational dermatoses, though in regard to the majority of these products the precise mechanism of their action is still obscure. The origin of these troubles would appear to be less complicated in the case of those which present the medical-legal aspect of an occupational accident. It is then a question of direct or more or less distant consequences of an accident (injuries caused by projection of chemical substances as a result of accidental breaking or splintering of receptacles, piping, etc.). In the most obscure
cases it is a question of more or less retarded complications where dermatoses are due, apart from the primary agent, to complications caused by excessive recourse to medicaments (peroxide of hydrogen, iodine, picric acid, irritating ointments) or to rapid or delayed infection of wounds. The complications of pathogenic agents may be further manifested by superimposed varicose ulcers, the development of blastomyces, trichophytosis, sporotrichosis, etc., on the parts of the skin exposed to recurring traumatism. These same traumasisms may favour localisation of certain infectious lesions (anthrax, malignant pustule, anatomic tuberculosis, syphilis). Finally, idio-pathic dermatoses or dermatoses of internal origin (psoriasis, purpura, certain types of scleroderma) may occur as a consequence of certain traumasisms (Aievoll).

Skin Resistance

The strength and elasticity of the healthy skin make it resistant to mechanical injury of average extent, as well as to many noxious fluids and powders. On the other hand, the various layers of the skin possess specific resistance with regard to the action of certain harmful factors. Thus the horny cells are unaffected by a 50 per cent. solution of mineral acid and pepsin. The kerato-hyaline of the granular layer is insoluble in alcohol, ether, chloroform, weak acid and alkalis. Boiling water is harmless to the spongioplasm of the tactile cells. Certain agents, however, readily destroy the cellular elements of the skin. The horny layer is soluble in weak solutions of potash, soda, milk of lime, alkaline earths and sulphides. Eudelin is rapidly destroyed by formalin, sublimate, acids and alkalis; the last disintegrate the spongioplasm and saponify the cholesterol and liquid waxes which form the protecting secretions of the sebaceous glands.

The openings to these, the hair follicles and the furrows on the skin's surface are its most vulnerable points. They constitute accordingly the points of origin of most if not all cutaneous troubles by reason of accumulation of oils, chemical powders and noxious liquids. It is at these points that bacteria penetrate, and it is there also that bites and stings of insects succeed in injecting poisons or pathological agents into the blood.

The skin is, however, to a greater extent than any other tissue subject to individual reactions, which it is necessary to take into account in ex-plaining the excessive resistance or sensibility of certain workers in regard to various dermatoses.

Modern research tends to support the conclusion that individual characteristics of the skin are dependent on the glandular equilibrium of the individual on various endocrine derangements or nutritional disturbances likely to set up highly varied reactions. Deseaux even goes so far as to consider the epidermis as an immense endocrine gland and seeks to establish on the basis of the chemical reactions which take place within the deep-seated epidermic cells and the dermic cells a pathogenic theory relative to cutaneous accidents. Hyper-sensibility — recalling anaphylactic phenomena — may be monovalent or polyvalent according as to whether it is a question of one or several substances provoking the reaction. In certain cases the limited areas of the skin present a special sensibility and even where it is a case of a product with a general action (absorption of a substance through the mucous membrane or the digestive or respiratory passageway) the phenomenon becomes located on a sensitised area of the skin. This fact has been experimentally demonstrated by allergic reaction of the sensitised dermic cells with regard to a given irritant applied to persons insensitive to this irritant. According to the products which may bring about an outbreak of the anaphylactic syndrome, it is possible to foresee what occupations would constitute exposure to these risks.

At times certain subjects, who for many years have enjoyed natural immunity as regards a certain harmful agent, contact with which has been more or less continuous, suddenly at a given moment develop, for a quite inexplicable reason (nutritional disturbances or derangement of the endocrine system, etc.), sensibility to the noxious agent.

As a rule, sensibility of the skin occurs after a delay which it is not possible to determine accurately, but it may be very brief. Once acquired, a very slight quantity of the product in question may set up extremely serious injury. In the case of certain substances, the intervention of an accessory factor such as light is essential in order to bring about sensiveness (anthraquinone, acridine, anthracene, pellagra, etc.).

This sensiveness of the skin may be diminished or intensified by various constitutional factors: age (immature skin of youth and the atrophied skin of age are particularly sensitive), sex.
SKIN DISEASES

which were of occupational origin. Gardiner (1919), among 1194 cases, 870 of
accordance with variations in the system of classification. It is placed at 1 per cent. by Finch Noyes,
and referring to the various organs (kidneys, digestive system, nervous system, etc.). The importance of these
factors has often been emphasised by various authors and as regards occupational accidents it has been noted that
their development is accelerated by several months in the presence of seborrhoea and several weeks where
there is excessive perspiration (Gardiner).

It is essential also to take into account the fact that in certain cases, subsequent to a slight initial attack of
dermatitis, there set in a period of acclimatisation of the skin to the harmful agent. Finally, it should be stated
that the skin injuries after a first attack of dermatitis may persist even after withdrawal from the action of the
harmful product.

Prof. Prosser White
(Manchester).

STATISTICS

At the present time the literature relating to occupational dermatoses is extensive, and the references are very numerous. But the evaluation of these statistics is not easy, because there has to be taken into account the influence of the personal factor, as well as the particular qualification needed for making a diagnosis. Speaking generally, it may be said that most statistics either over-estimate, or under-estimate, the etiological influence of occupation.

The proportion of occupational dermatoses in relation to all dermatoses is assessed differently by different authors. It is placed at 1 per cent. by Finch Noyes, at 2 per cent. by Fordyce (1911), at 4 per cent. by Lane, at 6 per cent. by Prosser White, at 7.5 per cent. by Gardiner, and even at 18.5 per cent. by Knowles (1913). This percentage may, however, be higher when the statistics deal with a period of observation not exceeding one year; it is 22 per cent. according to Oppenheim, who studied 2,040 cases of dermatoses in 1912; 25 per cent. according to Prosser-White, in a group of 250 patients; 57 per cent. according to Oppenheim (1928), among factory workers, the subjects of an investigation; 72 per cent. according to Gardiner (1919), among 1,194 cases, 870 of which were of occupational origin.

As regards eczemas, very variable rates have been given, the occupational origin being quoted sometimes at a third and sometimes at a quarter of the total cases observed.

Some Austrian figures dealing with a period of thirteen years, from 1907 to 1922, but not including the years 1911 and 1917, and relating to 27,500 cases of dermatoses give, according to Oppenheim, 20 per cent. as of occupational origin.

The proportion of occupational dermatoses to all diseases met with among workers is also very variable. Thus, Emmons gives a percentage of 2.4, based on 963 observations; Lane gives 6.8, basing his statistics on 71,575 cases observed in factory dispensaries, but the percentage fell to 3.8 when burns and wear-and-tear of the fingers were eliminated.

In the State of Ohio, 3,241 cases of occupational diseases notified during five years, from 1 July 1920 to 30 June 1925, included 2,632 cases of dermatoses. Recent figures dealing with 4,870 cases of sickness observed during three years in the clinic of industrial diseases of the hospital of Massachusetts included 592 cases of dermatoses, 147 of which were of occupational origin, according to Parmentier and S. Dubreuilh.

The relative incidence of the different forms of occupational dermatosis exhibits the following data according to Oppenheim among 1,061 cases collected in 1910 and 1915: eczemas and dermatoses, 341; burns and injuries by caustic substances, 483; rhagades, 51; excessive sweating, 30; impetigo, 126; chilblains, 12; herpes tonsurans, erysipeloid, 4; pimplies from oil, tar lesions, 10; poisoning of the skin by toxic substances, 2.

Numerous statistics have been collected in separate occupations, but references must here be restricted to only a few of them.

In Germany the number of cases of occupational dermatoses per 100 workers in a large chemical works between 1881 and 1904 has been classified by Leymann as follows:

<table>
<thead>
<tr>
<th>Occupation</th>
<th>Cases per 100 Workers</th>
</tr>
</thead>
<tbody>
<tr>
<td>Seamless Tube Workers</td>
<td>11.2</td>
</tr>
<tr>
<td>Plasterers</td>
<td>11.9</td>
</tr>
<tr>
<td>Chemists</td>
<td>12.0</td>
</tr>
</tbody>
</table>

In another statistical table relating to the whole of this industry in Germany during the period 1900-1910 the cases of occupational dermatoses per 100 workers are classified as follows:

<table>
<thead>
<tr>
<th>Occupation</th>
<th>Cases per 100 Workers</th>
</tr>
</thead>
<tbody>
<tr>
<td>All manual workers</td>
<td>8.10</td>
</tr>
<tr>
<td>Workers on sulphur, nitric and hydrochloric acids</td>
<td>11.06</td>
</tr>
<tr>
<td>Workers on crude and crystallised soda, caustic soda and salts of soda</td>
<td>26.40</td>
</tr>
<tr>
<td>Workers on caustic lime and chloride of lime (for the period 1891-1904 only)</td>
<td>8.10</td>
</tr>
<tr>
<td>Workers on regeneration of sulphur, sulphates</td>
<td>13.73</td>
</tr>
</tbody>
</table>

In Ontario, Canada, for the period from January 1921 to July 1925 there were reported 73 cases of dermatoses, out of 472 cases of occupational diseases; of
these 55 were caused by nickel, 15 by sugar and 5 by chromium. Only 21 cases of nickel dermatosis were compensated out of 173 cases compensated for occupational diseases.

Guy Lane was able to draw up the following occupational classification for grouping 1,342 cases out of 2,000 cases of occupational dermatoses:

<table>
<thead>
<tr>
<th>Occupations</th>
<th>Number of cases</th>
</tr>
</thead>
<tbody>
<tr>
<td>Housewives</td>
<td>702</td>
</tr>
<tr>
<td>Labourers and factory workers</td>
<td>175</td>
</tr>
<tr>
<td>Painters</td>
<td>87</td>
</tr>
<tr>
<td>Metal workers</td>
<td>73</td>
</tr>
<tr>
<td>Workers in the oil and fat industries</td>
<td>67</td>
</tr>
<tr>
<td>Sanitary employment</td>
<td>57</td>
</tr>
<tr>
<td>Sellers of fabrics, and tailors</td>

<td>48</td>
</tr>
<tr>
<td>Tanners and workers on skins</td>
<td>40</td>
</tr>
<tr>
<td>Makers of chemical products and medicaments</td>
<td>40</td>
</tr>
</tbody>
</table>

An investigation made in the State of New York for 1928 into 390 cases of dermatitis of occupational origin showed that 24.2 per cent. were incapacitated from work for twelve months, with one or several relapses in the year; 21.5 per cent. for one to three months; 16.4 per cent. for four to six months; 14.9 for two weeks to a month. The cutaneous lesions were as a rule situated on the arms and hands (91), lower extremities (30). In 118 cases charwomen were affected.

Cases of dermatitis reported by voluntary notification to the British Medical Inspectorate of Factories are numerous and interesting: 305 in 1924; 336 in 1925; 429 in 1926; 525 in 1927; 662 in 1928; 834 in 1929; 789 in 1930. In 1928, Bridge reported that 16.5 per cent. of the male cases and 8.8 per cent. of the female cases had had one or several attacks of dermatitis, and that the greatest number of these cases occurred in persons aged from twenty to thirty years.

In 1934 Bridge published the following table:

### DERMATITIS: PRINCIPAL OCCUPATIONS

Cases of dermatoses compensated under the British Workmen's Compensation Act (restricted to cases reported among factory workers, who, as a matter of fact, account for almost all the cases of dermatoses) give the following data: 1920: 391 cases out of a total of 869 factory compensation cases for all causes; 1921-1922: 215 out of 953; 1923-1924: 807 out of 1,834; 1925: 377 out of 1,119; 1926: 685 out of 1,106; 1927: 879 out of 1,394; 1928: 1,146 out of 1,571; 1929: 1,399 out of 1,942. An annual average of 966.6 out of 1,365.8; that is, over 50 per cent. of all the cases of occupational disease for the years 1930, 1931 and 1932, data are as follows: 1,445 out of 2,066; 1,229 out of 1,687; 1,484 out of 1,952.

In Switzerland, the National Accident Insurance Fund compensated, during the period 1922-1927, 702 cases of dermatoses from a single cause and 56 cases of dermatoses due to several causes of injury; it has, in addition, compensated 4 cases of permanent invalidity from dermatosis. The most common causes of injuries of the skin were: (including sulphuric, nitric and acetic), petrol, lime, the chromates, the nitro- and amido-derivatives of benzine, chloride and chloroform, tar and pitch, and chloride of tin.

### GENERAL SYMPTOMATOLOGY

The period included between the commencement of the action of the In-
juristic cause and the development of the dermatoses varies according to the nature of the agent and the personal reaction. Dust or fumes generally act less rapidly than liquids and solids which are not pulverised. Microbes always abound in the parts of the skin exposed during work to contact with the products, which accumulate, in preference, on the salient parts, articular folds, wrinkles, the hairs of the body, up to the edge of the scalp, at the palpebral borders, the auditory meatus, and at the nares. However, the lesions are quite often situated on covered parts, especially at certain points, for example the region of the belt, the inguinal folds, the genital organs in man and the site of the garters in women. For reasons not so far understood, certain regions are affected to the exclusion of others equally exposed: thus, on the hands, lesions may be seen limited to the palm, or, on the contrary, to the back of the hand, stopping abruptly, in this latter case, where the direction of the special epidermic folds indicate the commencement of the palmar surface.

Moreover, the cutaneous conditions may spread over a more or less extensive part of the skin, or become generalised over the whole surface of the body.

The clinical forms of occupational dermatoses vary according to the nature of the injurious agent, the duration of the lesion and the constitution of the individual.

The first stage is represented by vascular disorders, which are the consequence of an alteration in the nutritional elements of the skin; these react by a defensive process, if the irritation is not too acute; if the contrary is the case, they succumb.

Microbes, which always abound in the superficial parts of the epidermis, especially in persons who are not too particular, penetrate into the deep layers through the chafings which furrow the skin, and multiply in the exudates which were originally aseptic, thus transforming the dermatitis into a pus infection of the skin. The lesion may then extend by continuity and even by being transferred to a distant site, whence arise special lesions of the face and, in man, of the genital organs.

The vascular disorders consist chiefly of an erythema, often accompanied by oedema of the skin. On this erythematous base, vesicles next develop, the contents of which discharge and become dry, so giving rise to the formation of crusts. The vesicular type may take on an eczematous character; by secondary infection, the vesicles become transformed into pustules, when their confluence may originate lesions of many different forms.

It would seem reasonable to classify the extremely numerous clinical forms according to their etiology and origin; most of the cases this is difficult to specify. Further, the various ways in which the skin reacts are common to numerous irritants.

References should be made to the sections below dealing with "occupational stigmata," effects of heat and cold, including burns and chemical burns, and "nails and hair"; also to the articles on "Electricity," "Radium and Radioactive Substances," "Tumours of Occupational Origin," and "Infectious Diseases" for the dermatoses arising from the causes in question.

Affections of the sudoriparous glands and the sebaceous glands are due to such substances as resins, dust and oils, which penetrate into them and obstruct their orifices, leading to the formation of comedones and folliculitis. There are many recorded cases of oil pustule (eliaoconiosis) which affects workers in metal industries (see article "Petroleum"); acneiform folliculitis, met with among workers handling tar and its derivatives, lamp black, asphalt and pitch, among workers at petroleum refineries and paraffin works, and also among cement workers; toxic acnes, of which the best known are chlorine acne and bromine acne; follicular keratosis, seen among workers using a mixture of zinc oxide, emery and pumice stone.

Some substances, such as aniline and chloride of lime act on the sudoriparous glands, leading to hyperhydrosis, which, in its turn, favours the development of dermatocnosis; in other cases, the effect produced is an anhydrosis with toxic dermatitis.

Sweat may show a coloration varying with the material employed; such as green, in brass and copper workers; and blue, among those who handle methylene blue. It may also have an odour which varies according to the substance which causes it; as, for example, an odour of violets after the inhalation of turpentine vapours.

When eruptions are produced, in which the principal part is played by the integuments becoming sensitive to irritant agents, on the one hand, and, on the other, by the production of a hemoglobin shock breaking up the blood, which, however, is not constant, they may assume very different aspects: redness slightly marked with spots; erythema-morbilliform, diffuse or scarlatiniform; urticaria; lichen; oedema
without erythema; erysipeloid eruptions; vesicles or bullae. They may be generalised, or, as is more usual, localised; their development is generally acute.

Cases of dermatitis, due to the irritant action of a foreign substance, vary clinically with the nature of the irritation. Their intensity depends especially on the lesions of the epidermis, and the starting-point of the cutaneous affection.

Eczemas are very important on account of their frequency and the influence they exert on the economy of labour owing to incapacity for work.

Almost all authorities actually regard eczema as a disease caused by sensitisation. Oppenheim, however, distinguishes between skin poisonings or artificial dermatites and occupational eczemas properly so called. These last only appear on integuments which have become sensitive; they persist after, and in spite of, the disappearance of the injurious agent, thus differing from cases of dermatitis in which the cutaneous reactions are due to the activity of some irritant cause and disappear with it.

Jadassohn regards eczemas as poisonings of the skin due to cutaneous reactions against non-microbial irritants which are clinically and histologically quite clearly defined.

Predisposition may be congenital, i.e. an "idiosyncrasy", or acquired, i.e. a "sensitisation". A predisposition is necessary; but very little is known about the condition of sensitisation.

The theories advanced to explain the pathogenesis are still more numerous: on the one hand, an antigen, which is represented by numerous external substances or produced within the body, is suggested; and, on the other hand, a sensitisation resulting from hereditary or acquired changes in the body (Ravaut). Eczema may be regarded as resulting from an abnormal cutaneous sensitisation to certain agents, which may be a congenital idiosyncrasy or an acquired allergy; or eczema may be considered as a cutaneous affection due to an alteration in the sympathetic vaso-motor system (Millan).

Occupational eczema does not occur so much under the influence of the sensitisation to a definite substance as under the action of repeated and prolonged exposure to all the collection of causes of skin irritation which may arise during work. True occupational eczema should be considered as the result of physical or chemical changes in the corneal layer and of the epidermal fat, rather than as a pure allergic process. Oppenheim considers that water plays a very important part, because, after maceration of the corneal layer, it leads, by mechanical action, to fissuring of the superficial layers of the epidermis.

The symptomatology of occupational eczemas is similar to that of natural eczemas. The damage occurs chiefly on the uncovered parts. The right hand is more often affected than the left, and the dorsal surface more often than the palmar. The development is acute or chronic, with exacerbations, and sometimes it is complicated by a mixed infection. Cessation from the occupation generally leads to a cure, whilst the return to work may produce either a relapse or a second attack from causes which are often ill defined.

It is difficult to separate clearly the groups which have been discussed, for their symptomatology has many points in common. Each irritant product may, in different individuals, lead to manifestations characteristic of one of the groups, while developing towards conditions peculiar to other groups.

Substances of vegetable or animal origin, either in their natural or

---

1 It is proposed here to cite merely certain cases of skin affections observed as the result of handling plants belonging to the most varied species:

Buxus sempervirens: erysipeloid dermatitis in a gardener (Oppenheim).

Solidago virga aurea: maculo-papular dermatitis accompanied by itching and burning, in four peasants after three to twelve hours work at hay making (Sutton).

Chrysanthemum leucanthemum: inflammation of the face in a flower seller; the hands were not affected; cessation of work caused the condition to improve (Dawson).

Chrysanthemum indicum: a skin irritation of the face and hands, accompanied by fever, in a gardener (Hoffer).

Pyrethrum: dermatitis in gardeners and workers employed in crushing and packing. McCord distinguishes four forms: (1) vesicular dermatitis, the most frequent; (2) poisonous erythema (50 per cent. of cases); (3) popular dermatitis; (4) anaphylactic form (in an engineer at an insecticide powder factory).

Doronicum pardalianches: diffuse redness of the face, hands and feet in a woman employed on gathering these roots (Hoffer).

Helianthus annuus: dermatitis, observed by Dreger.

Equisetum tinosorum: exanthem on the forearms and neck of a woman who had cleaned metal objects with a decoction of equisetum, soda and animal bile (Kulp).

Graminaceous plants: popular exanthem with itching, often accompanied by fever, which lasts between six and twelve hours. Hoffer mentions several graminaceous plants which have caused epidemic dermatitis. Twenty-five members of seven families were affected with erythema after having cut Sorghum (Hoffer).

Exanthem resembling strophulus observed by Hodara in porters carrying rice sacks at Constantinople, by Loir and Légaugneur at Havre.
changed state, may cause cases of dermatitis (see articles "Poisonous Woods", "Cantharides", "Gardeners and Market Vegetable Workers", "Silk", "Sugar Refining", etc.).

Interest may here attach to mentioning, even though briefly, the morbidity anaphylactic syndrome characterised by different phenomena: superficial lesions of the mucous membranes, asthma, circulatory and respiratory disorders. The anaphylactic agent, whether of animal, vegetable or chemical origin—the antigen—has its effect explained by its action on some special soil, particularly prepared as the result of heredity, or reasons of diathesis and constitution, based on morphology, neuroses or disorders of the endocrine apparatus; this soil presents a predisposing state which is necessarily latent.

Melanosis, hyperkeratoses and atrophies are partly occupational stigmata or manifestations accompanying cases of dermatitis, folliculitis and the diseases properly so called. Melanosis,

by Alderson and Rawlins among dirty workers employed on rice (see article "Rice").

Quercrocho Schinopsis Lorentzii: a cause of dermatitis in the hands reported in the province of Santiago and due to contact with leaves, branches and sawdust. The symptoms reported by O. di Lulio (1926) were itching, oedema and a skin eruption.

Mucuna pruriens: a cause of dermatitis among workers on sugar-cane fields.

Phaseolus vulgaris: recurrent erythema in predisposed workers, due to contact with french beans in preserving factories (Sternthal). The factory inspection department at Brunswick has prohibited this kind of work for susceptible persons.

Asparagus: diffuse redness accompanied by swelling and military vesicles on the arms and hands of a woman employed in cleaning asparagus. A niece of the patient showed the same redness and swelling.

Hyaecithus: skin irritation on the sides of the fingers, occurring every year during work on bulbs (Broers). See also article "Gardeners".

Linnun ustutattismum: varioloïd exanthem in a young girl employed in a Russian flax mill for the lubricating oil (Purdue); among the spinners and bobbin boys (Leleij). Flax-workers' fever (Heijermans); attacks of asthma in flax grovers (Voskamp).

Cannabis indica: inflammatory dermatitis in a rope maker who sorted Indian hemp (Rorlas).

Humulus Lupulus: Skin affections accompanied by redness, fever and oedema in a young girl, twenty-four hours after a stay in a hop yard (O'Donovan). An exanthem on the face, hands and feet in a weaver of hemp for about forty years, after six days' work with hops (Streich).

Fumaria planifolia: redness and swelling of the hands, forearms and neck of a young woman, twenty-four hours after a stay in a hop yard (O'Donovan). An exanthem on the face, hands and feet in a weaver of hemp for about forty years, after six days' work with hops (Streich).

Vanilla planifolia: redness and swelling of the hands, forearms and neck of a young woman, twenty-four hours after a stay in a hop yard (O'Donovan). An exanthem on the face, hands and feet in a weaver of hemp for about forty years, after six days' work with hops (Streich).

which has been especially recognised since the war through work on experimental cancer in mice, appears as a pigmentational reaction which is due either to the direct pigmentary action of the material absorbed, or to the action of light-sensitive substances. It is chiefly met with among workers in tar, asphalt lubricating oils, arsenic and vaseline. Diffuse or circumscribed follicular hyperkeratoses accompany the folliculitis of hyperpigmentation and dermatitis in persons doing work where such derivatives of carbon as pitch or petroleum, vaseline or petrol, are used. They are also met with in butchers, pork-butchers, tanners, depilators of pig skins and washers of cobalt ore.

Atrorhizus spinosus and Atrorhiza grandiflora: dermatitis in gardeners employed on amelopsia quinquetoila (Harrison). Cases may also be mentioned of dermatitis from celery (Lortat-Jacob and Legrain), from tomatoes (Foä), from the juice and essence of lemon (Lorriga) and of orange, from Avundo donaz and of turpentine (Lorriga). These cases, due to a fungus. See also article "Perfumes".

SKIN DISEASES — 864 —
on to a previous skin lesion, or primary from the first. (See articles "Foot and Mouth Disease", "Glanders", "Syphilis (Occupational)", and especially the article on "Infectious Diseases". As regards skin lesions due to the action of various parasites, see article "Parasites").

**Prognosis**

In most of the cases it is not difficult to predict the development and the duration of occupational dermatoses.

Removal from the irritant cause, followed by adequate treatment, often leads to the cure of cases of industrial dermatitis and exogenic eczemas, provided that these lesions are not complicated by secondary affections or constitutional predispositions, which may greatly retard the recovery.

Prognosis, then, depends on the possibility of removing the patients; but, unfortunately, such a measure is not always understood; and very often patients are to be seen employed on work which is not suitable for them.

Another feature in prognosis rests on the individual constitution, from the point of view of resistance, either general, or of the skin. The most tenacious forms are the eczematous. The rapidity of the cure of ulcers or suppurations due to the action of irritants depends on the depth and the extent of the lesions. Some large rebellious ulcerations may leave behind chronic weaknesses, or become complicated by such secondary affections as panaritis, phlegmons, leading to vicious cicatrices, with retraction of the palmar aponeurosis, followed by pitting of the skin (pigeonneaux). Some products, such as derivatives of oils, tar or chlorine, may cause lesions with a tendency to malignity. In the early stages, the process is invariably local. Immediate extirpation, or immediate cessation from work, gives satisfactory results, and the neoplasm does not recur. New tumours may, however, develop years after exposure to the toxic product has ceased; and that is a point which must not be forgotten. On the other hand, some cicatrices may, after a certain time, become cancerous (Prosser White).

**Prophylaxis**

Prophylaxis depends on an exact knowledge of the occupational risks, on the efficacy of protective measures, on precise and minute attention to these measures, and upon the cooperation of everyone towards improving existing conditions.

There is a natural prophylaxis, for many of the workers become accustomed to resist the causes of the changes; they acquire a kind of adaptation of the skin to external irritation.

In addition to general hygienic measures in workshops, including ventilation, removal of fumes, gases, vapours, the use of closed apparatus, arrangements for preventing splashing and direct handling of certain products, there is a series of important personal measures: selection of personnel by medical examination on commencing work, with the exclusion of certain persons; periodical examination in order to eliminate from some kinds of work predisposed individuals or those already affected; the detection of injurious products — which is often very difficult; cleanliness of the skin; thorough drying and greasing of the hands and skin exposed to injurious products; with non-irritant substances at night and, if possible, during work; first aid even in the case of the smallest lesions; periodical examination of the hands and forearms; and the use of gloves.

The instruction and education of the personnel must be assured by bringing to their knowledge the dangers they run, and the measures of protection, by means of leaflets, posters and lectures. There are various types of poster, among which should be mentioned that issued by the British Medical Inspectorate of Factories: Form 307, April 1928: "Dermatitis Cautionary Notice"; that of 1929 on dermatitis in peelers of oranges and lemons; the regulations of the Industrial Association of the German Chemical Industry. Any measure, however detailed and strict, may be inefficacious if the persons who are exposed are not first convinced of the necessity for self-protection (Fischer).

**Legislation**

The general hygienic measures vary according to the etiological agents (see the articles devoted to various industries and occupations) and are contained in the texts of the Laws, Decrees, Regulations, and Orders made by responsible authorities.

In some countries as a result of compulsory medical examination before commencing work, persons affected with dermatoses are excluded by law (Japan), and also at periodical examinations.

Compulsory notification of dermatoses is provided for in the mandated territory of South West Africa, e.g., dermatitis by cyanide; in Germany and in France, dermatitis caused by chromic acid, by caustic products and lime, formaldehyde,
mineral oils, and epitheliomatous cancer of the skin; in Great Britain, epitheliomatous cancer of the skin and ulcerations due to chromium; in Missouri, dermatitis caused by mineral acids, acetic acid, alkalis, chlorine, and its derivatives, fluorine and its derivatives, the derivatives of copper, tar, and other corrosive or irritating substances used in industry, dermatitis of the fingers caused by handling silk, eczema of grinders, or dermatitis affecting workmen using tar, and the lesions due to cement and to the derivatives of hydrocyanic acid; in Queensland, for miners' itch, the itch from copper, dermatitis due to work in acid mineral waters, ulcerations from chromat, dermatitis from toxic woods, mineral oils, pitch and tar; in Switzerland, for the skin lesions arising from injurious causes enumerated in a schedule; in the U.S.S.R., for serious affections of the skin, incurable cases of dermatitis, inflammations, malignant tumours and atrophies due to X-rays.

Occupational dermatoses also entitle the worker to compensation in countries which have declared occupational diseases, by definition, to be accidents incurred at work (New South Wales, etc.). The Correspondence Committee on Industrial Hygiene of the International Labour Office studied, at its meeting at Düsseldorf in 1925, the question of the affections requiring to be added to the list of diseases to be compensated, annexed to the Convention voted at the International Labour Conference of 1925. Among these affections it retained also recurring dermatoses due to the action of dust and liquids, and epithelioma of the skin from handling tar, pitch, bitumen, mineral oils, paraffin and any compounds, products or derivatives of these substances.

BIBLIOGRAPHY

See end of article.

Nails and Hair

The various harmful agents which injure the skin are not without their effect on the nails and hair. As regards the former, the trouble is usually located on the skin which surrounds the nail (rhagades, eczemas, warts, forms of lymphangitis, etc.), either the matrix of the nail (modification of the quality of the new nail, deformation, cleaving, superposition of both halves of the matrix, heterotopy), or the root of the nail with affection of the nail properly so called (haemorrhage, sup-

As regards legislation concerning dermatitis from arsenic, chromium, chromat, cancer of the skin and ulcerations from tar, pitch, paraffin, soot, oils and X-rays, see the corresponding articles.
puration, dermatoses, hyperkeratosis, hyperidrosis, onycholysis, circulatory derangements, etc.). The nail properly so called may be eroded by physical or chemical agents, impregnated with colouring matters or attacked by moulds. The diseases of the ungual phalanx (hypertrophy; acromegaly; atrophy; sclerodactyilia), or general troubles (tuberculosis, syphilis, leprosy, gangrene, diabetes, arteriosclerosis, stasis of the blood, heart troubles, phthisis) all exert important effects on the health of the nails. On the other hand, any injury to a part of the nail has an effect on the entire organ (“ungual altruism”: Heller). Finally, general affections may lead to nail trouble. Thus, for example, a mason suffering from warty tuberculosis of the skin round the nails, a worker may suffer from nickel action or the phthisis may present hippocratic deformity (Beau); from rheumatism may show striae of the nail, etc. Thus, for example, a mason suffering from rheumatism may show striae of the nail, whilst a nickel worker may suffer from nickel itch capable of spreading to the nails, and a butcher who is a carrier of bovine tubercular bacilli on the hands may suffer from warty tuberculosis of the skin round the nails, etc.

The absence of all statistical data relating to occupational affections of the nails renders it impossible to convey an idea of the frequency of the occurrence of such troubles. It may, however, be concluded that skin diseases from which workers suffer are often accompanied by injury to the nails, and in this way it is possible to determine a certain proportion of incidence of such troubles.

First of all there are nail troubles which are not diseases properly so called but only alterations of physical character which do not cause deep-seated injury to the structure of the nail: deposits of dust (carbonates, powdered glass, vegetable dusts), animal debris, fatty substances, colouring agents (indigo, picric acid, pyrogallic acid), erosions (workers in the dyeing industry), polishing (pottery workers), loss of substance and pricks (dressmakers), rubbing away of the nails (packers), etc. On the other hand, diseases of the nails properly so called have been described, the outbreak of which is dependent on the individual constitution. Heller enumerates the following:

Onychomycosis of brewers due to hyphomycete and brewers’ mould. The latter usually attacks workers engaged in cleaning the fermentation vats; the nails present longitudinal fissure with facets and crusty excrescences at the root.

Ungual erosion of workers manipulating chloride of lime.

Ungual diseases of dye workers: the nails become thin, bluish in colour, deformed, and finally fall off (Gotthilf); warty proliferation, subungual hyperkeratosis (dyers and furriers, Leviseur); inflammation and suppuration (aniline dyes: Naegelin); ungual infection of furriers (Gilbert).

There is further alteration due to imbibing amongst workers handling formaldehyde (formalonychia: Galewsky); brown coloration, softening, periungual alteration and pigmentation (dark blue) amongst electro-platers, disarrangement of growth of the nails, atrophy and suppuration amongst workers engaged on cleaning vegetables, resorption and difficult regeneration of the nails amongst glassworkers (one case observed by Oppenheim) due to the use of caustic soda; forms of ungual inflammation amongst hatters are due to the combined mechanical action of the hair and of the substances employed (lime, sulphuric acid), transversal striaion and falling of the root of the nail amongst miners, poisoning by carbon monoxide (disaster at Courières: Lewin), hyperaesthesia in patches; these troubles were attributed to nephritis brought about by the poisoning; paronychia of confectioners due to burning sugar and affecting predisposed individuals; clinically, this affection takes the form of an acute ungual eczema.

In America in 1925 there was described a form of contagious paronychia amongst workers in jam factories. Bacteriological examination and experiment resulted in attributing the affection to the leaven used (Kingery and Thines).

Paronychia also occurred amongst peelers and squeezers of oranges (Sutherland-Campbell, 1929), and of lemons (Loriga, 1928).

Alteration of the nails occurs amongst painters — case of Thieberge and Weissenbach affecting a painter suffering from lead poisoning; there was said to be connection between the ungual trouble and the general poisoning; clinically, there is thickening and appearance of white spots on the nails; lancinating pains and falling of the nails without normal regeneration. Friability of the nails occurs amongst workers handling mercury (local action).

Cases of ungual trouble have been reported during mercurial poisoning (one case: Hirschfeld; two doubtful cases: Küssmaul).

Radiologists suffer from thinness and friability of the nails, and workers engaged in pleating straw from infection
of the nails by hyphomycete (one case: Dereuw).

Wearing of the nails with dorsal thickening of the ungual phalanx (combined mechanical and chemical action) occurs amongst workers engaged in rolling cigarettes.

Wearing of the exterior part of the matrix of the nail of the left little finger, especially on the radial side near the top of the finger, as well as recoiling and atrophy of the matrix of the nail of the right thumb has been noted amongst pianists.

Deforming scars and formation of fissures have been noted as a consequence of combustion and burning, and transversal striae and eczematous alteration of the nails due to exposure to cold and frost. Partial semi-lunar onycholysis has been noted amongst washerwomen (15 cases: Erismann), and diseases located on the nails and ends of the fingers amongst workers in the woollen industry. In the cellulosic industry the English medical inspectors (1927) and Casazza (1928) in Italy have noted special injuries to the nails which, according to Casazza, have a highly polished bright red appearance resembling the enamelled nails of fashionable women. The nail is flattened, thin, and presents fairly deep fissures; its edge is loosened and tends to turn. In Russian leather factories, Kiebenoff and Embdin (1927) have also noted modifications of the free border of the nails, as well as lesions of the skin surrounding the nail.

Injury to the hair consists in falling due to certain causes (light, heat, toxic products, various forms of dermatitis), or hypertrichosis or hyperpigmentation (porters who carry burdens on their head and shoulders) or, finally, varied coloration due, for instance, to copper (smelting, various products, munitions), to arsenic, chlorine, picric acid, etc.

**BIBLIOGRAPHY**

***

**Occupational Stigmata**

Pathological modifications of the skin which are typical of certain occupations, without exactly constituting a state of disease and without interfering with the functional aptitude of those affected, are described and designated by the term "occupational stigma". In certain cases involving callosities the work is even facilitated and gains in precision. Apart from that, certain organs (cartilages, bones, muscles and joints), as well as the skin, undergo typical modifications. The epidermis and the subcutaneous cellular tissues participate in this change, which frequently implies a reaction to various forms of irritation, either mechanical, chemical or physical, and it is in fact frequent recurrence of chronic irritation which brings about such changes. Pigmentation or deposits are, on the other hand, rather of an external and mechanical nature, and in no wise modify the skin or its functions.

The combination of external irritants, particularly those of a chemical or mechanical nature, engender stigmata which may appear after a few weeks, a few months or, more rarely, a few years. It is certain experts who are inclined to classify stigmata under the group of occupational changes of a transitory nature.

The production and symptomatology of occupational stigmata have engaged the attention of numerous recent authors, amongst whom may be quoted Blaschko, M. Oppenheim, Teleky and Koechs as regards those affecting the teeth, Heller those affecting the nails, and B. Chajes and Natori (Japan) as regards the formation of callosities, etc.

It is not always possible to distinguish between occupational stigmata and forms of dermatosis. The majority of workers engaged in a trade develop such stigmata, those remaining immune forming an exception due to absence of predisposition. On the other hand, the production of dermatoses occurs sporadically, being strictly connected with individual and constitutional factors.

Stigmata are of practical importance from the point of view of industrial medicine, both as regards diagnosis and as regards their medico-legal aspect for purposes of compensation.

From the anatomo-clinical aspect, occupational stigmata may be grouped according to type and according to duration.

Oppenheim mentions among permanent changes: pigmentation, corni-

---

1 Oppenheim has utilised since 1916 in the study, preparation and determination of occupational skin changes particularly those assuming the form of callosities, atrophies and cicatricial formations, etc., a procedure anal-
ication, callosities, telangiectasis, tattooing, and cuticular formations. Amongst the transitory changes he includes pigmentation, deposits, rhagades and excoriations of the skin with typical localisation, as well as changes in the nails, teeth and mucous membranes. Almost invariably the injurious occupational agent exerts its action directly on the skin, and more frequently indirectly (circulatory passages), producing in this instance melanoderma argyrosis of the entire cutaneous surface or of certain more or less extensive areas thereof.

Individual predisposition is essential for the pigment formation in occupational stigmata. Pigmentation of the skin does not present extensive biological modifications of the deep-seated regions of the skin. It may affect the hair, the nails, the mucous membranes and the teeth. The majority of the clinical pigments usually disappear as a result of physiological desquamation of the epidermis.

Certain forms of pigmentation are the result of chemical modification of the cellular elements produced by certain substances: yellow, reddish brown coloration (nitric acid); brown (black sulphuric acid); brown (chrome); greenish yellow on the skin and olive green on the hair (picric acid: melanitits (Matussewitsch); yellow-green or apricot (tetryl); yellow or brown (dinitrobenzene and trinitrotoluene, more especially impure products); locking coal have been described by Fabry-Dalton, which transfers to the skin by means of special localisation of the mechanical pressure and friction chiefly and also ichthyosis and hyperidrosis play an etiological role. Ichthyosis sets up on the buttocks through sitting on hard seats, callosities taking the form of ridges on the folds of the finger joints (drawing of the thread); tailors: palm surface and fingers (hot pressing), front of the thumb (from holding the scissors), terminal phalanx of left first finger (from pressure of the needle and pricking); locksmiths: right palm surface (use of the hammer and file); bakers: palmar and cubital surface of the little finger (pressure on the kneading board); file cutters: same localisation, limited, hard pressure of the thumb; region (Teleky); farriers: fourth and fifth fingers of the right hand and tip of the little finger; hatters: internal palmar region (from pressure on the board), first phalanx of the third finger (annular callosities caused by the strings); cloth printers: cubital region of the hypothenar eminence of the little finger; workers engaged in carrying weights: region of the shoulder (pressure of the boxes or cases); painters and varnishers: second phalanx of the second and third right hand fingers (painter's brush), palm and index fingers of the right hand (pressure on the palette); clerks: terminal phalanx of the middle finger; workers engaged in manipulating morocco leather: index finger of the right hand (putting of the leather); saddlers: region of the wrist joint of the right hand (pressure of the thread), extensive callosities on the

alabaster, bronze (Carozzi), glue (Chajes), lime mortar, cement, varnish, colours (workers in the building trade, painters), animal substances and hair (furriers, hatmakers, stable boys, brush manufacturers), etc. Various forms of deposits found amongst workers handling coal have been described by Fabry-Beckolt and K. Pichler.

In the production of callosities and pathological cornification mechanical pressure and friction chiefly and also ichthyosis and hyperidrosis play an etiological role. Ichthyosis sets up hard dark callosities whilst hyperidrosis gives rise rather to soft translucent alterations of a clear yellow tinge. Very hard pressure may in certain instances cause extensive callosities and in certain cases blistering and atrophy.

Certain occupations are characterised by special localisation of the mechanical action exerted giving rise to typical callosities at the site in question: joiners: thumb and fold of the first finger of the right hand; middle of the palmar surface (pressure of the plane); shoemakers: fold at finger joints (pressure of the handle of the hammer), thigh, towards the kneecap (pressure whilst manipulating the leather), callosities on the buttocks through sitting on hard seats, callosities taking the form of ridges on the folds of the finger joints (drawing of the thread); tailors: palm surface and fingers (hot pressing), front of the thumb (from holding the scissors), terminal phalanx of left first finger (from pressure of the needle and pricking); locksmiths: right palm surface (use of the hammer and file); bakers: palmar and cubital surface of the little finger (pressure on the kneading board); file cutters: same localisation, limited, hard pressure of the thumb; region (Teleky); farriers: fourth and fifth fingers of the right hand and tip of the little finger; hatters: internal palmar region (from pressure on the board), first phalanx of the third finger (annular callosities caused by the strings); cloth printers: cubital region of the hypothenar eminence of the little finger; workers engaged in carrying weights: region of the shoulder (pressure of the boxes or cases); painters and varnishers: second phalanx of the second and third right hand fingers (painter's brush), palm and index fingers of the right hand (pressure on the palette); clerks: terminal phalanx of the middle finger; workers engaged in manipulating morocco leather: index finger of the right hand (putting of the leather); saddlers: region of the wrist joint of the right hand (pressure of the thread), extensive callosities on the
left hand (from pressure of the needle); makers of trimmings and embroideries: callosities on the dorsal region of the fingers; glove makers: similar alterations (resin?); stonecutters: palmar region of the first phalanx of the little finger of the left hand (chisel); printers and compositors: terminal phalanx and tips of the fingers (pressure of the type); house painters: palmar surface (pressure of the brush); engravers: palmar region of the little finger (engraving tools); cigarette makers: six types of stigmata on various fingers due to the effect of the special knife used and to friction of the fingers against the table (Pineiro), etc. (See also alphabetical list of callosities classified under the various occupations prepared by B. Chajes.)

The combination of mechanical and chemical effects favours the outbreak of callosities on the palmar region in pork butchers (Matzenauer), cloth makers and tailors, etc. The combination of thermic action (boiling water and steam) and of colouring agents, etc., used in the manufacture of military blankets causes linear callosities on the palmar surface of the hand more pronounced on the left than on the right hand (Oppenheim), dark pigmentation ranging to brownish black is caused by pressure of the coloured wool against the revolving drum which is covered with very fine steel pins. Diffused callosities of the skin are often met with in cooks. Acrobats and gymnastic teachers suffer from callosities on the palmar surface of the hand and on the legs, and soldiers on the thighs and calves of the legs.

Natori in Japan has made an exhaustive study of callosities (300 cases) connected with various types of work, not only from the point of view of the date of their first appearance and its relation to the duration of working experience of the worker but also to the date of disappearance of the callosities subsequent to removal from the occupation. These researches are chiefly devoted to workers in the silk and thread dyeing industry, and in the textile industry (Nishijin), masons, stonecutters, ironers, photographers and sculptors.

In the various operations in question in Japan the formation of callosities dates from the first or second month, or at least from the period of one year after engagement. Permanent deformation of the fingers does not occur until the worker has been engaged in the industry for a period of three years. The intensity of the work engaged in exercises an effect in this connection.

Prosser-White has made a study of, and described and prepared, pictorial reproductions of forms of cutaneous callosities affecting various workers in British industries.

Other special forms of callosities have been met with in women workers engaged in polishing (nodules caused by leather polishing with emery, situated on the dorsal region of the fingers of both hands after twelve years in the industry: Hess); amongst milkmaids (callosities on the scalp caused by carrying pails on the head: K. Pichler); amongst musicians: J. Flesch, doctor and musician, has published a comprehensive study of these occupational stigmata; in the case of violinists they are located on the left lower jaw, on the tips of the second and fifth fingers of the left hand, on the radial side of the right forefinger, on the inner edge of the right thumb; in the case of double bass players the callosities are situated on the tips of the four fingers of the left hand and especially on the left forefinger and the little finger of the right hand; amongst dancers, on the toes and especially on the inner side of the big toe. Abnormal arching of the foot may be noted in ballet dancers as well as shortening and thickening of the tendons Achilles.

The span of the hand of pianists, violinists and harp players is more extensive than that of other workers; amongst pianists, players of the harp and in the left hand amongst violinists and double bass players there is likewise a characteristic extension of the distal interphalangeal joints. It is with reference to this characteristic stigmata that the Italian double bass player Dragonetti was nicknamed "mano mostro" (monster hand). The callosities are localised on the tips of the thumb and first three fingers of the left hand, and they are more extensive than those of violinists. On the right hand they are located on the dorsal or radial region and often on the tip of the little finger and are due to pressure from the bow. Wind instrument players show small scaly patches as well as a painless annular excrescence on the lower lip. In the case of flute players eczema of the lower lip is occasionally met with and attributed to a special composition of the mouthpiece (resin?). Pianists occasionally suffer from loosening of the edge of the nail of the left little finger and of the right thumb. The nail of the left little finger is frequently atrophied and loosened at the root. The terminal phalanges are short and broadened.

Perspiration of the hands constitutes a source of inconvenience to pianists
and violinists, etc. This condition favours the outbreak of forms of eczema which appears around the folds of the joints of the forefinger. There has also been reported a form of dermatitis due to the action of rosin amongst violinists; keratosis of the lower jaw due to permanent pressure against the chin rest of the instrument (or the varnish of the violin: rosin, anthracene, acridine).

Work in the open air, in the sun and in all weathers, as well as occupations effected in enclosed premises where the workers suffer from exposure to radiant heat from hearths, sets up forms of pigmentation more or less accentuated or at times exclusively confined to the uncovered regions of the skin notably the face and hands: agricultural workers, gamekeepers and trappers, fishers—and violinists; keratosis of the lower jaw also been reported a form of dermatitis of the forefinger.

Pigmentation occurs subsequent to erythema and may be followed by cutaneous atrophy or the formation of warts and epithelioema (peasants, sailors). The effects of heat are responsible for trouble of this kind amongst workers at blast furnaces, foundry workers, those engaged on autogenous welding, blacksmiths, locksmiths and glass workers, etc.

A contrary phenomenon consisting in depigmentation of the teguments has been noted amongst workers in mines and tunnels.

Under the name of argyrosis is designated darkish coloration ranging to black of the skin of the face which recalls the glistening aspect of graphite (Teleky), and may affect the conjunctivae and the cornea (K. Steindorf), as well as the buccal mucous membrane. This argyrosis is caused by the absorption of small quantities of silver solution (nitrate of silver) by way of the mouth, notably amongst workers engaged in making beads by means of the blowpipe.

A local form of argyrosis has been noted amongst workers engaged in the preparation of silver-leaf. The buccal mucous membrane shows a dark brown coloration, whilst the teeth become greyish brown colour (Koeisch).

Arsenical melanosis causing a darkish brown pigmentation of the skin is seen in workers handling arsenical products (miners, foundry workers, electro-platers, etc.). Pigmentation by arsenic is due to increase of the physiological pigment in the deep-seated regions of the epidermis, possibly in consequence of stimulation of the apparatus of the chromatophores of the skin and the suprarenal glands.

Tar likewise causes toxic melanoderma of occupational origin (E. Hoffmann, Habermann) known as "peau de goudron" (tar skin), due to the action of this product under the influence of various sensitising substances. Asphalt fumes have been known to cause reticular coloration of the face, neck and forearms (Dufke and Berndkopf). Buschke has noted that the pigment was only found in the chromatophores and not in the epidermis, whilst H. Fischer found it around the hyperkeratic pores of the sebaceous glands and considered it to be an expression of the elimination of toxic substances absorbed. Workers engaged in the impregnation of railway sleepers with creosote suffer from melanosis of the teguments of the skin of the face and of the body and the same is true of metal turners (Hudelo, Rahut, calliaud, Mornet, Cézary, Pasteur, Valléry-Radot, Benovist) and amongst workers in coal mines (Barnewitz).

Mention should likewise here be made of patches of purpura seen in compressed air workers ("caissons") due to the increase of arterial pressure and to vascular irritation.

Impregnation and tattooing, which Oppenheim classes in a single group, are considered by K. Pichler as due to the penetration into or under the epidermis at the moment of violent contact of foreign bodies with a sharp or cutting edge coming from the materials utilised in the course of work (specially stone, metal, etc.), or of the implements used.

These particles may become chemically modified in the skin, being reabsorbed and transported into the lymphatic circulation, or may remain in position, giving rise to permanent or transitory pigmentation.

They are noted chiefly in workers in metallic mines in the silver and steel industries, etc., and amongst workers manipulating stone and powders; likewise amongst electricians, millers (grinding of mill stones), workers making grindstones (black patches either pointed in appearance or recalling freckles in their dimensions, localised on the back of the hands, the fingers and the fore-arm; permanent globules above the joints especially of the left hand, of a brownish colour due to iron oxides or sulphate); other workers affected are coal miners, chimney-sweeps, manufacturers of margarine and coconut oil (small fragments of the vegetable capsules which may or may not be accompanied by slight inflammation according to the depth of penetration: Chento).
Cooks, blacksmiths, gardeners and coachmen suffer from dilatation and neo-
formation of the cutaneous pre-capillary vessels shown on the face, cheeks and nose and on the hands and back of the fingers by vascular arboration, which disappears on pressure. It is most usually accompanied by hypo-
pigmentation and freckling, which disappears on pressure.

Wounds, often of small dimensions (pricks, scratches, patches), of a form characteristic for certain occupations in certain cases, present an atrophic and exceptionally hypertrophic (chel-
oid) character. Localization varies according to the occupation but is more usually restricted to the uncovered regions of the skin (hands, fore-arms, feet).

In certain cases such wounds are accompanied by pigmentation or other stigmata of impregnation, by deposits, comedones, open sores, inflammation, stigmata of impregnation, by deposits, comedones, open sores, inflammation, etc. Such cicatricial formations at times assume a linear form on the back of the hands and are often accom-
panied by hardened areas and rhagades of recent formation (basket-weavers); in the case of milkmaids such forma-
tions are found in the interdigital folds of the second, third and fourth fingers, being the marks of former suppurating fistulae caused by the hairs of infected cows deposited there during milking (Pichler).

The auricle of dockers and porters often presents formations and callosi-
ties due to pressure and friction (Oka-
jiima).

Mention should further be made of intentional deformations, such as al-
lowing the nails to grow an exceptional length and cutting them specially short in accordance with the needs of special work, as well as noted stigmata amongst clock makers and pianists.

Various authors, notably Koelsch and Kraus, have described serious modifications of the naso-buccal mucous mem-
brane accompanied by more or less typical coloration and erosion, and dental defects due to the action of vari-
ous noxious agents: acids, coloured matter, mineral dusts, chloride of lime, arsenic, dust from soda, cement, chrome, lead (Burton line), sublimate, organic sugar (dental caries due to sugar). On the other hand, mechanical modifications of the teeth occur amongst shoemakers, dressmakers, glass blowers, etc., accompanied by flaccidity of the skin of the cheeks.

Hessberg has described numerous stigmata of the antero-posterior region of the eye as well as of the crystalline lens, and J. Heller has referred to occupational deformations and modifica-
tions of the nails due to various harm-
ful agents.

Prohaska has described transversal striation, Mulzer, Oppenheim and Wolf, a dome-shaped excavation of the nails and onychosis due to the use of tur-
pentine soap, and soda amongst washergirls. In the case of leather workers, cutaneous ulcers are exhibited, and they present excoriations and small painful ulcers at their edges. Workers engaged in slaughtering ani-
mals suffer from excoriation commencing on the third finger and often accom-
pained by disappearance of half of the nail after the first month of work. These lesions generally heal after rest and may be prevented by the use of rubber gloves.

Brine causes leuconychia which is manifested by the appearance of white spots on the nail (Elsner).

Many further occupational stigmata may be noted, amongst them stigmata due to the electric current such as those described by S. Jellinek, Landois, E. Heyman, etc., as well as metallisation and various types of pigmentation and scarring subsequent to burns.

Combined stigmata are of more fre-
quent occurrence than simple modifi-
cations. Mescerski has noted among shoemakers and makers of felt slippers a type of keratosis of the palms accom-
pained by ulceration. Amongst polish-
ers of parquet flooring, there has been noted neo-formations and synovial fluid on the knees.

Amongst stone- cutters and millstone grinders such changes affect the elbows. Workers en-
gaged in spinning suffer from tricho-
stasis and melanosis due to mineral oil, with pointed formations and com-
edones covering 2 to 10 hair follicles (Fuh.s).

For mineral oil, see article "Petroleum". Among engine-drivers there has been noted dilatation of the blood vessels, traumatic scars on the hands, telangiectasis, callosities and hygroma (Mermorkij).

Combinations of black speckled tat-
toing and patches on a reddened cutaneous area with rhagades have been noted among gas workers (Oppen-
heim); among postal and telegraph employees A. Jordan reports the occurrence of callosities, cyanosis, longitudinal striation of the nail due to the use of glue and the influence of low temperatures.

Rhadages accompanied by friability of the nails and disappearance of the lines on the hands and finger tips may be noted among enamel workers and modelling designers in porcelain and china clay factories (Kavalerov and Kogan). Amongst shoemakers the
sternal region shows pigmentation accompanied by comedones and inflammatory changes such as common acne (Oppenheim).

**Prof. K. Ullmann**
(Vienna).

**Effects of Heat and Cold**
(Burns, Scalds, Lesions due to High-Tension Currents)

French: Lésions d'origine thermique. —
German: Thermische Hautschädigungen: Verbrennungen, Erfrierungen, usw. —
Italian: Lesioni di origine termico scol'tature, geloni, ecc. — Spanish: Lesiones de origen termico quemaduras, ecc.

Cutaneous lesions of thermic origin (including chemical burns, wounds caused by high-tension current) form a very important group in industrial pathology. These disease forms are often highly complex, being complicated by other lesions of traumatic, mechanical or physical character.

Effects due to heat sources in the strict sense of the word and brought about by high temperatures exceeding considerably body temperatures, are in general designated by such terms as "burns" and "scalding" and "catching fire"; those produced on the subcutaneous tissues by the prolonged action of very low temperatures are usually designated as chilblains, frostbite or various forms of chills.

This section is divided into three parts as follows: (a) burns; (b) chemical burns; and (c) injuries due to heat and cold.

(a) **Burns**

The surface of simple burns of the skin due to the action of high temperatures depends essentially on the physical type and constitution of the heat source in question (incandescent body, actinic radiation, incandescent metals, boilers, furnace lining, electric cushions, radiators, various substances carried to red and white heat, cinders, slag, incandescent coal and numerous heating apparatus). The materials which take effect in contact with the body are hot solids carried to red or white heat, hot liquids, gases, or superheated steam as well as ignited material and gases.

The depth and gravity of the burns, i.e. their degree, depend on the elevation of the temperature, duration of exposure and above all on the heat capacity and the state of aggregation of the burning substance. In the case of radiant heat they depend on the wave length, on the incandescence at red or white heat, as well as on the duration of the radiation.

Where the temperature varies between 50° C. and 100° C., it is the duration of contact (radiation) and especially the constitution of the skin which are all important. The thicker and the more callous the skin is, the less sensitive will be the part exposed, and, on the contrary, the more delicate and fine the skin is, the more sensitive it will be to heat. With moderate temperatures below 60° C., the age, race, habits, as well as acclimatisation to heat, the state of health, latent dyscrasia, tuberculosis, syphilis, anaemia and chlorosis, must all be taken into account. The skin and the mucous membrane throughout their extent or in certain parts develop acclimatisation to high temperatures; fakirs and professional fire-eaters and workers in many industries (blacksmiths, locksmiths and those engaged in chiselling, etc.) constitute instances of this kind. As regards radiant heat, coloured races are less sensitive than white races.

Among the most frequent cases of occupational burns and scaldings may be cited:

1. **Solid bodies**: heated metals, organic substances, silver, phosphorous and other chemical substances, concentrated sulphuric acids, sodium, oxide of calcium, slaked lime (which, under the influence of heat, enters into combination with the skin, or by rapid loss of water heats the skin); molten resins, rosins, pitch as well as bodies which solidify immediately on contact with the skin.

2. **Heated liquid bodies** which remain in a liquid state on the skin and which spread themselves over the skin according to their density; hot water, fats, oils.

3. **Gaseous bodies**, super-heated steam, air or other heated bodies, gaseous products of distillation.

4. The action of flames fed by ignition, and the transformation into a gaseous state of readily inflammable matter: wood, coal, petroleum, petrol, alcohol, gas, combustible gases alone or mixed with air; flames from welding lamps, explosive mixtures of inflammable gases with other hot substances of a solid or liquid character which exert a thermic action on the skin. As agents of this order may attain temperatures rising to 3,000° C. during explosion or ignition, an effect of even extremely short duration may give rise to deep-seated injuries.
When the heated substances exert their effect by means of contact, the aspect of the burn is usually outlined on the surface of contact. On the contrary, lesions due to flames, super-heated explosive gases or hot liquids very often show displacement of the heat source above, below or to the side, and the parts first attacked are the most seriously affected whilst those attacked later in the case of liquids for instance, the more deep-seated parts are much more slightly affected. Where it is a question of splashing of hot liquids or semi-liquid bodies, it is always the centre of each injury which is the most seriously affected part (carbonisation, scarring), whilst the peripheral part merely shows erythema at its edges.

Liquids which are poured over the clothing are apt to retain their heat and exert a much more intense effect than when the same substances are spread over the uncovered skin; scalding by hot water, alcohol, etc., causes less serious injury than hot eis liquid resin or even liquid metals. Hot water, as well as other liquids, only exceptionally gives rise to scalding of the third degree and only then when it attacks the skin for a certain time; scalding usually causes a burn of the first or second degree, the more deep-seated noted even when an entire limb has been plunged into hot water.

In the case of ignited substances, liquids or solids, small in extent but of high temperature, the injuries are distinctly outlined and are generally in the form of a crust.

In the case of gases, the gradual cooling of the gas by removal from the heat source is of capital importance in regard to the seriousness of the burns. In the case of explosions, there are not infrequently found side by side burns of varying degrees according as to whether the skin has been in contact with super-heated gases, liquids, solid bodies or explosive particles, or merely subjected to the secondary action of burning clothing.

With lower temperatures the absorption and distribution of heat on and throughout the depth of the skin exerts a perceptible attenuating influence. The thermic action is likewise modified by evaporation and humidification of the skin.

Under the action of heat, the epidermis becomes detached at certain points, becomes folded and falls from the skin in large shreds. As a characteristic sign of explosive burns and burns due to the action of flames or ignited gases, there has been noted a special radiating distribution with a clearly defined intact zone around the mouth and eyes, the play of the muscular reflexes having served as a protection to them. In the case of less serious injuries, there have likewise been remarked bands of skin of yellowish-brown colour slightly reddened alternating with lighter normal zones at the base of the folds. On the contrary, the top of the folds are discoloured, showing evidence of burning.

When particles of earth, dirt or grains of powder become encrusted in the skin, the latter shows characteristic blue-black smudging similar to tattooing, or marks produced by firing at close quarters.

Changes of the buccal and nasal mucous membrane even extending to the back of the throat and the pharynx are caused by penetration of quantities of incandescent gas, modifications which may vary in gravity ranging from whitish opacity of the mucous epithelium up to oedema and the formation of blisters, ulcers and scars.

The prolonged action of radiant heat from metals brought to dark or bright red heat as a rule merely causes formation of erythema with consequent pigmentation of the skin of varying degree, whether it be uncovered or protected by clothing. Where exposure is more prolonged, more serious injuries are encountered: thickening, dilatation of the blood vessels, warts which may degenerate into ulcerations, or cancerous tumours.

Cutaneous lesions, due to radiant heat from heating devices (Kangri apparatus used in Kashmir), and the Kairo, an earthenware pot filled with charcoal, utilised in China), or the electric radiator, may be noted amongst workers who work in the open air in the cold season and are in the habit of warming themselves by placing heating devices of this kind under their clothes or against their chests or stomachs.

Amongst the more frequent causes of burns should be mentioned: jets of steam, of boiling liquid, of petrol, petroleum, etc., and likewise explosions, contact with incandescent parts of machinery, apparatus, tools, etc., handling of molten metal (welding), boiling substances (asphalt, pitch), as well as back-firing of stoves, boilers, etc.

For electric burns, see article "Electricity".

It is impossible to enumerate completely all types of burns, whether characteristic or not, reported as occurring in the various trades or industries. Mention will therefore be restricted
Numerous injuries due to welding by blow-pipe (metal workers, tinsmiths, incandescent lamp makers, chisellers, engravers, etc.) assume the form of distinctively outlined linear burns, located on the back of the hand, on the fingers, or in the inter-digital spaces. They are of varying gravity as regards depth and generally have a small surface.

In the case of blacksmiths and locksmiths, burns are localised on the hands and forearms. They are generally restricted to blisters, and there is rarely charring.

Projections of molten metal cause burns amongst foundry workers which are slight and are localised on the top of the foot. Transporting, touching and removing pieces of hot metal in tending furnaces, as well as hammering of hot metals and spurtng of these, constitute frequent causes of burns.

The localisation and gravity of such burns vary extremely in the case of makers of precision instruments, as well as amongst cabinet workers, painters, tin founders, dentists’ assistants, workers handling feathers, etc.

Shoemakers often utilise metallic tools with sharp edges which, after heating in the flame of an alcohol or gas lamp, are used to smooth the heels and soles of shoes. These instruments slipping from the hand may cause superficial burns on the hands, fingers, and especially thumbs.

Burns are caused in hot pressers and tailors by the use of irons, and are chiefly localised on the back of the left hand. Those new to the work and liable to speeding up their work may receive burns from the hot steam escaping between the metal handle of the iron and the cloth holder, produced by the wet material. Burns localised on the hands and arms, almost invariably on the left side, usually consist of erythema and blisters.

Burns occur fairly frequently amongst bakers and confectionery makers, and are caused by flames from the oven, contact with the oven tool, or metallic closing devices in the piping, handling of working materials: liquids, hot moulds, splashing from hot masses, escapes of steam, etc. The same facts are true of cooks and kitchen workers. Most usually such accidents are attributable to haste, imprudence, or lack of skill on the part of young inexperienced workers. This is particularly the case in connection with spurtng by jets of hot steam and burns due to red hot coal and hot cinders.

Amongst washerwomen working in private houses or in washing establishments (steam laundries) the number of cases of scalding is very high.

Nevertheless, in recent years, despite increase in the number of such establishments and of the workers engaged by them, especially unskilled workers, there has been a decrease in the incidence of burns which is to be attributed to more careful training in schools providing instruction of the various occupations.

In large industrial establishments (distilleries, breweries, chemical products factories, sugar and confectionery factories, sugar and petroleum refineries, silkworks, dyeworks, etc.) workers are exposed to scalding by jets of steam, splashing due to spurtng of boiling liquids in course of transport from vats, due to the opening of valves, pipes, covers, etc. Workers may also sustain burns by falling accidentally into hot liquids, or carelessly plunging their hands or feet into these. Such cases usually consist of burns of the second degree, rarely of the third, and are usually restricted to erythema and blisters, and only exceptionally show charring. In glassworks it is usually young workers who sustain burns on the legs, but such injuries cannot be said to be typical. Amongst glass-blowers there has been noted around the cheekbone a characteristic pigmentation, ranging from reddish brown which constitutes a kind of stigmata and which persists during several years. There has also been noted a redness in the region of the nose, cheeks and around the socket of the eye. The hair of these workers becomes dry and stands on end as a result of the action of radiant heat.

In metal works and in the case of workers in the metal industry and those engaged in mechanical engineering the skin is liable to injury caused by slag and metal splashing. Even in modern factories possessing improved plant, it is chiefly reverberatory furnaces and electric furnaces attaining temperatures of 1,500-1,600° C. which cause burns, due in the first instance to the introduction of material into furnaces which are already hot, to radiant heat, and to spurtng of hot metal. Nevertheless, charging of furnaces by mechanical processes is beginning to be more and more frequently resorted to with the effect that workers are enabled to remain at a distance from the furnace doors.

During tapping of the molten metallic mass which flows in a rapid jet into the ingot moulds, it is almost impossible to avoid splashing, especially
when the liquid metal reaches the top of the receptacle, whence it is liable to spurt out. Cases of workers falling accidentally into such incandescent masses of metal have even been known to occur. The removal, by means of gripping-irons or cranes, of incandescent blocks of metals does not always prevent the occurrence of injuries which are at times serious or even fatal. During cutting, pressing or rolling of the incandescent blocks at 1,000-1,200° C., and more especially during rolling of bars which whistle through the air, imprudent workers working near these may sustain burns on the feet. Forty per cent. of all the total cases of burns occur under these conditions, whilst 20 per cent. only of the victims sustain burns during charging of the furnaces (report from the Poldi Foundry).

The location of burns on various parts of the body shows the following percentages: hands, 35; feet, 20; arms, 11; face, 10; chest, stomach, back, hips, 3-4; internal angle of the eye, 20.

This latter localisation is met with chiefly amongst metal workers and is due to flying particles of hot metal (about 300° C.), often also the caruncula and conjunctivae, and the eyelids may be affected. Amongst workers engaged in the manufacture of ingots in Martin furnaces, it is the external side of the right forearm which is most exposed to risk. Projections of slag, cinders, etc., often cause burns on the feet of the almost naked workers, who usually wear wooden clogs. Injuries of this kind are also met with in glass works.

In these industries the combined action of light and heat radiations is likewise the cause of burns during casting of the molten metal or the slag.

For burns affecting firemen, see that article.

The effect of electricity on the tissues of the skin depends on the kind of current, the intensity, the extent of the contact surface, the duration of the contact, and also on the resistance of the body. This resistance depends on the humidity of the skin, formation of horny skin, and general shock (shock amounting at times to fatal shock), that is to say, on the organic predisposition and the nervous system.

The voltage cannot provide in itself satisfactory explanation of the gravity of electrical burns. Whilst the electric arc causes injuries due purely to the action of heat, that is to say, a burn, and even destroys the clothing, a force which is purely electric or mechanical causes chemical destruction and brings about changes which to some extent are purely electrolytic.

The burns are localised usually on the limbs, the face, back of the neck, but also at times on the body, in accordance as to whether contact is effected through the unprotected hands or feet, or by accident, or falling, or finally, by the victim remaining suspended to a conductor.

(b) Chemical Burns

The various forms of radiation (ultra-violet rays, Roentgen rays and radium and mesothorium radiation) constitute a frequent cause of injuries to the skin resembling closely burns and chemical burns, despite the fact that the chemical light rays and radio-active emanations above referred to are not accompanied by any commensurable elements of heat. This is not true of chemical burns which range even to the production of charring of the skin and are accompanied by increases of temperature and which involve a disintegration and decomposition of the ionic elements with hydrolysis or dehydration, with the result that the effects produced are more or less resemble burns.

Such chemical burns of the skin permit the differential diagnosis by reason of the fact that there is central disintegration at the spot at which the product exerts its action most effectively and that around this spot there occur peripheral inflammatory reactions.

Caustic alkalis penetrate the skin most profoundly owing to the fact that they saponify the fat involving dehydration, forming alkaline albuminates, and thus causing swelling to begin with, followed by charring of the tissues.

The acids also exert a dehydrating action with even more rapid destruction of the epithelium and connective tissue forming albuminous and acid proteins. The corrosive action of organic acids is proportional to their fluidity and volatile properties; that of the inorganic acids is very different and varies according to their degree of concentration.

Chemical burning due to certain products (concentrated acids, quicklime) is due in part to the heat given off by dehydration of the tissues and hydration of the product in question. It is strange to remark that, when attacked by an acid or an alkali, the tissue heals almost immediately. Concentrated hydrochloric acid has a lesser caustic effect than nitric or sulphuric acid. Trichloracetic acid would appear to be absorbed by the tissues like phenol and acts rather as a poison of
the protoplasm. Lyes require a considerably longer lapse of time for bringing about a reaction of the tissues.

Contact with irritant chemical substances does not necessarily involve burning or chemical burning of the skin. At times special forms of cutaneous inflammation are noted.

In chemical laboratories attached to scientific institutions or factories burns may occur as the result of contact with utensils, hot metals or hot glass, by overturning or spurting of, overturning, or spontaneous ignition. Burns of a chemical nature, however, may occur as the result of contact with acids and lyes, by means of a pipette or by careless emptying of reserve receptacles containing acids, by neutralisation when effected carelessly, giving rise consequently to the sudden formation of fumes and causing spurt-ting, or stopping material, ignition of hot liquids, breaking of hot receptacles in front of melting furnaces, ignition of working clothes by flames or radiant heat, ignition of combustible, wrapping, or stopping material, ignition of rubber, fat, etc., spontaneous ignition of readily combustible liquids, coal and ether, alkali, petrol, etc.

Chemical burns on the mouth occur as a result of imprudence in aspirating acids and lyes, by means of a pipette or by careless emptying of reserve receptacles containing acids, by neutralisation when effected carelessly, giving rise consequently to the sudden formation of fumes and causing spurt-ting, or stopping material, ignition of hot liquids, breaking of hot receptacles in front of melting furnaces, ignition of working clothes by flames or radiant heat, ignition of combustible, wrapping, or stopping material, ignition of rubber, fat, etc., spontaneous ignition of readily combustible liquids, coal and ether, alkali, petrol, etc.

The development of burns of varying gravity is dependent on their extent, their degree, their localisation and even on the age and constitution of the workers. Duration of development and scarring is also subject to the influence of eventual infections. Amongst workers the danger of primary infection of wounds is not infrequently connected with the material handled or, again, also with the application of inadequate first aid, even in the case of very slight injuries. It is of primary importance that in these complications and especially infection there be a suitable therapeutic treatment (wax, ambrine, lanoline, or tannin dressing) applied immediately by trained persons, or treatment at first-aid posts. Such posts are indispensable in large factories liable to the risk of fire.

It is only under such conditions that workers may reap the benefit of the great progress realised in the therapeutic treatment of such injuries, more especially in very serious cases necessitating blood transfusion, changing of dressings and plastic operations, etc.

As a later complication there should be mentioned erysipelas, gangrene, pyaemia, but chiefly persistent suppurating of wounds and also the well-known condition of collapse due to shock and toxæmia in the initial stages, conditions which may be readily avoided or prevented, thanks to opportune treatment by factory surgeons.

**Statistics**

Burns constitute the most frequent causes of accidents. Whilst there is a certain incidence of burns amongst women in the course of their household occupations (manipulation of combustible products especially in cooking, wearing of more readily inflammable clothing than that worn by men, etc.), burns of occupational origin are due, to a certain extent, to accidents of unforeseen origin: explosions, spontaneous combustion of stores of material and, especially, short circuits. It is impossible to present here the various data available in this connection relative to the different trades and industries.

The statistics assembled, however, by factory doctors prove that it is chiefly unskilled workers, and particularly women, who are the victims of occupational burning accidents, whilst skilled workers are rarely affected. As regards small-scale industry the classes of workers most frequently affected include bakers, confectionery-makers, engravers, metal founders, tailors, bookbinders, hook makers, upholsterers, painters in the building trade, mechanics, etc.

The incidence of burns varies according to the size of the staff in proportion to the size of the establishment and the type of work effected. In industrial establishments, and it increases during periods of economic depression. Incidence diminishes in the industries enumerated above parallel to the development of more thorough factory inspection, and application of measures of industrial hygiene.

Out of 3,014 cases of accidents noted during the period 1910-1913, 144 or 4.8 per cent. were burns (North German Iron and Steel Trade Association at Magdeburg).

Out of 11,275 cases of accidental reported during five years in the German chemical industry, 1,516 were covered by indemnity; 1,275 (of which 44 were compensated) were cases of scalding and burns. Sonnenburg and Tschmarke drew attention to the fact (1915) of the very high proportion of burns in occupational accidents (3.14 per thousand) occurring in the chemical industry in Leipzig, the operations involved being highly dangerous (risk of fire). It is, however, certain that this percentage has been considerably reduced, and the same is true of industrial establishments throughout the world.

According to United States accident statistics prepared over a course of many years, burns come fourth in order of frequency, following motor accidents, falls, and drowning accidents.

Since electricity has replaced the use of lighting gas, the number of burns of the skin has somewhat diminished.

As regards the ratio between the incidence of occupational and non-occupational burns in a town or in the same country only an indirect estimate can be made, since the majority of occupational burns do not appear in statistical returns either because they are not sufficiently serious or because they have escaped

---

1 These refer to both (a) and (b) above.
notification. For this reason the statistics in the annual reports of the Vienna Voluntary Aid Societies are highly interesting and show in particular the ratio between burns due purely to the action of heat and to chemicals and burns of electric origin.

Prophylaxis 1

The prophylaxis of burns, chemical burns and injuries due to electricity require, on the one hand, the installation, maintenance and periodical control of all apparatus, machines, electric plant, etc., and on the other, adequate instruction of employees relative to the danger and risks incurred by them and particularly relative to the current transformers to which they are exposed. It is necessary further to assure installation and regular maintenance of means for combating fire (hose, fire extinguishers, etc.), as well as all necessary measures capable of limiting or isolating as rapidly as possible the sources of burning, chemical burning or electric accidents, as well as means of protection for those adjoining the scene of such accidents and means of providing immediately adequate first aid for the victims. Systematic instruction, physical training and selection of workers are also essential. Constant supervision on the part of factory inspectors, factory doctors and foremen is required in large-scale industry, and likewise in small-scale industry adequate supervision by those in charge.

The use of asbestos or leather gloves, wooden clogs, high boots, leather kneecaps and gaiters, aprons and large-brimmed head gear, etc., is indispensable in certain cases and should be made compulsory.

Efforts should be made in the heavy metal trades to effect operations involving risk by the increasingly extensive application of mechanical and automatic methods. It is necessary in addition, however, that workers should, as in small-scale industry, devote attention to protecting themselves by individual devices already referred to, as well as by the wearing in certain circumstances, of goggles and helmets. In establishments in which readily inflammable or explosive material is handled workers should be forbidden to smoke and infringement of this regulation should be punishable. Wherever there is any risk of short-circuit it is essential that means of fire extinction, already referred to, should be provided, especially in the case of goods which are highly inflammable, and it is essential also that notices providing indication of the means of using these and of replacing safety devices, circuit breakers, as well as relative to the proper utilisation of machines and apparatus, should be posted up. Operations of cleaning, maintenance and testing should always be effected by trained personnel. Unfortunately, the very fact that workers have become used to the danger constitutes in itself a source of danger. It is essential that the workers should be instructed and trained with a view to developing their initiative in protecting themselves against risk.

Wireless apparatus also involves a certain amount of risk. On this account it is essential to arrange for insulation of the apparatus to prevent eventual contact with the high-tension current. It is important that the public, as well as the working classes in particular, should be instructed in the risks incurred in connection with electricity and in the best means for combating these.

In the chemical industry, in laboratories, etc., notices should be posted at points where readily inflammable substances are liable to give rise to explosion (cigar and cigarette ends carelessly thrown down); wherever danger of chemical burning exists it is advisable to provide water jets enabling the parts of the body affected to be rapidly sprinkled with water; sand should also be readily available to extinguish fire, for instance, in the case of ignition of petrol or carbonic acid extinguishers should be provided. In certain cases it is further essential to provide carbon tetra-chloride for the extinction of substances which cannot be extinguished by the water spray (petrol, carbon di-sulphate, heavy oils, naphthlene, alcohol). Carbon tetra-chloride can only, however, be used in small quantities and then only when there is no danger from the formation of phosgene.

In the storage of fine pulverised metals (iron, magnesium, zinc) and vegetable products (flour liable to spontaneous combustion) very special precautions should be taken against the action of toxic fumes (phosgen, phosorphorous fumes, etc.); adequate ventilation should be provided as well as means of withdrawal of inflammable gases; facilities for first aid should likewise be provided.

Legislation 1

Burns, chemical burns and injuries due to electricity of professional origin are

1 Refers to both (a) and (b) above.
compensated in the various countries by accident insurance legislation.

(c) Injuries Due to Cold and Frost

Occupational diseases of the skin and organs due to cold are much less frequent than those caused by heat. In factories and workshops cold plays no part, at least in regard to serious injuries except where damp, cold and the manipulation of wet materials involves frequent wetting of the hands and legs in those industries in which the work is carried out in the open and in a wet state (independent of the temperature of the surrounding atmosphere). In such cases cold may give rise to frostbite of the first and second degree. In the case of injuries due to cold and frost, predisposition, constitution, age, race, the state of the health, the complexity of the skin and other circumstances play a much more important and even predominant part than in the case of burns.

Apart from the general action of cold (see article "Temperature"), there occur persistent forms of erythema (first degree) from frostbite with or without blistering; forms of frostbite (perniosis: second degree) and cold ulcers with gangrene (third degree). There have been noted further forms of dermatitis due to traumatism caused by cold and finally nervous troubles of retarded development. Very few fatal cases of occupational origin due to cold are known.

Changes of the first and second degree have also been observed at higher temperatures exceeding 0° C., that is to say, at temperatures above the freezing-point. On the other hand, frostbite of the second degree with blistering, ulceration or gangrene are only observed at temperatures below 0° C.

The action of cold exercises its effect in the surrounding atmosphere, in the open air or in cold workrooms, especially by way of air circulation or by contact with good heat conductors such as: metal, water or in the open during a thaw when workers are obliged to work in trenches or in work of excavation. Frostbite is facilitated by inadequate footgear or clothing, especially when the former arrests the circulation and is not watertight.

Frostbite of the hands and feet are known to occur amongst soldiers, agricultural workers, foresters, gardeners, road-menders, ploughmen, night-watchmen, customs officials, policemen, woodcutters, workers engaged in removing snow, porters especially when the work is effected at night, or when the watchman sleeps in the open.

In the case of women, the wearing of inadequate clothing frequently leads to frostbite of the hands, and more frequently of the feet, the calves of the legs or the arms. It is, however, chiefly the fingers and toes which are affected.

In certain industries there have been noted serious frostbite, necrosis and gangrene of the limbs, fingers and toes, yet such conditions are rarely of purely occupational origin: porters and manufacturers of ice for the preservation of food, workers in the refrigerating industry, due to contact and transport of metallic objects, to standing or sitting on cold stones, workers working in water, agricultural workers or foresters, fish vendors, and vendors of other food products, etc. During ventilation of gas piping by means of carbonic acid snow it may happen that compressed carbonic dioxide comes in contact with the worker's fingers causing frostbite of the second degree (Oppenheim).

From the pathogenic point of view, the modifications in question are vascular in character, forms of paralysis with alterations of the colour of the skin which becomes cyanosed and assumes a blue-red colour or undergoes secondary ischemic changes ranging even to gangrene and finally necrosis of the tissues of the fingers and toes, etc.

Complications consist in necrosis, gangrene, rarely tetanus, which has, however, been known to occur during work in the open air or digging. In serious cases it is necessary to proceed with the greatest care and only to effect more extensive amputation after having circumscribed the gangrene in order to avoid further mutilation and invalidity. There has also been noted a dystrophic phenomenon for instance of the nails, with continued sensibility.

Amongst the retarded manifestations and nervous troubles should be mentioned the frequent occurrence of partial or peripheral paralyses as a sequence to nephritis due to cold particularly in predisposed individuals. The part played by the nervous system is demonstrated by the symmetry of lesions of this kind and by very distinct demarcation within certain nerve centres (internal or external edge of the foot). There have been noted, but less frequently, motor paralyses and paraesthesias.

Work in a cold damp atmosphere (cleaners, washerwomen, workers in the dyeing industry) causes zones of
anaesthesia and asphyxia of the fingers, often limited to the extremities, troubles which tend to heal when the patient abandons her occupation and submits to rational treatment.

The majority of injuries caused by frostbite generally affect the pre-cutaneous layers, the deeper seated organs remaining immune, but the skin is often also affected throughout its whole thickness. Local lesions of various origin are connected with certain parts of the skin and make their appearance regularly in the form of massive manifestations of the condition in question: redness of the face and hands in fishermen, dockers, sailors, workers in ice factories, butchers and especially shop keepers obliged to work in cold places, provides an instance of this. Further, conditions of housing and working conditions, in the case of damp cold dwellings or working places, represent a further cause of frostbite of varying degrees.

In the case of numerous workers cold merely accelerates the outbreak of a definite form of dermatitis. In this connexion may be mentioned, for instance, caloric and racemose lividity, acrocyanosis, acropaesthesias, dermatitis accompanied by atrophy, Reynaud's disease, erythremelgia, sclerodactyly, etc. In the case of these affections, the action of the cold supervenes to aggravate the neuro-trophic vasomotor predisposition. Melanodermia due to cold readily causes disfigurement and is noted amongst workers, affecting especially the face and hands. It is doubtful whether cold constitutes an etiological factor in the case of angioneurodermatitis of the toes and it is rare that workers suffer from pustulous hiemal acrodermatitis of the hands.

Statistics

It is hardly possible to draw up statistical returns relative to injuries due to cold, since the factor of temperature is of doubtful etiology and the part played by it is open to doubt on scientific grounds, especially in those rare cases in which the action of cold is due to work effected inside a factory, nor is the recording of cases occurring in the open air free from difficulty, exception being made in the case of war statistics relating to soldiers, which again merely include serious forms of injuries.

Hygiene

Local injury from cold ought to be combated by exercising care with a view to preventing arrest of the circulation by tight clothing, and the wearing of garters, and by protecting the body by means of bad heat conductors (hair, wool, etc.); wearing of absorbent mat-
Slate

French: Ardoise. — German: Schiefer. —

**Composition and Properties**

Slate is a dense, fine-grained, argillaceous schistose rock produced by compression of aluminous silicates of clays, shales and certain other rocks, so as to develop a characteristic cleavage lying at any angle to the bedding plane and causing ready cleavage into thin slabs having great tensile strength and durability. It is generally dull bluish or greenish-grey in colour though the presence of limonite or haematite sometimes renders it brownish. Cleavage is the result of subjection to tangential stresses set up by folding and recrystallization induced by pressure. Slate consists largely of fine plates of mica arranged parallel to the cleavage faces. These faces have usually a slightly silky lustre due to the abundance of minute scales of mica lying parallel and reflecting light simultaneously from their basal planes.

An additional component is quartz in minute lens-shaped grains. Minute rods or prisms of rutile are also common as well as well-formed cubes of pyrites which are often visible on the splitting faces. Chalcedony slates show elongated straight sided crystals which may be one half to several inches in length, though these are as a rule more or less completely weathered to white mica and kaolin. In other cases, more especially near mineral veins, slates are filled with blade needles of tourmaline or are calcified and impregnated with mineral ores. Much folded slates may be traversed by mineral quartz veins. Pure slate dust is rarely met with.

An analysis of slate dust yielded the following constituents, showing a higher silica content: 61.57 per cent. for red schist, and 65.42 per cent. for green schist; and also rich in alumina, 19.32 per cent. for red schist, and 19.98 per cent. for green schist.

One authority states that the dust examined microscopically appears to be made up of irregular but sharply angular particles, often serrated, while another describes the grains as being soft and oily to the touch rather than hard and inelastic.

**Industrial Uses**

Slate quarries may be above or below ground. The material is generally got by hand, but is sometimes won mechanically by channelling machines. When blasting is done advantage is taken of the natural cuts or joints and the rock is readily thrown off these. After blasting the loosened mass is detached with crowbars. Good blocks are selected and sent to the slate huts for splitting and dressing. Apprenticeship is often passed in the cutting and splitting huts at the surface, and later on the young worker descends to take part in the work of extraction.

Descent may be made in trucks, but it is more often made by ladders or steps cut in the schist. The slater is often obliged while engaged in cleaving the slate face to take up a recumbent position at the foot of a crevasse of rock. In this position he loosens the slabs of slate with his pickaxe or pick. The next process is done by means of the cutter's pick, to the accompaniment of clouds of dust produced at each stroke of the pick. The slate bed once loosened on all sides is finally replaced by a mine, breaking away in blocks.

The sawyers often have to mine the blocks as well as to cut them. Boring is done by hand or by a compressed-air borer. In hand boring the worker holds the borer, while his mate applies a hammer to it with all his strength. After each blow the borer is drawn out, bringing with it much dust. The workers who remove the debris to take the blocks to the cutting huts, climbing from the foot of the quarry to the trucks or hoists, work in the same dusty atmosphere as the extractors.

The blocks are then cut into smaller pieces weighing from 50 to 100 kg. and over. These are carried on the workers' backs to the trucks and thence to the surface. The blocks, on arrival at the cutting shop, are cut into ever thinner slices until they reach the required thickness for roofing material. This operation is effected by blockers and splitters in a sitting position. The blocks are placed between the knees and split by the use of a chisel and mallet. The dust produced as work is heavy and falls to the ground and often the blocks are wetted down with a swab or mop prior to splitting as this is essential to good cleavage.

From the blocker or bankman the block passes for further splitting to the splitter seated on a cushion or wooden seat, his legs protected by a rug from slate splinters and from damp and cold. The blocks are then placed horizontally on a vertical iron stand by the dressers who, by means of a sharp knife or cutting machine, trim the edges and make the plates into the required sizes. The cutting machine is often operated by foot power.

The remaining processes come under "mill work". Mill-men usually constitute about one-fifth of the total number of slate workers.

Slate slabs after cutting, squaring, planing, dressing and where necessary enamelling and polishing, are used for roofing, for chimney pieces, billiard...
tables, wall linings, cisterns, paving stones, tombstones, electrical switch boards, etc. Fine varieties are used for writing slates and for slate pencils. Slate is becoming less and less used for roofing owing to the increasing use of artificial roofing materials and the vogue for flat roofs.

**Working Conditions and Risks**

In regard to the occupational hazard involved, one authority states: “Taking all circumstances into consideration, slate workers are subjected to conditions highly calculated to produce respiratory diseases.” In countries where the majority of operations are performed out of doors, there is not so much risk; but where slate sawing and dressing is effected in closed shops without efficient dust removal apparatus, the risk may be considerable.

Slate workers like miners may be the victims of landslides and explosions. When descent and ascent of quarries is effected by ladders or steps cut in the schist, much additional strain and fatigue is involved. During the operation of cleaving the rock face with the pick the worker, forced often to adopt a cramped and tiring attitude in a very restricted space, may be exposed to much dust, and ventilation is often very defective. Gas from explosions lingers long in such places and helps to vitiate the atmosphere. Each stroke of the pick causes dust to rise in the worker’s face, and if he is in a hollow crevasse where breathing is difficult and therefore deep, entrance of the dust into the respiratory tract is favoured by this fact.

During the operation of boring, each time the borer is withdrawn it brings with it much dust which envelops the workers, and where a compressed air borer is used the workers are enveloped all around, one authority states: “Taking all circumstances into consideration, slate workers are subjected to conditions highly calculated to produce respiratory diseases.” In countries where the majority of operations are performed out of doors, there is not so much risk; but where slate sawing and dressing is effected in closed shops without efficient dust removal apparatus, the risk may be considerable.

During the operation of boring, each time the borer is withdrawn, it brings with it much dust which envelops the workers, and where a compressed air borer is used, the workers are enveloped in dense clouds of dust and have to change with a companion after ten to fifteen minutes. The work is more rapid and efficient than in the case of hand boring but more dangerous for those employed.

Usually workers in slate mines work in an atmosphere thick with dust, fumes and gas from dynamite and carbon lamps. The only ventilation is by a communicating gallery which does duty for a ventilating shaft. There is therefore insufficient renewal of air in heavy, unhealthy weather and the dust, along with gas and fumes from explosions and from acetylene lamps, remains suspended in the atmosphere for quite a long time before being dispersed, and the worker is thus often obliged to resume work after an explosion before the working post is sufficiently free from the products of explosion.

The workers who transport the blocks to the trucks or hoists are exposed to the same dusty atmosphere as the quarrymen and have, in addition, to endure the great physical strain of carrying on their backs blocks weighing 50 to 100 kg. or over. The blockers and splitters are obliged to adopt a very bent position which interferes with the respiratory function and favours the inhalation of dust. The shops are usually very low and badly ventilated and if the cutters may be said to be less exposed to risk than the quarry workers, they are nevertheless by no means exempt from it.

The making of marbled slate involves an additional dust hazard. Manufacture of slates for school use involves polishing (done wet), generally by a machine, and ruling also done by machine and coloured red with minium.

Alcoholism is often held responsible for the ill-health prevalent among slate workers, and while it is true that by reason of their employment, which provokes thirst, many workers are addicted to alcohol so that it may well be said to aggravate to some extent the symptoms from which they suffer, it is certainly not the whole cause of them. Heavy physical labour, often accomplished under poor conditions of hygiene, facilitate the progress of disease amongst slate workers.

**Statistics**

A statistical investigation covering the years 1855-1880 gave the average length of life of slate workers as forty-eight. More recent statistics for certain districts in Belgium (between 1900 and 1920) showed that of 189 deaths among slate workers 133 occurred before the age of fifty-six was attained, while 56 were those of workers above that age. Figures affecting one district in particular revealed 51 deaths of slate workers as compared with 188 for the male population in general. Of the slate workers in question 35 died under the age of fifty and 46, or 90 per cent., under the age of fifty-six years, while 5 alone survived it.

The deaths amongst slate workers as compared with the male population in general constituted (totalling the figures for the districts dealt with) 36 per cent. Of 561 deaths from all causes among slate pencil makers (American enquiry), 67, or 64.2 per cent., were attributable to pulmonary tuberculosis and 25 to other diseases of the respiratory organs. The average age at death of slate pencil makers was estimated to be 45.7. In 1907-1914, amongst 93 deaths of slate workers 12, or
12.9 per cent., were caused by pulmonary tuberculosis, 10 by non-tuberculous respiratory diseases, equaling 10.8 of the mortality from all causes. One authority estimates after statistical investigation that tuberculosis supervenes through contagion in one-quarter of the tubercular cases and is due to heredity in the remainder.

The mortality rate for English slate workers for the period 1910-1912 was as follows (figures relative to 1,000 living): for all causes, 896; for pulmonary tuberculosis, 220; for pneumonia, 57; for bronchitis, 25; and for other respiratory diseases, 18; for diseases of the circulatory system, 118; for chronic nephritis, 26; for accidents, 61. (See articles "Miners' Diseases" and "Lead").

Analysis of the mortality figures for tuberculosis per 1,000 living at different ages and for the same period (1910-1912) provides the following figures: fifteen years of age, 1.16; twenty years, 2.43; twenty-five years, 2.11; thirty-five years, 2.82; forty-five years, 2.83; fifty-five years, 7.91; sixty-five years and over, 7.05.

According to Collis, the total number of slate workers is not very high so that the mortality rate calculated should be accepted with some reserve. Comparative mortality rates for tuberculosis amongst slate workers is lower than that for workers in the stoneware industry (415), but very much higher than the tuberculosis mortality rate amongst workers in the lime-stone industry (159). The mortality rate for other respiratory diseases and for chronic nephritis is not high. These figures, however, do not exclude the hypothesis that, as regards the tuberculosis bacillus, dust of alumina exercises an influence analogous to that of silica dust.

**Pathology**

At forty to forty-five years of age the slate worker is often obliged, on account of poor health, to leave the quarry and return to the cutting shop, since after fifteen or twenty years of subterranean work, or even earlier, exhaustion and breathlessness set in, followed by bronchitis which tends to become chronic and later set up pulmonary infections. Slate workers' disease is a pneumaticosis due to infiltration of the respiratory organs by schist dust, which in its late stages may or may not be complicated by tubercular infection (see article "Dust").

Slate workers are described by one authority as prematurely old, breathless with the least effort, wheezing, and later subject to hectic fever, and they often die like tubercular patients between the ages of fifty and fifty-five years without necessarily the agency of the tuberculosis bacillus.

In Italy serious affections of the respiratory apparatus are fairly often met with amongst slate workers. These lesions are specially characterised by numerous centres of chronic systematised pneumonia, sometimes confined to one lobe and sometimes to several, being in direct relation to the distribution of the peribular lymphatic vessels. When there is no co-existent tubercular lesion the case presents a more or less extensive sclerosis with insufficient haematoxis and cachexia, which may terminate fatally even without the presence of the Koch bacillus. This pneumoconiotic cachexia is almost always accompanied by serious cavities (Devoto, Cesbianchi).

**Hygiene and Prevention**

Where the compressed air-borer is used a water jet should be applied to draw back the dust in suspension in the atmosphere to the hole from which it is emitted. This eliminates entirely the dust hazard, but has not been widely applied so far and is not welcomed by the workers. In general the dust hazard in quarries should be reduced by manipulating the materials in a wet state and in the huts at the surface by frequent watering of the floors and spraying material. The air of the galleries and workshops should be changed by a powerful mechanical ventilation apparatus. Electric or other lamps should be substituted for carbide lamps which give off acetylene and smoke.

Trucks should be used for raising and lowering material to minimise fatigue. Even when these are provided they are sometimes not used because employers do not guarantee them as safe. By reason of the very considerable amount of dust given off during the finishing processes in the manufacture of writing slates, in spite of the installation of exhaust slates, in spite of the installation of exhaust fans and hoods, a considerable quantity escapes and falls to the ground on account of its weight, and ventilation other than localised exhaust devices only renders conditions worse. To meet this difficulty the installation of a perforated work table provided with a water trough underneath has been found productive of good results.

Propaganda for personal hygiene amongst slate workers for personal cleanliness, prevention of spitting and temperance is required to combat the forces which lower disease resistance.

**Legislation**

***

Soap Industry

Soaps are combinations of fatty acids with the alkaline metals, sodium and potassium, but the word "soap" is also given to combinations of these acids with various other metals, e.g. calcium magnesium, manganese, iron, and zinc.

Fatty acids occur in fats and oils in the state of glycerines. Natural fats are really mixtures of various glycerides; palmitin (glyceride of palmitic acid: C_{15}H_{31}COOH), stearin (glyceride of stearic acid: C_{17}H_{35}COOH) which are solid; olein (glyceride of oleic acid: C_{17}H_{33}COOH), which is liquid.

Soaps are, therefore, also blends of the alkaline salts of these acids.

Only the soaps made from potassium and soda are called "soaps" in the technical sense of the word; they are the only ones completely soluble in water. They contain, in addition to alkaline salts and the fatty acids already mentioned, salts of fatty acids with a lower boiling point which occur in small quantities in natural fats. They contain, further, alkaline salts of resins added in the process of manufacture, while cosmetic or medicinal soaps contain a great variety of substances.

RAW MATERIALS

The raw materials for the making of soap are: fats from all sources, the hydrates of potassium and sodium (caustic potash, and caustic soda) or the corresponding carbonates of potash or soda, and resins.

Animal fats. — The following are the animal fats most commonly used: suet of beef, mutton, goat, etc., fat from the horse and pig, and bone marrow, spermaceti oil, neat's-foot oil, fish oil, etc.

Vegetable fats. — Oils of coco, palm, olive, colza, sesame, ground nuts, linseed, hemp and the caster-oil plant.

Soap factories do not usually prepare the fats, but buy them from outside.

In order to obtain fat from the soft parts of the animal, they are treated in boilers heated by steam. During this operation the products of decomposition of the albumen and the volatile fatty acids become disengaged; this causes an offensive smell, very unpleasant for the workpeople and the neighbourhood of the factory. This inconvenience can be reduced by means of exhaust ducts which carry the charge with odorous substances to a furnace or to washing devices (e.g. Somnier system).

Establishments of this kind, however, are only permitted in districts which are sparsely inhabited. They should only be erected in the neighbourhood of large towns when the prevailing wind will cause no nuisance to the town.

The escape of the vapours must be dealt with in an efficient manner. The noxious fumes, which are given off when acrolein (see article "Acrolein") or any organic waste is burnt, must be carried off by high chimneys placed above the bars of the furnace where these materials are collected. Residual water, especially that from making stearin which is sulphurous, should be purified, as it may be a source of danger.

It is the same in dealing with bone marrow, the raw material of which gives off, before any treatment, a very offensive smell due to particles of flesh adhering to the bone.

Fat represents only about 6 per cent. of the weight of bone. It is obtained by crushing the bones mechanically, followed by steam heating, as in dealing with soft parts, or by extraction with petrol. The first method is well adapted for the making of soaps. Besides the offensive smell emitted during boiling, there are certain important factors from a hygienic point of view to be considered in the crushing of bones, e.g. it is really useful to know the source of the raw material in order to tell if it may possibly be a carrier of infectious germs. The raw materials must not be touched with the hands. Washable overalls should be available for workers, and employers should install and maintain properly-fitted bathrooms. It may be remarked, however, that factory inspectors have scarcely mentioned any case of anthrax contracted during work on bones. This is probably because workers come little in contact with the raw material.

When the extraction is done by the use of petrol, it is possible for the workers to breathe the fumes when poisoning may result which is, however, scarcely ever fatal. But the dangers increase considerably when use is made of benzol, which is notoriously much more poisonous (see articles "Benzine" and "Petrol"), or other solvents: carbon tetrachloride, etc.

In some cases the crushing of the copra (the dried meat of the coconut) has caused
It should be added that handling decomposed or rancid oils containing aldehydes and fatty acids may cause certain forms of dermatitis, known as "copra-itch". Red oil (a term usually employed for crude oleic acid) is certainly one of the commonest sources of cutaneous lesions among soap workers. Dermatitis or lead pipes. This decanting by liquefaction is carried out in a place where no one enters while the operation is going on, for it causes a discharge of steam accompanied by an offensive smell. The air of the vicinity of the machine suffered from a grave irritation, of these lyes require great care, their decomposition into glycerine and fatty acids following a combination of these acids with the alkaline metals to form soaps. The name of saponification is, however, given to various decompositions of fats, whether these decompositions are produced by any metal (calcium for example) with the formation of the corresponding soap or whether they accompany the setting free of fatty acids. Soap is still made by two old processes, which consist either in heating the fats directly with caustic alkali or in treating the fatty acids with a solution of soda. This second process is rarely employed as the fat has to be first saponified, which operation can be done in three ways: by heating with concentrated sulphuric acid, by treating with steam superheated to 315° C., or by fermentation by means of seeds of the castor-oil plant. An aqueous solution of glycerine is always obtained as a by-product. Works in which soap is prepared by heating fat with potash or caustic soda receive the alkaline lye in large iron hermetically-sealed casks. Manipulation of these lyes require great care, for they are strongly caustic. Caustic soda is sometimes received in solid form in tinned iron receptacles (soda in drums: Trommelsoda). The dissolving is in this case difficult, with risk to the skin and the eyes of workers as the addition of warm water often causes spurring.

The tallow, fats and oils are first clarified, and then purified either with sulphuric acid alone or sulphuric acid and bichromate, or by bleaching in chlorine. The products are then stored in tanks until required for use. The first operation or engouage (making into a thick paste) consists in mixing, whilst hot, fat and alkalai
in a large vat furnished with a stirrer. The materials were formerly heated over a fire; this is now done by steam. The lye should be added in small quantities, for it causes at first much frothing and the liquid rises. At the end of a certain time it simmers quietly. There is very little danger in this operation for the workmen, for all necessary precautions are taken to prevent them falling into the vat by a false step. However, there is considerable liberation of fumes and this makes it essential to carry on the process in lofty buildings where the roof has louvred outlets.

The mass so obtained still contains all the glycerine and water. The soap is separated by 
relargage, that is to say, by the addition of a strong pickle which makes it insoluble. The handling of the salt may produce with some workers wounds and ulcerations, but such cases are quite rare in soap works.

After being left to stand for several days, the lye is drawn off and the soap pumped into a mixer, which gives it a uniform consistency. At this stage are added the perfumes or other ingredients of certain soaps (sodium silicate, sodium carbonate, borax, alcohol, nitrobenzene, resins) which may be injurious to the health.

Separation by 
relargage is not always practised. It may be replaced by heating the mass which expels all the glycerine and water. The soap is drawn off while it is still sufficiently warm to be liquid.

A new method of manufacture consists in forming first a soap of lime by treating fat at 95°-100° C. with milk of lime in an iron vat provided with a stirrer. The milk of lime is prepared at the factory itself from quicklime (see above regarding the dangers of dissolving lime). The soap so obtained is cut up by a machine, and then ground in a mill. Dust formation is slight during this operation on account of the high proportion of water and glycerine in the product. The next process consists in washing with water in a vat, the bottom of which is formed by a sieve and a canvas filter; in this way the glycerine is eliminated. The mass is then carried by an Archimedean screw into a vat where it is agitated in contact with a current of steam. Soda is then added to change the lime soap into soda soap.

From the hygienic point of view this process does not differ from the preceding ones. They all expose the workers to heat and damp and may consequently be a source of rheumatic, neuralgic, myositis and other complaints. When the soap has been prepared it is cast into blocks or into bars in moulds cooled by water. It is then cut and stamped with the mark of the factory, etc. None of these operations presents any danger from the chemical point of view. The risk of accidents from mechanization is very small, except in the case of presses used to imprint the trade mark.

Nevertheless, the workers who handle the soap are liable to contract diseases of the skin. A factory inspector noticed in 1910 in Bavaria that a workman who had been employed for over 20 years in cutting bars of soap suffered from a sudden onset of a severe eruption on the hands. Special medical treatment was of no avail and the workman had to change his work. The following year, again in Bavaria, skin disease was noted as affecting two soap workers who similarly were compelled to abandon their work. In 1912 an Austrian factory inspector noticed that a workman employed in pouring the caustic lyes into the heated cauldron for 
empâtiage (making into a thick paste), according to the old process, suffered from burns on the hands and forearms. A slight modification of the process was in this case all that was needed to remove the risk.

It has been found that the acid fumes may cause erosions of the teeth and gastro-intestinal troubles.

Cramer has reported (1925) caustic burns similar to lime burns in a soap factory worker, due to "red oil" (castor oil and sulphuric acid) and followed by the loss of an eye through necrosis of the sclerotic.

Bichromate solutions and dusts can produce lesions of the skin and the nasal cartilages; and chlorine, respiratory inflammation, pulmonary oedema, and if the poisoning is serious and chronic, emphysema.

Among the various products of soaps may be mentioned soap powders or washing powders used for the making of cosmetics or for washing linen. They are often adulterated by the addition of soda. Their preparation involves risks to the health of workmen particularly in the last case, but the inhalation of soap, even if pure, is, to say the least, very unpleasant, and may irritate the respiratory channels.

The basis of the various preparations for washing clothes known as soap powders, is Solvay carbonate of soda, to which is added sodium silicate and Marseilles soap. The manufacturing process consists in dissolving the sub
stances in water in the proper proportion, allowing the whole to crystallise, and producing the product thus obtained. In 1921 Bargeron and Gandois found among women employed in this industry at Paris erosions on the back of the hands at the base of the fingers in small bleeding patches; these were due to desiccation and alterations in the elasticity of the skin by chemicals. During all these processes much dust is generated. The workmen generally protect the nose and mouth with a rag, the eyes remaining uncovered. Large masks which cover the face completely are so uncomfortable to wear that workmen cannot be asked to wear them continually. The only hygienic process consists in pulverising the soap and putting the powder in packets by means of closed-in machines connected with good exhaust ventilation. A Prussian factory inspector in 1918 wrote: “Numerous cases of irritation of the eyes have occurred, particularly among workmen employed in pulverising the soap or weighing or packing the powder. As this trouble was not noticed in time of peace, it must be ascribed to substances which, in accordance with the ordinance of the Federal Council, are incorporated with soap powder, i.e., soda, sulphate, soluble glass and kaolin.” As a matter of fact, a medical district assessor has shown that it is particularly the soda, used in very fine powder, which gets into the eyes and produces irritation. The grinding of the soap should be done in sealed apparatus, the powder being withdrawn automatically, while the workmen should wear goggles completely surrounding the eyes.

The weighing and the filling of boxes are sometimes done by machines which, however, may work so imperfectly that it is necessary after all to continue the operation of filling and to do the weighing by hand. These processes inevitably cause clouds of dust which get into the eyes of the women employed as they lean over the work table. The wearing of goggles completely surrounding the eyes has therefore been enforced for this process as for others. In addition, great cleanliness should be observed and the women employed should avoid rubbing their eyes with their hands so as not to introduce any soap powder.

In the old process a lower aqueous solution containing 2-3 per cent of glycerine is formed which is separated by evaporating the water. The process of Kreutiz provides a solution much richer in glycerine. Glycerine is used in the preparation of toilet soaps.

Special soaps (fancy soaps).—Cosmetic or medicinal soaps are usually hard soap (soda soaps). Blocks of soap are cut into slabs, then converted into shavings by means of revolving cylinders armed with blades. As this appliance may cause serious injuries to the hands, the cylinders should be protected by a device the removal of which prevents the running of the machine. The shavings are next passed between two rollers and are then welded together into a ribbon. The rollers should be guarded so that the fingers of the workmen cannot be caught. The ribbon finally passes through a drying stove where a current of hot air circulates. The drying was formerly done on screens. The material had to be turned very often and the workers suffered from the heat. This process is no longer actually used except to dry thoroughly certain soaps intended for powdering. An Archimedean screw carries the ribbons of soap into a mixer when essential oils and perfumes are added. In order to avoid possible accidents from the mixer, the apparatus should not function except when its lid is in position. The mass so obtained passes into a mixer fitted with rollers, and then, after being heated, it is converted into a band which is cut into pieces of suitable length.

The moulding of cakes of soap is done in a press. For the large size electric presses are used, but for the smaller ones the presses are worked by foot pedals. Electric presses should be furnished with protection devices. A technical study of presses has been published by the International Labour Office. Work at a foot press is fairly tiring for the workwoman, since for each cake of soap she has to make two violent movements which do not correspond to the structure of the leg (antero-posterior position with forward movement of the foot). Thus the workwoman in a day’s work of eight hours has to make more than 3,000 of these double foot movements.

The powdering of soap calls for consideration from the hygienic point of view (see above) as well as the addition of carbonate of lime, which, being done with a spade, gives rise to considerable clouds of dust. The mixture is heated in a melting pot fitted with a mixer, and colouring material or perfume is then added. The paste is then put into tubes by means of a machine from which there is little risk of accident.
The further point must be stressed that perfumes, essential oils and the various substances which are added to special soaps are preserved as alcoholic solutions, etc., which are highly inflammable. The warehousing ought, therefore, to be done in places provided with central heating. The employment of nitro-benzol fairly often gives rise to certain troubles, such as headaches, vertigo, nausea and other symptoms of poisoning by benzene.

**HYGIENE**

Soap works present a problem to the hygienist as they send out annoying and nauseating smells. Over and above general hygienic measures for the district, ventilation of the workshops, and measures against humidity, it is necessary to take a complete series of special precautions such as the installation of efficient ventilating shafts above the saponifying boilers, prohibition of discharging waste water and residues into the ground or into streams; prohibition of any accumulation of putrifying or badly smelling materials. If it is necessary to preserve these temporarily it must be insisted that they be kept in airtight vats protected against the weather. Workmen must be supplied with the tools necessary to avoid all contact with materials which are being used; also airtight gloves or failing them, ointments (neutral fats). The use of raw materials such as give off of themselves or during saponification nauseating odours must be forbidden. Precautions must be taken against fire (raw materials, essences, factory products, etc.) and dust explosions.

**LEGISLATION**

The French legislation excludes women and also youths under 18 years of age from employment in the extraction of oils contained in the greasy waters for the manufacture of soaps and for other purposes, and from workshops where sulphide of carbon is employed. In Russia the ordinance of 27 December 1924 lays down measures of special protection for the workers employed in soap factories. In Holland there is compulsory notification of diseases of the skin (eczema and dermatitis), pulmonary affections and ulceration of the nasal, palatine or buccal mucous membrane which arise among workers handling or making powdered soap. In Italy, benzene poisoning among soap workers is compensated by law.

**Social Welfare — Personnel Work**

Industrial welfare is of comparatively recent development. It may be defined as a movement directed at maintaining the moral and physical health of the human factor in production in order to assure conditions of economic health in industry.

According to an American definition, welfare comprises "anything for the comfort and improvement, social or intellectual, of the employees, over and above wages paid, which is not a necessity of the industry nor required by law".

Boettiger (1923) has defined welfare as "the effort of the employer to establish and maintain standards in respect of hours, wages, working and living conditions of his employees which are neither required by law nor by the conditions of the market".

*From the workers' point of view,* according to this author, welfare has for its object:

1. Improvement of the living conditions of workers: (a) economic advantages (minimum-wage, profit-sharing, premiums for length of service, housing, shopping facilities for foodstuffs, restaurants, canteens, etc.); (b) intellectual and social advantages (leisure, sport, clubs, instruction, collaboration in regard to social services); (c) occupational training (apprenticeship, trade schools); (d) general education and instruction (continuation schools and libraries, etc.).

2. Stabilisation of living conditions of workers and their families: (a) attempts to make work more regular and stable (research into the cause of dismissal and turnover of workers, selection and engagement of workers, etc.); (b) study of conditions of the labour market with a view to rendering work more stable (control of production, budget, etc.); (c) workers' insurance schemes (old age, accident, sickness).

3. Protective measures for the health and physical capacity of workers: (a) reduction of fatigue (study of working hours, rest periods, holidays, etc.); (b) per-

---

1 In English-speaking countries the two terms used to describe this work are "welfare" or "personal work". The first expression being in accordance with English usage and the second being currently used more recently in the United States. Though both expressions designate one and the same movement founded on the same principle, they tend to become applied to varying systems presenting difference of form, scope and method.

Dr. E. Brezina
(Vienna)
sonal hygiene; (c) medical treatment for sick persons and victims of accidents; 
(d) campaign against occupational diseases and accidents (ventilation, lighting, 
removal of smoke, fumes and gas, safety devices, etc.).

From the point of view of the employer, Boettiger assigns to the welfare movement the following objects:

1. Increase of efficiency by selection of workers: (a) systematic occupational training (trade schools, special methods of apprenticeship, schools for foremen, etc.); 
(b) adaptation to work (selection and vocational guidance, engagement of workers, medical examination on entry, turnover, promotions, trade analyses, research into causes of dismissal, etc.); 
(c) adaptation of the working surroundings (workers' education, schools of lan-

At the outset experiments in welfare were originally the result of initiative on the part of an employer. Robert Owen was a pioneer of this movement for introducing welfare into industry by methods which he developed at New Lanark. The seed he sowed, however, did not quicken until after being overwhelmed by the economic conditions resulting from the Napoleonic wars. It had lain buried for nearly a century. Nevertheless, certain advanced employers, such as Jean Leclaire in France, Van Marken, Storck and Company in the Netherlands, Francis Cabot Lowell, Nathan Appleton in the United States, and Zeiss and Krupp in Germany, followed in Owen's footsteps. In 1913 a conference devoted to the

Fig. 126 — Welfare building belonging to a large Swiss firm.

2. Increased efficiency by economic methods (minimum wages, profit sharing, premiums for length of service, etc.) by indirect means: (a) economic methods (pensions for invalidity, old age, benefits in case of sickness or accident, life insurance policies, stability of work, etc.); 
(b) health measures (reduction of fatigue, regulation of working hours, rest periods, holidays, restaurants, canteens, organisation of workers' leisure, workers' housing schemes, personal hygiene, medical treatment, reduction of risk from occupational disease and accidents); by collaboration with the workers in regard to social services. 

study of problems of industrial welfare met in York, at which thirty English firms were represented. This actually occurred at a time when such a thing as modern hygiene, equipment or up-to-date first-aid requisites and protection devices for the worker were unknown in industrial premises except where compulsorily exacted by legislation in a few dangerous trades, or maintained at the instigation of Government inspection departments. 

It was, however, chiefly the war of 1914-1918 which stimulated the development of this movement by again bringing into prominence the value of the
human factor, previously eclipsed by the growing importance of power machinery, at a period during which, owing to the sudden withdrawal of man-power, the need for conserving what was still available became urgent.

Welfare, which in its essence constitutes a response to the fundamental social economic and psychological requirements of the working classes, has assumed various forms in the course of its development before attaining its present stage, during which its particular character is manifested in cooperation on the part of all those affected.

First of all, as has been noted, there occurred the intervention of the employer who, moved by a philanthropic impulse to interest himself in the fate of his workers, created various schemes for assisting them which had no direct connection with work. Such were the "paternal" aims of Dale, Owen, Krupp and Lowell.

Subsequently, there was a tendency to consider efficiency in the strict sense of the word without bestowing due consideration on the personality of the worker in his capacity of eventual collaborator. It was judged sufficient to entrust questions of workers' welfare to a welfare secretary made directly responsible to the employer or general manager without any attempt to appeal to collaboration on the part of the workers.

An attempt to put into effect this latter aspect characterises, however, the third stage, during which, side by side with efforts towards increased efficiency, there has developed a tendency to take into account the harmonious development of industry as a living organism. It is this latter phase which is characteristic of welfare as understood at the present time, and it is essential to recall that the first con-

Fig. 137. — Hall of the building shown in fig. 136.
George A. Ranney, secretary of the Welfare Institutions of the International Harvester Company, which gives employment to 40,000 workers, has said in this connection that every attempt to improve industrial life should lead to reciprocal benefits. Where no benefit accrues to the employer as well as to the worker not only do such institutions lack justification on economic grounds, but further they tend to be harmful to the staff by assuming an aspect of charity or becoming imbued with the spirit of discipline based on unjustified interference in the worker's life. However that may be, it is possible to have a combination of the three stages of development outlined above, and numerous instances of this collaboration should exist between services fulfilling this purpose and medical services in the factory, works management, and production and wages departments.

The practical side of such activities may be outlined as follows: the welfare department, being notified of the need for workers for certain work, organizes selection prior to definite engagement. It thus succeeds in eliminating the futile arrival and departure, consequent on faulty selection, of newcomers likely to throw up the work at the outset, a disadvantage which certainly represents a heavy loss for the industry in general, the employers as well as the employed: slow work and waste of time and mater-

Fig. 128. — Welfare building of the firm of C. Erba and Company at Dergano-Milan. Canteen, cloakrooms, douche baths, medical department, etc.

still exist, notably in Great Britain and in the United States.

WELFARE ACTIVITIES

Activity in the welfare field is of necessity extremely extensive since it is a case of ensuring the well-being of the worker from the moment of his entry into industry, throughout his activity there and even throughout his hours of spare time and rest. On this account it is indispensable that close attention be paid to the creation of works councils, the utility of which rests chiefly in their educative value and in the fact that they bring to light the community of interests which bind employers and employed.

Medical supervision plays in this connection a role of primary importance, since the doctor must direct his atten-
tion not only to the general state of the worker’s health but also to various functional reactions connected with the kind of work on which the worker is engaged. It is interesting to recall in this connection that in the Ford factories, as a result of supervision of this type, it has been possible to give employment to 4,032 invalid workers (2,637 had lost a leg, 670 were without legs, 715 had only one arm and 10 were blind). Under similar conditions the Crane Company of Chicago, which gives employment to about 5,000 workers, has succeeded in reducing the turnover amongst its workers from 42.2 per cent. (1910) to 16.4 per cent. (1915), passing successively from 29.6 per cent. (1911), 40.2 per cent. (1912), 47.9 per cent. (1913) to 18 per cent. (1914). The Dennison Manufacturing Company, which employs 2,200 workers, has also reduced the turnover of its staff as follows: 68 per cent. (1911), 61 per cent. (1912), 52 per cent. (1913), 37 per cent. (1914), 28 per cent. (1915).

Harry Mock has stated that the profits of an establishment are proportional to the care bestowed on the health of its workers. It is precisely for this reason that any schemes of welfare should include above all general supervision of conditions of cleanliness, ventilation, lighting and heating of workrooms. On the other hand, distribution and maintenance of working suits (overalls, aprons), gloves, protective glasses, installation and maintenance of cloakrooms, lavatories, sanitary conveniences, sick rooms, ambulances, first-aid posts, rest rooms, crèches, canteens, restaurants, etc., form an essential part of this work.

Cleaning (sweeping and dusting), ventilation, lighting and heating should be effected in conformity with hygienic principles (see articles “Air of the Workroom”, “Heating”, “Industrial Lighting”). The same holds good for the equipment and maintenance of cloakrooms, lavatories, sanitary conveniences, etc. (see article “Industrial Hygiene (Workshops)”).

Choice of the best type of working clothes, protective glasses and respiratory apparatus, etc., cannot be left

![Image](image-url)
ing at the counters where the food is distributed should be obliged to take cash payment.

In dining-halls or canteens installed for thousands of workers it is desirable to simplify the service by a system of "counter service" current in the United States. The worker follows a railing which leads from the door to the shelves, whence he takes a tray; he then arrives at a counter furnished with a hot plate on which are arranged plates containing portions of food from the menu. He chooses what he wishes and proceeds to the cash box where he receives his bill before taking his shops, otherwise the workers will not be inclined to frequent them. Further, canteens and restaurants should be of ready access, and with this end in view it may be preferable to have several small restaurants than one large hall. Canteens should be furnished and decorated in a simple but tasteful manner. A badly installed canteen is likely to encourage a certain amount of negligence and carelessness in the workers' habits, whilst an attractive and carefully installed hall may on the contrary stimulate improved habits. The canteen, which constitutes a rest room as well as a restaurant, should place at table. This system has the advantage of avoiding delay and allowing the workers to choose what they want and reducing the service requirements to a minimum.

Apart from the meal hours the restaurant service should assure distribution of tea in winter or cool drinks in summer. For this purpose small tea-wagons on wheels which facilitate transport through the workshops should be used.

As regards the position of canteens, it is highly important that they should not be too far distant from the work- have comfortable seating accommodation for each worker, long benches or forms without backs being quite inadequate in this connection. Workers who have gardens should be encouraged to provide fresh flowers for the tables or, in default of these, pot plants and ferns may be used. Collis relates that he has seen very poorly installed workrooms brightened by provision of flowers cared for by the foreman, and he remarks that where it is impossible for plants to live conditions are also unfavourable for human beings.
A workers' committee should be formed to participate in the administration of the canteen and would prove highly useful for the maintenance of discipline. It should deal with complaints and organise meal-time recreation.

A well-organised factory canteen has other uses than merely a place for taking meals. The worker should, for instance, have facilities for buying for his personal use groceries and other foodstuffs from the canteen reserve, paying for these the wholesale price obtained by the management. He might also be able to obtain prepared dishes for taking to his home.

There are great possibilities for indirect circumstances, involves undue fatigue. Further, by assuring provision of good meals, much may be done in the way of preventing digestive disorders and in consequence incapacity for work or at least frequent discomfort. Indirectly also it contributes to educating the workers by rendering them more cleanly and careful in their habits and, finally, during the time spent by the workers in the canteen opportunity is provided for thorough and effective ventilation of the workrooms.

Canteens should be able to cover their expenses without either profit or loss. Certain firms place at the disposal of the canteen management not only a

CREATING THE PHYSICAL, INTELLECTUAL AND MORAL WELFARE OF THE WORKERS AND THESE PROPOSALS, REACTING ON FAMILY LIFE, MAY EXERT A VERY WIDESPREAD AND FAVOURABLE INFLUENCE. AMONGST THE NUMEROUS ADVANTAGES OF CANTEENS SHOULD BE NOTED THE FACT THAT ONCE THE WORKERS HAVE MADE A HABIT OF frequenting these they are less likely to be tempted to leave the factory and visit cafes and public-houses where they may succumb to the temptations of alcoholic excess. On the other hand, it also relieves them of the necessity of going home and returning to the factory at midday, which, under certain circumstances, involves undue fatigue. Further, by assuring provision of good meals, much may be done in the way of preventing digestive disorders and in consequence incapacity for work or at least frequent discomfort. Indirectly also it contributes to educating the workers by rendering them more cleanly and careful in their habits and, finally, during the time spent by the workers in the canteen opportunity is provided for thorough and effective ventilation of the workrooms.

Canteens should be able to cover their expenses without either profit or loss. Certain firms place at the disposal of the canteen management not only a

room, but also provide lighting, heating and service for cleaning and even advance the sum required for purchasing wholesale foodstuffs and combustibles, etc., or they may supply these products directly at wholesale prices or again they may place at the disposal of the canteen management a piece of ground near the factory for the cultivation of vegetables.

As regards health supervision of the workers, where there is not a doctor permanently attached to the factory (see article "Factory Surgeons"), there should be an ambulance, or first-aid post in charge of a nurse or a specially
trained member of the welfare staff. These should be fitted with simple first-aid equipment (medical, surgical instruments, bed, stretcher) (see article "First Aid"). The address of a doctor or doctors should be posted up and, where possible, a telephone number. The service should record and make a special study of all cases not receiving medical or surgical treatment and notify the management of the results. The management should also be in a position to know at any given moment whether the number of accidents or cases of sickness exceed the usual average.

Rest rooms, particularly useful in factories employing female workers, are often provided adjoining sickrooms and placed in charge of a nurse. Rest rooms provided with a bed or couch are of inestimable service in cases of slight indisposition (transitory headache, etc.). In this way the worker is not obliged to leave the factory, one hour's rest often sufficing for effecting an adequate cure.

In American factories three categories of rest rooms are known: "sitting-rooms" provided with armchairs, couches, tables and adorned with flowers and green plants, which the staff may use as a reading-room or centre for music and conversation, etc.; "rest rooms" properly so called, where silence is imposed and which only contain couches and armchairs; and "isolation rooms" adjoining the medical department and provided with beds for cases of indisposition or sudden illness.

Where working mothers are employed in the factory, rooms for nursing and crèches attached to the factory are of great utility. It was chiefly in France during the war that this question came before the attention of employers and the competent authority, at a time when man-power was depleted in in-

![Fig. 142. — Service for distribution of dishes in a Swiss factory.](image)
given employment in sewing rooms
where working clothes, towels or other
articles are made and repaired, or any
other easy work of this kind is effected,
for which adequate remuneration
should be paid. During this period it
would be possible to provide some in-
struction for the women relative to
their future maternity and the best
means of caring for their health be-
fore and after the birth. Efforts
should be made to encourage breast
feeding as far as possible. In certain
countries legal provisions exist which
require provision of rooms for nursing
of infants in industrial and commercial
employers most excellent results are
achieved. In proof of this, in France
and in Italy the question of breast feed-
ing is coming to be considered as one
of the most important problems con-
ected with the employment of women
in the factory.

The first crèche was organised at
Beauvais in 1846 by Dupont, and since
then the number has steadily in-
creased. More particularly in the
North of France a very rapid develop-
ment has occurred. Even before the
war it was announced at a congress
that information was available concern-
ing twenty-six State establishments and

establishments. Such an arrangement
makes for health protection of the in-
fants and at the same time is of value
in combating infant mortality. In
practice, not infrequently circumstances
concur which constitute certain diffi-
culties in achieving such objects. The
woman worker finds difficulty in get-
ting to the crèche which is placed at
some distance from the workroom, and
in consequence tires of the arrange-
ment and prefers to resort to bottle
feeding. Nevertheless, in services for
infant protection which have been
voluntarily organised by certain em-

fifty industrial establishments possess-
ing accommodation for nursing or
crèches (Feilhøen). At the present time
there may be mentioned as model
crèches those organised by the adminis-
tration of the Tobacco Monopoly in
Italy (Milan, Bologna, Naples, etc.)
(see article "Tobacco").

It is not possible to lay down fixed
principles for the best installation of
crèches. The solution of the problem
depends largely on the number of
women likely to use the room, the space
available and the type of rooms which
can be utilised and the situation of
the factory, etc. Only breast-fed children should be admitted and every effort should be made to avoid crowding and the risks of contamination involved thereby. The nursing room should not contain more than ten infants; small children should be kept away from it and should have at their disposal where possible a small park or play-field surrounded by a railing. An isolation room is advisable. Further, it is essential that a special room should be set apart for nursing mothers and that the children should wear protective overalls and should take adequate precautions as to cleanliness. The infants should be changed in a special room to which no one except members of the staff under adequate supervision should have access and in which cradles or cots are provided.

It is thus seen that a well-organised crèche involves as a minimum the following rooms: an entrance hall with cloakroom and individual lockers, a wash-basin with hot and cold water, provided with soap, nail brushes, towels, etc.; a nursing room with low chairs for the mothers and a weighing-machine; a changing room with seats, wash-basins and, where possible, baths with waste for withdrawal of water and closed receptacles for soiled linen; a dormitory with cradles, light, well aired and sunny if possible. Bedding should be simple, washable and easily cleansed. The various rooms should be centrally heated. A small kitchen is necessary for the preparation of supplementary milk, where such is considered indispensable for certain infants, and of soup and light dishes for the other children. In certain establishments there are special canteens for the mothers providing more abundant and suitable meals and drinks (milk, various infusions, beer, etc.) after nursing.

An important problem is that of the choice of staff to be entrusted with supervision of the crèche. A nurse with a special training in infant management is the best person for this task. Further, a medical specialist should visit the crèche each week or be within call in the case of suspected illness (see also article "Welfare Workers").

In certain industries or certain seasonal agricultural work in which the local labour supply is inadequate, it is necessary to recruit workers from a distance and for these it is essential that dormitories conforming to hygienic regulations imposed by law should be provided. These places should provide cubic air space not under 14 cub. m. per person. They should be well aired and ventilated and provided with windows or other apertures with mobile frames giving direct access to the outside air. Their height should be at

![Fig. 144. — "Ronuk" hall (see fig. 139) arranged for a concert (England).](image-url)
least 2.50 metres. The ceilings should be watertight and covered with a smooth coating. The exterior walls should be made of watertight material or insulating material of sufficient thickness; the flooring should be watertight and provided with well-fitting boards lending themselves readily to cleansing. The walls should be lime-washed or covered with washable paint and adequate measures should be taken for the destruction of parasites where necessary. In malarial districts special preventive measures should be taken against mosquitoes; drinking water, wash-basins with all the necessary etceteras, sanitary conveniences (shut off from the dormitories) should be placed at the disposal of the workers.

Dormitories should permit of separation of the sexes and private rooms intervals are regularly interspersed throughout the working day, where it is unduly long, or in the course of monotonous or trying work. It is of advantage to distribute to workers instructions relative to movement study and rhythm likely to facilitate their work.

The study of causes of accidents treated in the ambulance department may be of value in solving the problem of their prevention.

Finally, always in collaboration with the works management, the welfare department should impose adequate measures relative to pregnant women or convalescent workers working on short hours or half-days in order to prevent complications likely to result from relapses brought about by a long day's work. In this way it is possible

![Staff dining room and recreation hall at the works of the Gas Light and Coke Company, London.](image)

should be provided for married couples. Beds should be separated from each other by a distance of about 80 cm. Each person should have at his disposal bedding and a cupboard for his belongings. Sleeping in workrooms should be prohibited.

As regards welfare during work, responsibility for this also rests with the welfare staff, whose task it is to make the maximum effort in this direction in collaboration with the technical services.

It would also be advisable to furnish seats for workers engaged on certain types of work1 and to see that rest

---

1 The German Industrial Hygiene Society published in 1929 a note on the rational utilization of seats during industrial work. Besides not only to promote partial earning capacity but also to encourage eventual return to the factory.

A welfare department can only attain maximum efficiency by the organisation of a well-conducted system of reference. An individual card should be provided for each worker bearing the date of his entry, his age, sex, results of medical examination, his work, wages, eventual changes in occupation, diseases or accidents and finally the date and the causes of dismissal. It is only by constant verification of these cards that it is possible

---

1 This, several German publications, some of which are official, contain useful indications in this connection. (See also article "Personal Hygiene ")
to take account of the results of each new effort. The first result to be looked for is a reduction in the time lost by absence, in the number of accidents and in lost time in general, and, further, the direct influence exerted on output. By simple reference to figures the welfare department should be in a position to provide proof justifying largely the expenditure which it involves. It should not in any wise depend for its subsistence on philanthropy on the part of the management. Where this is the case it runs the risk of being summarily suppressed at a time when business is bad, that is to say, at the time when it becomes most necessary.

The study of the question of transport of workers by trains, trams or buses is related to general welfare. It is at times possible to facilitate arrival at the factory by obtaining slight modification of time-tables. In districts where it is possible to do so, it is often advisable to organise a motor bus service.

Visiting sick employees and workers in their homes is one of the most important tasks of the welfare department, which should obtain daily a list of workers absent through sickness. The visiting nurse should be entrusted with this activity. When good feeling exists between the welfare department and the workers (a condition essential to a well-conducted service of this kind) such visits, far from being suspected by the worker, will be welcomed. The visiting nurse should make sure that medical treatment provided in the home is effected under the best conditions, and of such a nature as to reduce duration of the illness and activate restored health, or at least bring about a return of the earning capacity. Where necessary, it is part of her duty to send the patient to a clinic or hospital, or arrange for special treatment or for

Fig. 156. — Gymnasium, Welfare Department of Imperial Chemical Industries, London.
convalescence in an institution for this purpose.

The welfare department should establish relations with various philanthropic institutions where such exist. It should keep in contact with dispensaries, convalescent homes, doctors in the district, schools attended by young workers prior to entry into the factory, employment bureaux, technical schools providing evening continuation classes, etc.

The welfare department should further encourage habits of economy, especially in the case of young persons, by establishing various types of savings banks. Social life may be rendered more agreeable by the creation of open spaces (grass parks, etc.) where children may play under the supervision of a trained person.

Cultural efforts on the part of the workers should be stimulated by instituting libraries, organising popular lectures and supplementary courses of instruction. Libraries should contain dictionaries, books of reference, and technical books dealing with the work in which the workers are engaged. They should besides contain a choice of good fiction likely to create a taste for good literature. A workers' committee should be created for the purpose of choosing the books, a system which has been found to lead to good practical results. Courses of instruction should be organised to supply the need of better technical instruction, and it may here be recalled that many employers in industry have organised real trade schools for their apprentices and workers.

Workers' gardens constitute an excellent means of recreation. The welfare department is in a position to encourage their development by seeking facilities for obtaining small allotments of ground, by buying manure and seeds at wholesale prices, and by organising competitive flower and vegetable shows, etc.

The welfare department may again
encourage the organisation of consumers’ co-operative societies, the utility of which it is hardly necessary to insist on. Such societies, by suppressing the profits which accrue to the middleman, are of value in the campaign against high prices.

Shops most frequented by the working classes are grocers, butchers, pork butchers, fishmongers, and, apart from provision stores, drapery and shoemakers’ establishments. It would be advisable, therefore, to stimulate the convenient grouping of such shops to facilitate shopping in centres possessing adequate transport facilities.

Finally, there should be mentioned amongst social efforts calculated to contribute to the well-being of the workers the example of certain employers who have organised industrial orphanages or funds for providing sums of money in cases of marriage or for providing family allowances. These latter constitute a very effective means of combating depopulation. In this connection may be cited the procedure followed in a large French factory. Considering that the daily wage of a good worker should suffice to feed his family, however numerous it be, this factory has decided to grant large allowances to its workers. In 1926 these allowances amounted to 75 francs per month for a child under sixteen, 150 francs for two children, 300 for three children, and so on, with a monthly increase of 100 francs per child above that number. The same establishment grants birth premiums to its workers, 400 francs for the first child and 250 for the following children. The system is completed by allocation of benefits in the case of absence from work on account of pregnancy, premiums for nursing mothers, and reductions in the rent of workers’ dwellings.

RELATION BETWEEN THE WELFARE DEPARTMENT AND THE MEDICAL SERVICE IN THE FACTORY

The field of action of a welfare department in industry such as has just been described is very much more extensive than that pertaining to the medical service. Nevertheless, their common aim is the maintenance of the workers’ health. It is therefore highly important that the relation between these two departments should be clearly defined. Generally speaking, where

---

**Fig. 148.** — Bedroom in the Swiss welfare building shown in figs. 136 and 137.
there is a permanent medical service, final decisions should admittedly be left to it. A few examples may serve to illustrate in what manner these two departments may collaborate where the medical service is only intermittent. The doctor is called upon for his advice, for instance: before the engagement of a candidate for work, who has to be medically examined; in regard to measures to be taken to prevent propagation of infectious diseases; in regard to measures of cleanliness and prevention of occupational diseases, more especially where workers, by reason of the nature of their work, are brought into contact with harmful or irritant products; in regard also to improvements to be effected in apparatus and devices for eliminating dust, smoke, etc.; in regard to the necessity for leave or for rest in a convalescent home; in regard to the length of the working day to be fixed subsequent to an accident or illness; and in regard to reasons in favour of a change of occupation on health grounds, etc.

In each case it is the task of the welfare department to ensure that medical advice is faithfully followed, and in a certain measure to render assistance to the doctor in his work. It possesses further a large sphere of activity which is quite outside the sphere of the medical service. Nevertheless, those directing these two services must never lose sight of the fact that they have been created with a view to maintaining and improving economic health in industry and safeguarding the physical and moral health of the worker.

SOCIAL WELFARE IN VARIOUS COUNTRIES

Social welfare has, at a more or less rapid pace, made great progress in the majority of industrial countries, in which it naturally has assumed varying characteristics peculiar to the country concerned. Thus, for example, in the United States, it demonstrates a tendency towards assuring better adaptation of the worker to his job. In Great Britain, its aim has rather been to establish more satisfactory relations between the management and the workers. In France, Belgium and Italy it is characterised by special interest devoted to health conditions and social surroundings (dwellings, family life) of the wage earners.

The importance of social welfare in industrial or commercial establishments varies accordingly from one country to another.

In Belgium a recent enquiry (1930) undertaken by Langelez, comprising 2,555 factories and 494,412 workers belonging to the most varied industrial groups, has furnished the following data: in 480 factories (31 per cent.) aptitude for work is made the subject of examination on engagement; medical examination takes place in 497 (22 per cent.) on admissions.

Fig. 149 — Workers' dwellings in Switzerland.
of apprentices, and in 472 (21 per cent.) on engagement of adults.

Medical examinations are periodically effected in a number of establishments liable to special risk. One hundred and twenty-four establishments, 10 of which are coal mines, engage visiting nurses, and 43 welfare supervisors, entrusted with the physical and moral welfare of the workers and with visiting the workers' homes, etc.; 174 factories provide first-aid in case of accident or sickness, entrusted to certifying surgeons; in 16 establishments, 14 of which are coal mines, there is a permanent medical service, and 269 dispensaries or sick rooms, and in 30 cases radiograph departments have been instituted. In 22 cases there is an electromecano-therapeutical service, and in 19 cases a room for treatment by ultra-violet rays; 37 factories make provision for hospital accommodation for victims of accidents, despite the absence of a fully equipped hospital; 219 have their workers cared for at a factory dispensary, and 35 establishments have organised surgical treatment for troubles unconnected with occupational accidents. In 15 factories the members of the worker's family enjoy similar advantages. The latter services are in 30 instances free of charge, and in 10 instances subject to financial participation on the part of the workers.

In connection with treatment of disease, the Belgian worker has recourse to medical and pharmaceutical treatment by belonging, together with his family, to mutual insurance schemes. Services for treatment of sickness, which still exist, represent merely a survival of older conditions. There still exist 128 such services for treating sickness, amongst workers only, and 98 for workers together with their families. In 18 cases free service is provided, and in 62 cases on payment of fees; 250 factories grant financial help to sick workers, and 76 coal mines, by means of a convention, assure their workers 20 to 35 per cent. of their wages in case of illness. In 275 factories special grants are made to women workers or wives of workers during pregnancy; 454 factories possess canteens for the workers; 533, cloak rooms; 1,057, wash basins; 111, douche baths, quite apart from establishments where installations of this kind are imposed by law. Efforts in welfare are further manifested by creation of the following institutions: 5 maternity centres, 7 crèches, 4 centres for nursing mothers, 23 centres for infant care, 58 parks for sport, 54 savings banks, 44 open-air colonies, and 374 schemes for paid leave. Finally, 149 factories have instituted schemes such as pensions schemes, lending schemes, schemes for construction of workers' dwellings, facilities for gymnasiums and entertainment, musical and dramatic organisations, etc.

In France an enquiry undertaken in 1927 by R. Würtz into hygiene and welfare in the workroom, and covering 32 large establishments, has revealed the fact that the majority of industries have bestowed their attention on hygiene in regard to workshops (construction, equipment, cleanliness), on workers' diet (canteens, restaurants), on sport, the prevention of accidents, and on the establishment of medical services and crèches. In a great number of cases the chief of the staff fulfils the functions of welfare superintendent. In certain factories a special manager, designated as "welfare manager", is entrusted with the creation and control of such institutions, and is responsible for their working. His task is that of constantly ascertaining the necessity for and, where possible, carrying into effect of anything which may contribute to improving working conditions. In other establishments a welfare super-
intendent is entrusted with the supervision of social schemes in the factory and their good management. She is likewise responsible for maintaining contact with other municipal schemes of a private or public nature, for looking after the workers' families, pregnant women and infants, and for distributing birth and nursing premiums accorded by industrial societies. Her role is that of serving as an intermediary between the factory management and the employees.

In certain factories—such as, for instance, those of the General Company for Locomotive Construction at Nantes—a special welfare superintendent is appointed to look after the working class suburbs belonging to the Company. Würtz expresses the desire that in all industrial enterprises of a certain size a welfare superintendent should be appointed, enjoying the rank and remuneration of a department manager, directly responsible to the employer and entrusted with the study and practical application in the factory of all questions relating to hygiene, safety, welfare and training of the staff. On the other hand, he suggests the creation of training centres or courses of instruction intended to provide training for welfare supervisors, and more generally for stimulating development of the welfare spirit amongst factory managers.

In Great Britain the welfare movement arose during the war, at a time when the large munition factories were very restricted for man-power. The Health of Munition Workers' Committee having drawn attention to the importance of the well-being of the workers, a service was created within the Ministry of Munitions and entrusted with the study and realisation of certain measures proposed. The work was mainly concerned with women and young persons, and much less with men. It dealt with needs both inside and outside the factory.

Welfare within the factory comprised supervision of general working conditions, engagement and selection of workers, their transfer from one department to another, progress of apprentices, questions of dismissal, and, in general, all questions relating to the human factor. The official in charge of the welfare department was likewise called upon to devote his attention to hygiene in the workrooms (cleanliness, ventilation, heating, seating accommodation, etc.), canteens and first-aid posts. He had to keep a record of cases of sickness and of accidents, and he was responsible for distribution of working clothes and for supervising cloakroom accommodation, lavatories, and sanitary conveniences.

Outside the factory, the activity of the welfare department was directed to the housing problem, to the provision of facilities for transport for going to and coming from the factory, to visiting the sick, to the creation of scout organisations and the institution of recreation of all kinds, to education and instruction of the workers, and to the employment of means tending to improve their economic conditions.

Commencing with the pre-war period, conditions relating to the allocation of creches for breast-fed infants in factories were studied. Committees including workers' representatives were constituted in order to assure from the outset the support of the workers. In this manner the welfare project was facilitated and many real or imaginary obstacles were overcome.

Efforts made during the war have left an indelible mark on the outlook of the employers, and even to-day, despite the industrial depression, there exist at least a thousand large enterprises possessing welfare departments.

In the coal mines the movement in favour of workers' welfare is based on a law passed in 1930 which created a fund drawn from rents paid to the mines and proportional to their output. This fund was intended for social welfare, schemes of recreation and improvement of workers' conditions, both inside and outside the mines.

The sum devoted to this purpose, amounting to £1,000,000 per annum, is controlled by a central committee composed of representatives of miners and of employers. In principle four-fifths of the sum collected must be spent in the district from which it has been drawn, the remaining fifth being contributed to objects of general utility to the industry.

In practice the central committee is advised by a local committee of workers and employers as to the manner in which the sums collected should be spent in each district.

Up to the end of 1925 money was expended in acquiring sports grounds and creating various institutions (£2,000,000), in providing sanitary installations, convalescent homes, ambulances, sick rooms and douche baths (£1,000,000).

A fifth of the sum, which for the first five years amounted to £1,000,000 was spent as follows: 50 per cent. on research relative to hygiene and safety, and 50 per cent. on instruction for the mining population.

In Italy, an enquiry made in 1923 by the General Department of Labour provides an account of the state of development of institutions for workers' welfare. In 872 establishments giving employment to 333,410 workers, about 120,000 of whom were women, the following manifestations of the welfare movement were noted: medical treatment (723 establishments); paid holidays (523); organisation of special hygiene measures (759); canteens and soup kitchens (427); mutual benefit funds (321); libraries (32); rest periods within the factory (133); special installation of washing accommodation (523); installation of douches and baths (163, with 265 baths and 314 douches); cloakrooms for coming and going to and from the factory reducing the working hours prior to leaving the factory in order to permit of the workers attending to the needs of personal hygiene were accorded in 341 factories. Out of
427 establishments which had instituted canteens, 137 possessed soup kitchens, under the direction of the factory management in 37 cases, and run by the workers in 39 cases, etc. According to a report published by Mr. Olivetti (1928), the institutions provided by employers in activity between 1923 and 1927 were as follows:

In the Netherlands welfare methods were introduced fifty years ago in the factories of I. C. Van Marken, Delft, and in the factories of Storck and Company at Hengelo. These measures included improved working conditions from the health aspect; treatment for sick, incapacitated and aged workers; construction of workers’ dwellings; provision of reading rooms, and organisation of evening entertainments; the institution of committees representing the interests of the worker within the management; and, finally, the creation of a printing works which has since become the property of the workers.

In Sweden the metallurgical trades have for the past fifty years possessed typical welfare institutions run by the employers on paternal lines. At the present moment welfare supervisors are appointed to run institutions of this kind. There is at present a marked tendency for the municipal authorities to take over this work originally instituted by the employers.

In Switzerland very remarkable work has been effected by the Volksdienst, the object of which is to improve the moral and material conditions of workers.

On the other hand, almost all large industrial establishments possess welfare funds (Wohlfahrtsfonds), intended for the creation of social schemes run by the factory or as a subsidy for existing schemes (crèches, holiday colonies, etc.).

In India social welfare has largely developed since the end of the war, and its object at the present moment is that of obtaining improved material conditions for the workers. This task is generally in the hands of organisations which are independent of the factories, such as the Y.M.C.A.

In Japan the Government enquiry effected by the Prefect of Osaka, covering 281 industrial establishments employing each upwards of 100 workers, showed that already in 1919 certain measures were taken for promoting workers' welfare. These measures concerned distribution of the most necessary foodstuffs (popular restaurants, provision shops, etc.), housing of workers, medical treatment and sanitary installations, encouragement of thrift and insurance, financial assistance and mutual insurance schemes, instruction, organisation of workers' spare time (clubs, excursions, theatrical entertainments), crèches, provision of legal advice, etc. In 1927 the Government decided to allocate 100,000 yen per annum for the encouragement of sport in factories and mines.

In the United States an enquiry undertaken by the Labour Bureau and published in 1927 shows the development of measures adopted in various factories with a view to promoting the comfort and recreation of workers. Out of 430 establishments, giving employment to 1,977,000 workers, covered by the enquiry, 235 provide clubs, reading, recreation and billiard rooms and gymnasiums for their workers, 318 organise conferences, cinemas or concerts and furnish funds for creating orchestras.

In the course of the enquiry a certain number of industrial employers stated that they were averse to introducing any institutions of this kind in order to avoid the impression that they had any desire to interfere with the independence of their staff. Others, on the contrary, were of the opinion that all efforts with a view to promoting distraction of workers during their spare time are well received and succeed provided the workers themselves have a final say in their organisation. Finally, certain employers stated that they had been obliged to abandon entirely or partly such attempts because their workers did not take sufficient interest in them or because the expense involved was out of proportion to the results obtained.

In the majority of establishments the types of insitutions which render the greatest service are rest rooms and recreation rooms.

The following figures give an idea of the importance which a large American undertaking, the Steel Corporation, accords to workers' welfare. Sums destined for the organisation of these schemes appearing in the budget from 1 January 1912 to 31 December 1925 are as follows:

<table>

Total 155,988,048

There should be added to this, over and above the total, pensions paid to employees amounting to $13,014,843 and other funds for indemnities and administrative expenses giving a total of $509,338.
In the Ford establishments the Social Welfare Department gives employment to 400 persons and is organised in seven sections: employment bureau, welfare superintendence, a school for the English language, medical service, sociological service, safety service and legal service. The first three sections come under the general management, whilst the last four are under the direction of a single manager, though they remain quite independent as regards their action.

Finally, to quote another example, may be mentioned that of the National Cash Register Company, which possesses a welfare department comprising various sections: health and safety, education, instruction, etc.

LEGISLATION

In numerous countries social legislation in force comprises the majority of measures above referred to with a view to the protection of health and provision of hygienic surroundings for work (see articles "Personal Hygiene" and "Industrial Hygiene (Workshops)"). Special Orders ("Welfare Orders") have been issued in Great Britain, acquainting employers with their responsibilities in regard to the creation of installations for the welfare of their workers (canteens, provision of drinking water, working clothes, washhouses, cloak rooms, first-aid posts). Legislation in several countries provides for the creation of crèches: Argentina (1924) (industry and commerce, where over 50 women are employed); Brazil (1924) (industry and commerce); Colombia (1924) (establishments giving employment to upwards of 50 women); Denmark (1913) (establishments employing upwards of 25 women); France (1928) (industry and commerce, upwards of 100 women); Italy (1927) (industries employing at least 50 women); Peru (1925) (establishments employing upwards of 25 women); Poland (1927) (industry and commerce, where upwards of 100 women are employed); Portugal (1927) industries giving employment to upwards of 50 women); Rumania (1928) (industry and commerce, employing upwards of 50 women); Yugoslavia (1922) (industries in which upwards of 100 women are employed). Finally, special Acts are devoted to the protection of women (see article "Women's Work") or the organisation of workers' spare time (the Dopolavoro organisation in Italy, etc.).

In the field of international industrial legislation the majority of Conventions and Recommendations adopted by the International Labour Conference may be considered as measures calculated to promote workers' welfare. Special mention should further be made of the Recommendation adopted in 1924 dealing with workers' spare time, which recommends that: * having due regard to the requirements of different industries, local customs, and the varying capacities and habits of the different kinds of workers, consideration should be given to the means of so arranging the working day as to make the periods of spare time as continuous as possible; that by means of a well-conceived transport system and affording special facilities in regard to fares and time-tables workers should be enabled to reduce to the minimum the time spent in travelling between their homes and their work; as well as the encouragement of individual hygiene by provision of public baths, swimming pools, etc.; the encouragement of legislative or private action against the abuse of alcohol, against tuberculosis, venereal disease and gambling; the increase in number, if necessary in co-operation with the national or local authorities concerned, of healthy dwellings at low rents. *

The Recommendation further provides for *improvement of the workers' domestic and family life (gardens, allotments, poultry keeping, etc.); the development of the physical health and strength of the workers by means of games and sport, and the extension of technical, domestic and general instruction, etc.; the encouragement of legislative or private action against the abuse of alcohol, against tuberculosis, venereal disease and gambling; the increase in number, if necessary in co-operation with the national or local authorities concerned, of healthy dwellings at low rents. *

(Cardiff)
Sodium

French: Sodium. — German: Natrum. —
Italian and Spanish: Sodio.

Sodium, symbol Na, is very abundant in nature and is found in a state of combination in numerous ores (cryolite, glauberite, borax, etc.) and more abundant still in the form of chlorides (rock salt, sea-water, which contains up to 3 per cent.), sulphate, carbonate, double fluoride of sodium and aluminium, of nitrates (sodium nitrate or Chili saltpetre).

Sodium was prepared in a free state for the first time by Davy by electrolysis of the hydrate of molten sodium. Industrially, all sodium is now prepared by electrolysis of caustic soda or solutions of chloride of molten sodium. Molten lead is used as the cathode with which the sodium liberated passes into the alloy. The latter passes into another compartmert in which the molten caustic soda acts as an electrolyte. The alloy then acts as the anode and all the sodium is deposited at the cathode without any consumption of NaOH. Several methods of electrolysis of chlorides of molten sodium are known, but do not seem to have replaced the caustic soda method.

Metallic sodium has a silvery aspect and a density of 0.97. It melts at 97.6° C. and boils at 742°. Sodium is used in the preparation of silicon, magnesium, peroxide and cyanide of sodium, sodium amide and certain colouring matters. It is also used for freeing petrol from sulphur.

In the state of pure metal it may cause burns when it comes into contact with clothing or damp skin (chemists, students, laboratory attendants who have to manipulate sodium: Egli-Rust). From the point of view of industrial hygiene, it is the combinations of sodium which are of interest by reason of their caustic action (caustic soda) or irritant action (sodium chloride). (See also article “Alkali”.)

In connection with alkaline chlorides may be recalled necroses of the skin amongst workers occupied in the transport of sacks of kitchen salt, which have been described by Somogyi. As regards the hydrate of sodium (caustic soda) and carbonate of soda, mention will here be confined to a few instances. The former exercises violent caustic action, and there have been noted cases of injury to the eyes and visible mucous membrane as well as to the skin where these have been exposed during a certain time to the action of the hydroxide. In view of the widespread application of this substance in industry and chiefly in organic and non-organic chemical technique, it is of first-rate importance that the attention of those called to manipulate it should be drawn to the relative precautions which it is advisable to take. It should be stated that in daily practice a crude product is used which is a mixture of soda and caustic potassium, the latter possessing besides similar properties and involving the same risk and danger as caustic soda.

As regards the carbonate of soda there have been reported cases of caustic burns affecting workers in soda factories, caustic burns chiefly situated on the nasal mucous membrane, recalling thus the injuries caused by chromates (Müller and Fischer). Derangements of the digestive system have been met with amongst workers engaged in manipulating carbonate of sodium and sulphide of sodium as a result of swallowing of dust containing these substances (Roth).

In the soda factories of Beresnikow utilising the Solway and Loewy processes, Noworassow found in 1930 that the atmosphere close to the caustic soda boilers contained 0.0033 to 0.041 mg. per litre of this substance. The caustic action was however slight, and at a distance of 3 metres from the boilers transformation into carbonate of soda commenced to take place.

For further data see articles “Alkalis” and “Chemical Trades”. For injuries due to chloride, bi-chromate, sulphate, cyanide and sulphide of soda, etc., see articles “Chlorine”, “Chromium and Chromates”, “Sulphur Mines” and “Cyanogen and its Compounds”.

The irritant or caustic action of the compounds of sodium affects very often the visible mucous membranes and in particular the ocular conjunctivae (chloride of sodium noted amongst workers engaged in spinning and dipping flax: P. White and Müller), and naturally also on the skin: bi-carbonate of soda (papular eczema affecting chemists and druggists; sulphate of soda affecting persons engaged in cotton-dyeing establishments: P. White); phenolate of soda — at the moment of crystallisation of the naphthalene; cyanide of soda (dermatitis localised often on the genital organs), etc. There should in conclusion be recalled serious injuries, especially of the genital organs due to small fragments of caustic soda when it is used in a solid state.
For compensation for injuries due to caustic soda, see article "Alkalis". Those due to chlorides are accorded compensation under Russian legislation when it is a case of dermatitis. Those due to sodium sulphide receive compensation in Switzerland.

Soldering, Welding, Burning or Coating with Lead

"Lead soldering" is a term given to work involving the use of metallic lead, either in the construction of cisterns, containers and piping, which is carried out by uniting separate pieces of sheet lead, lengths of piping, etc., by means of a blowpipe, and is lead soldering in the strict sense of the word; or, in lining wrought-iron or cast-iron utensils with an adherent layer of lead by the aid of a blowpipe (Homogen-Verbleitung).

This article will not include soldering done on tinware with a blowpipe, where lead or alloys of tin with a more or less high percentage of lead are used as superficial solder for uniting various metallic parts.

From the sanitary and hygienic point of view, these operations are different from actual lining or coating with lead.

In a broader sense, may be included soldering work carried out with a blowpipe when fitting lead pipes or attaching to them tinware or "sheeting".

To the industrial hygienists, soldering carried out as a special trade for long periods of time, and, generally, in special factories, presents a certain interest.

It is therefore essential to take into consideration the lead-lining of articles for the chemical industry, particularly that which is carried out in large factories and chemical works (the aniline dye and synthetic ammonia industries), and in special soldering concerns working for the chemical industry, and, upon a less extensive scale, soldering and lead lining in other industries, such as the manufacture of electric batteries.

**TECHNICAL OPERATIONS**

In the chemical industry light lead-lining is employed as much as heavy lead-coating. In factories working for chemical industries it is particularly lead-coating which predominates. Superficial lining or lead-surfacing is employed for re-coating and re-surfacing cast-iron containers, reaction and distillation vessels and evaporating and crystallising dishes. The construction of large lead chambers, for the manufacture of sulphuric acid, obtained by soldering together lead sheets, also comes under the heading of lead-surfacing and lead-lining; lead-coating is utilised chiefly in the construction of apparatus designed to withstand high pressures and temperatures, such as autoclaves, apparatus for working under steam pressure and for use in the construction of armatures and agitators.

The material employed in these various processes is almost exclusively soft lead. For the construction of apparatus used in the food and the pharmaceutical industries, lead is replaced by pure tin.

The technique of the work in the two forms of lead covering is profoundly different. For lead-lining a lead sheet is moulded to the shape of the container by hammering and beating, and introduced into the container. It is fixed by folding over the overlapping edges and finished off by burning together the edges of the lead sheets. This work is carried out almost exclusively with a comparatively small oxyhydrogen flame; but more rarely a flame of hydrogen and compressed air or of coal gas and compressed air is employed; in this case, the temperature ought not to be above that which is just necessary for melting the additional metal and the edges of the lead sheet. Lead-coating consists in doubling an iron surface with a layer of solid lead by establishing an intimate fusion between the tin lead-coating applied to the iron and the lead. The thickness of the lead in this case may be as much as 10 mm. thick. For this purpose the surfaces of the iron object are prepared beforehand; that is to say, they are treated with dilute hydrochloric acid or "pickled". In the case of small objects, such as piping, after the acid bath, the surfaces are tinned by immersion in an alloy of molten lead and tin (80 per cent.), in order to facilitate the adhesion of the lead layer. This is done in two ways, one of which is only used for external coating, whilst both methods are applicable for internal coating.

In the method used for both categories of lead covering, the molten lead is poured in sufficient quantity in a thick layer upon the surface, which has been prepared and treated with sal ammoniac or other flux. The layer is then intensely heated with the blowpipe, which is moved about over the surface to smooth it and to form cohesion with the underlying tin or tin lead-coating.
By using powerful flames and sometimes lightly stirring about with an iron wire, the required rise of temperature may be expedited in the underlying layers.

When it is a matter of lead-coating of cylindrical interiors, those parts of the interior surface which are to be submitted to the operation is brought into position by rotation and outlined by wires; this permits of successive coating of the whole interior surface. After these operations, the layer of lead often appears in sections of polygonal form, which, after cooling, necessitates a further operation to restore the interior of the pipe to cylindrical form. When it is a question of covering a concave cavity, an arrangement is used which allows for tilting the cavity in such a way as to bring successively all the parts of the surface into a horizontal position.

In the method which can only be used for external applications, lead, in the form of little strips, is melted by the blowpipe as required and dropped in small quantities upon the tinned iron surface, where it is melted together. Treatment of the leaded surface with the blowpipe flame then ensures that all irregularities are obliterated. This method can only be employed for the external soldering of pipes and agitators or for uniting parts of apparatus which have previously been submitted to the process of lead-coating.

A secondary operation, but an important one from the hygienic point of view, is the removal of old layers of lead prior to renewal. This work is done by “burning off” i.e. by melting the surface by means of a powerful blast on the leaded surface.

The flames generally employed in the various operations described above are preferably the oxyhydrogen or the hydrogen-compressed air flame; this latter is particularly used for burning off; more rarely the oxy-acetylene flame is used, or that of coal gas and oxygen or coal gas-compressed air.

In these cases the jet employed for external plumbing is of small dimensions, but it is larger for internal plumbing and burning off. The use of electric arc “jets”, or of electric soldering apparatus is still in the laboratory test stage at present. Nor has the replacement of lead-coating by metallisation (see that article), which would present hygienic advantages, for the stream of lead cools down immediately, yet been used for plumbing in thick layers.

Mechanical processes are only used for lead-covering of the inside of pipes; in this case the molten lead is poured between the interior tinned surface and a mandrel inserted into the bore of the pipe.

In the manufacture of electric batteries, lead soldering is in the first place employed at the junction between positive and negative plates, and for soldering the lead rod which serves as an electrode. The soldering is effected with the assistance of a small flame which melts a little strip of soft lead placed between the joints of the prepared and formed plates.

In the second place it is quite usual for lead soldering to be applied to the interior of battery cells, made either of wood or some other material. In this case the work corresponds in principle to that of lead lining. The lead sheets, having been fitted to the interior surface of the cell, are soldered along their interior joints with a small blowpipe, or else the forms destined for lining the cells may be moulded beforehand, and the sheets, which compose them, soldered along their joints prior to being inserted in the case.

In certain American factories, a mechanical method is used whereby the edges to be soldered are fused together with a pointed flame (A. Hamilton). The hydrogen-compressed air or the oxyhydrogen flames are chiefly used; less often the coal-gas-oxygen or the acetylene-oxygen flame.

Sources of Danger

Soldiers come into direct contact with cold sheets of lead; but lead poisoning does not originate in this way, as is known from the immunity of men who handle sheet lead in the manufacture of sheet lead and lead piping. Exposure to lead dust is a different matter, and a serious hazard which plays a part when adjusting sheet lead covered with carbonate of lead, and, in particular, during the operation of removing the parts affected by corrosion and formation of sulphates, or during repair work. But it must be added that even in these cases the risk of lead poisoning is relatively reduced. This risk is greater during the operations of lead-coating when, because of the raised temperature, there is volatilisation of the lead and danger of inhaling “lead fumes”. The importance of this risk is clearly revealed by comparing the large number of cases of lead poisoning among men who work at lead-coating, with the number among workers who carry out lead-lining or merely the operations which precede the latter, such as transport, cutting up, and shaping of lead sheets. The greatest part of the lead-lining process is represented by mani-
pululating cold lead, while the soldering proper and the rapid and superficial blowpipe work, with comparatively small flames constitutes an operation of minor importance. On the other hand, those who do lead-coating only use the lead en masse in the molten state for internal coating, or in small drops obtained from the melting of lead strips for external coating. But the blowpipe work is of long and continuous duration and the strong flame employed, particularly for internal coating, entails a considerable rise in the temperature of the lead surface. The greater danger that lead-coating involves must, in consequence, be accounted for by the volatilisation of the lead.

In lead-coating work the conditions for the volatilisation of lead differ from those which exist in lead foundries. In this connection the burning of tinned lead with a blowpipe produces in the neighbourhood of the flame, on the surface, and down to a certain depth in the lead layer, temperatures which come near to the temperatures of the hot oxyhydrogen or oxy-acetylene flame (2,400° or 3,000° C.); or at least equal to the melting point of lead (1,600° C.), at normal atmospheric pressure. The volatilisation of the lead is probably assisted by the draught caused by the flame which carries off the fumes as quickly as they are formed. In passing through the flame, or, at latest, at the moment of passing out of it, the lead fumes are changed, on making contact with the oxygen of the air, into lead oxide. This constitutes dust in a state of molecular dispersion in colloidal suspension in the air, e.g. lead fumes, and forms a very stable layer floating in the surrounding atmosphere. The volatilisation of the lead depends on the extent and the intensity of the flame which is used; nevertheless, temperature plays the chief role, so that one may say that different flames of varying temperatures under similar conditions determine volatilisation to a greater or less extent in proportion to the degree to which the temperature of the flame is raised. The least volatilisation is produced by the coal gas-compressed air flame; its extent progresses successively with the use of hydrogen-compressed air oxyhydrogen and oxy-acetylene flames.

According to the researches of Engel and Froboese, volatilisation is influenced by the chemical conditions of the flame; a reducing action, due to lack of oxygen and the presence of hydrocarbides, as in the lighting gas or acetylene flame which tends to less-
of the quantities of lead fumes given off during soldering, and, on the other hand, the medical examination of workers justifies the statement that danger from inhaling lead is considerable only in the immediate vicinity of the blowpipe flame, that is to say, at the working posts. The possibility of the accumulation in the air of workshops of lead fumes in a quantity sufficient to be dangerous to health need not be feared if the ventilation conditions are even approaching normal, since the quantity of lead that is volatilised as a rule is quite small.

The maximum danger exists during lead-coating operations, and particularly in internal coating. In this case, the danger is greater the larger the object to be lined, as oxyhydrogen and oxy-acetylene flames are used, and as the workers bend over or enter the interior of the casing or container which, in the case of repair work, may only possess a small outlet to the outer air. Under these conditions, accumulation of lead fumes is inevitable. This danger ceases to exist in cases of external lead-coating; besides, weaker flames are generally employed, particularly the hydrogen-compressed air or coal-gas-oxygen flames, and the heating of the lead does not reach such a high degree of intensity as that used for internal lead-coating. The danger is still less during lead soldering, which often involves the use of small pointed flames and requires accessory and preparatory work during which the blowpipe is not used.

Among accessory operations in lead-coating “burning off” causes important volatilisation of lead; this is due to the comparatively generally hydrogen-compressed air — for removing old lead coats; and to the high temperature, which may reach a considerable degree, especially when it is a question of melting a lead-coating covering two sides of an object or a piece of apparatus. The danger of the formation of lead fumes is, in this case, scarcely inferior to the danger in lead-coating, and it is only mitigated by the duration of the process, which is always short. The volatilisation of metallic lead during tinning, with an alloy containing 80 per cent lead, need scarcely be considered, as the danger is much less than with burning with pure lead.

Solder may contain as impurities, antimony, iron, copper, zinc, phosphorus or arsenic. This explains why solderers may be exposed to harmful effects brought by fumes from the metals in question or their compounds. In one large soldering factory, workers suffered from zinc fumes, with founder's ague.

Formerly, more frequently than at the present time, lead workers were threatened by the presence of arseniuretted hydrogen in the hydrogen used for the blowpipe and prepared in the factory itself from impure zinc and sulphuric acid. The use of hydrogen prepared by electrolytic means does away with this danger. Cases of poisoning from phosphuretted hydrogen were reported in Austria in 1920. During the war, the use of a “lead mercury” solder for the manufacture of batteries caused mercurial poisoning, which at times was quite serious.

The use of coal gas, of residual hydrogen containing carbon monoxide, or impure acetylene constitutes a danger of poisoning, if the piping is badly maintained. In fact, cases of carbon monoxide poisoning have been observed.

A fairly important source of danger is the work of repairing and fitting up apparatus employed in chemical industries, in which there are residues of toxic products. Poisoning has been observed among lead workers due to nitro- and amido-aromatic derivatives, and particularly to dinitrobenzines and dinitrochlorobenzines. It is especially workers employed at chemical works who are exposed to this type of poisoning.

The risk of lead poisoning among men employed in lead-accumulator factories corresponds pretty nearly to that of men who work at lead lining in the chemical industries. This danger appears to be more serious in British and German factories than in the United States, where the work is carried out on a belt conveyor, and by operations to a large extent automatic (A. Hamilton). The risk from lead fumes is, in this industry, greater in the work of lead-burning of cells than in the work of soldering battery plates, especially when the leading takes place after the lead-lining has been introduced into the battery case. In this instance the lead fumes which are given off are concentrated in the confined atmosphere which the worker must breathe when he puts his head into large cases or tanks (A. Hamilton and Wützdorff).

Lastly, a further danger is present in the dust caused by handling lead sheets coated with oxide.

Koelsch has observed corrosions of the buccal cavity and upper respiratory passages by fumes from the acid used for soldering.

See also article "Autogenous Welding".
At the time of the enquiry there were 5 workmen on the sick list, or 0.9 per cent, and the sickness statistics for 510 solderers showed, for a period covering two years, the following figures (in percentage): anaemia, 0.9; slight lead poisoning, 0.6; lead colic, 0.9; constipation and abdominal pains, 1.5.

Of the total, there were 2.9 per cent, of lead poisoning cases causing incapacity for work. The number of treated cases fit for work was far lower than this percentage.

At the time of the examination, 68, or 17.5 per cent., of the 388 skilled solderers, and 5, or 3.1 per cent., of the 161 assistants showed marked symptoms of lead poisoning, with positive results on blood tests, showing basophilic red corpuscles, and on urine tests, showing porphyrin. Of the trained solderers, 174, or 44.8 per cent., and 109, or 67.7 per cent., of the assistants were free from any objective symptoms, including the lead line.

Thus, there were 37.7 per cent, of doubtful cases among the skilled solderers, and 39.3 per cent, among the assistants.

The results found among the skilled solderers could be apportioned, according to the various types of work, as follows: lead-coating, positive 44 per cent., negative 17 per cent; lead-lining, positive 3, negative 94; tinning, positive 53, negative 13; manipulating lead in a cold state and transporting it, positive 0, negative 88.

The lead line existed among 30 per cent, of the skilled solderers, 64 per cent, among those employed on lead-coating; and 21 per cent., among those on lead-lining; with the lead soldering facies in 61 per cent, (lead-coating, 24; lead-lining, 0).

The blood pressure was very high, especially among the older men. The following are the figures (given as percentages):

<table>
<thead>
<tr>
<th>Age-groups</th>
<th>Years</th>
</tr>
</thead>
<tbody>
<tr>
<td>Above 154 mm.</td>
<td></td>

<tr>
<td>54.0</td>
<td>30.0</td>
</tr>
</tbody>
</table>

Thus the risk of lead-poisoning among lead solderers is relatively high, compared with this risk among other lead workers (Engel), although serious cases, either chronic or acute, and in particular paralysis, or lead colic, are not very frequent.

On the other hand, there are mild forms of poisoning which are characteristic of this category of workmen: anaemia, digestive troubles, and spastic constipation, which only occasionally leads on to colic. Circulatory disorders, and particularly hyper-tenions, are frequent, especially among the older men, among whom it is complicated with renal changes (saturine nephritis) and with arterio-sclerosis, localized especially in the cerebral blood vessels. The lead-lining extended, among the older men, the cerebral symptoms with lead amilobip, psychic troubles, and the symptoms of pseudo-uraemia which manifest themselves under the form...
of chronic saturnine encephalopathy with acute exacerbations. Hergt has described a case of chronic saturnine encephalopathy — a mental condition with initial visual troubles and a fatal termination through suicide — in which examination had failed to reveal arteriosclerotic changes. On the other hand, acute encephalopathy has not been found among lead solderers. The frequent occurrence of chronic saturnine encephalopathy, where the flame of the blowpipe is moved about rapidly with a back and forth motion over a fairly considerable surface. Even for work carried out at a work bench, as for lead-coating of piping, and for soldering lead in accumulator factories, the points which have to be soldered vary in position. On the other hand, a powerful exhaust with a large radius presents technical difficulties and causes inconvenience to the workers owing to draughts, so that for work of this kind it is only possible to employ movable exhaust hoods or cowls fixed at the end of elastic and flexible metal piping. In American accumulator factories, where the work is partly mechanical, the exhaust is carried down through a perforated plate which covers the benches of the men who lead the cells (A. Hamilton).

According to British medical inspectors, lead-poisoning among workmen engaged on leading sheet-iron by a process analogous to that of "tinning" in lead-covering, does not exist; but, on the contrary, it is particularly frequent among persons engaged in tinning hollow ware, where a special circumstances favour abundant volatilisation of lead chloride and the release of lead dust (Duckering). McBurney, of New York, in 1927 studied the health of 202 workers, 21 of whom were women, occupied on soldering work. Out of this total he found 30 cases of lung diseases, 18 of rheumatism, 1 of malaria, and 3 of various diseases. Examination of the blood disclosed the presence of basophilic granulations in 61 cases, anaemia in 57, and polychromatophilia in 47.

**HYGIENE**

In order to prevent lead poisoning, the requisite measures must be taken for suppressing the lead fumes which are given off during soldering, and so for avoiding their inhalation as far as possible. This is particularly important in lead-coating. The surrounding atmosphere cannot be kept satisfactorily pure, either by natural or artificial ventilation. Moreover, a dangerous concentration of lead fumes is only encountered, even in very crowded factories, at the work benches, and in the immediate vicinity of the blowpipes. In consequence, exhaust ventilation ought to be carried out locally wherever possible. However, effective working of such exhaust draughts is somewhat difficult of attainment, notably in the case of interior lead-coating, where the flame of the blowpipe is moved about rapidly with a back and forth motion over a fairly considerable surface. Even for work carried out at a work bench, as for lead-coating of piping, and for soldering lead in accumulator factories, the points which have to be soldered vary in position. On the other hand, a powerful exhaust with a large radius presents technical difficulties and causes inconvenience to the workers owing to draughts, so that for work of this kind it is only possible to employ movable exhaust hoods or cowls fixed at the end of elastic and flexible metal piping. In American accumulator factories, where the work is partly mechanical, the exhaust is carried down through a perforated plate which covers the benches of the men who lead the cells (A. Hamilton). When it is a question of interior lead-coating and of lead-lining cells of a definite size, effective movable exhaust is very seldom realisable. In these cases, and especially for the execution of repair work of short duration, such as the lead-covering of enclosed gear, the use of respirators is recommended. The most practical model is a mask supplied with fresh air through a tube.

It is a simple matter to organise a system of individual protection such as this, especially where compressed air is in use. In spite of their relative efficacy, respirators which have pads for absorbing colloidal lead fumes are less practical, on account of their prolonged use and the difficulty in maintaining them. In lead-lining, exhaust apparatus or masks may be dispensed with, especially when it is not a matter of interior working on tanks, or repair work performed at a work bench. Danger of lead poisoning during the removal of old lead from gear undergoing repair, or during the fitting of lead sheets may be avoided by the temporary use of filter masks.

In order to lessen the volatilisation of lead and the formation of lead fumes, the blowpipe flames should not be any larger, or their temperature any higher, than the technical process requires; moreover, the use of compressed air instead of oxygen or acetylene and gases containing hydrocarbons (Engel and Froboese) should assist in lessening the formation of fumes. But all these possibilities are rather narrowly limited from the technical point of view.

Generally speaking, lead-soldering shops ought to comply with all the hygienic requirements in force throughout every department where lead is worked; premises should be spacious and well ventilated and provided with
The lead risk, particularly in lead-lining work, from direct contact with the metal, or lead dust, which is quite a secondary danger as compared with inhalation, can easily be dealt with by installing lavatories where the workers can wash and have baths, rest-rooms and canteens. Special attention must also be paid to working clothes and to adequate cleaning of the shops, which should be undertaken with the object of preventing any accumulation and development of dust. These measures of cleanliness are particularly important, especially for solderers who come into contact with chemical products.

Medical examination on engagement, and periodical medical examination thereafter should be arranged at any rate for lead-coating factories, in order to detect in good time any slight symptoms of lead poisoning among the solderers. The possibility of transferring solderers who have been working at lead-coating to comparatively light work, such as lead-lining, tinning, transport and handling of cold lead should be considered, whenever they show any symptoms of lead poisoning.

Adequate instruction must be given to workers on the early symptoms of lead poisoning, as well as on the sources of danger and the means for avoiding them. Young men should only be employed as apprentices or assistants under medical guidance. Women should be excluded.

**LEGISLATION**

Measures for the protection of the health of solderers are in general to be found in regulations concerned with the prevention of lead poisoning, and, especially, in those relating to the equipment and working of electric accumulator factories. Thus, for instance, the German Regulations of 1888 lay down that soldering with a hydrogen or coal-gas blowpipe should, when the nature of the work permits it, only be carried out at fixed working places provided with effective exhaust. The elements used for the preparation of hydrogen, both the zinc and the sulphuric acid, must be technically pure, in order to prevent poisoning from arseniuretted hydrogen.

The instructions lay down adequate rules concerning the hygiene of the workplaces, their maintenance in a state of cleanliness, the installation of wash-basins and baths, and of canteens, the provision of working clothes, the organisation of periodical medical examination, and the prohibition of employment of women and children.

Compensation for lead poisoning among solderers who use lead solder or solder containing lead is granted in countries possessing a schedule according compensation for lead poisoning in accordance with the Anglo-Saxon formula (see article "Occupational Diseases: Definition and Compensation"), by France, Sweden, and the U.S.S.R. Sweden also grants compensation to solderers for injuries due to radiant heat and light.

### Solvents

**French:** Dissolvants (Solvents). — **German:** Lösungsmittel. — **Italian:** Solventi. — **Spanish:** Disolventes.

Under the names of solvents or dis-solvents are included liquids used to suspend or dissolve different materials used in numerous operations of painting, lacquering, pasting, cleaning or in the extraction of fats and oils. Speaking generally, mixtures of different solvents are used in industry, mixtures which vary according to the technique of the process pursued.

The solvents most commonly used are: solvents with an alcohol base — amyl alcohol; butyl, whether synthetic or obtained during the making of acetone; ethyl, in the form of denatured alcohol; allyl, which is rarely used; and synthetic methyl alcohol. All these alcohols are generally used in the form of ethers.

It is interesting to note that to-day American industry prepares alcohols, superior to those usually found in laboratories, for volatile solvent purposes, especially in the varnish trade, to act as volatile solvents of acetate and nitrate of cellulose. As raw materials olefines are used or hydrocarbons not saturated with
gases and vapours, arising from "cracking" heavy petroleums, which are treated with sulphuric acid. Thus are obtained additional products whilst condensable saturated carbons remain unattacked. Hydrolysis of additional products, such as ethers and acids, ultimately enables alcohol and sulphuric acid to be obtained. When treatment is carried out at a sufficiently high temperature, ethylene also enters into the reaction, which makes it possible to obtain ethyl alcohol. The gases and fumes issuing from the "cracking" apparatus, are freed of their sulphurated compounds and then compressed. The greater part of the condensable products are thus liquefied. The secondary alcohols resulting from the hydrolysation are then separated by fractional distillation. The most abundant is isopropyl alcohol, which is colourless and has a pleasant smell; it is sold under the name of "petrolate".

In addition must be noted: 

Chlorethylalcohol beta (form.: C₂H₅ClO₂) (CH₂Cl₂H₂O₁), the importance of which from the industrial point of view has recently (1927) been shown. It is a clear colourless liquid analogous to glycerine, with an aromatic odour of alcohol, a density of 1.2 and a boiling point of 132° C. It splits up on boiling with water in any proportion; it splits up on boiling with water at 100° C. into glycol and acetaldehyde, and, when heated alone to 184° C., into crhoroethane and acetaldehyde. As an intermediary product in the manufacture of indigo, it has been made for twenty years in large quantities and sold commercially in the form of a solution of 40 or 100 per cent. of the pure product.

Acetone and its substitutes: the acetates of amyl, of ethyl, of butyl, adronal, acetal, ethylacetone, methylacetone, propylacetone, and cyclohexanol; and also formic acid and amyl formiate.

Benzene and its homologues; their nitro- and chloro-compounds; solvent naphtha; the phenols; sulphide of carbon; tetra-chloride of carbon, which enters into a product known under the name of "Dermatine" or "Dermantine".

Petrol benzine, either heavy or light, which is less used; the ethers of alcohols of the aliphatic series; acetic, ethyllic, and formic ethers, with, eventually, the addition of lactic ether.

The fatty series of the chloro-hydrocarbons. Dating from 1908, chloro compounds, colourless liquids, prepared by making chlorine act on acetylene, were put on the market as "uninflammable solvents"; they do not form explosive mixtures with air, and do not attack the metal parts of apparatus; further they only suffer a minimum loss in operation, from 0.14 per cent. They are: dichloroethylene or diene, a solvent of india-rubber; trichlorethylene or trine, a solvent of fats, paraffin and vaseline; tetra-chlorethylene or etilene, a good agent for degreasing materials; tetrachlorethane or tetrane; pentachlorethane or pentaline; and hexachlorethane; chloroform; sangujol, a mixture of limited hydrocarbons, naphthene and benzene; white spirit; pine oils and residues from manufacture; heavy and light oils of camphor; oil of turpentine.

As a substitute for this last, para-cymene (1 methyl-4 isopropylbenzene) may with advantage be used to replace toluene, especially in the preparation of varnishes with a basis of cellulose ethers; it is a by-product, up till now generally lost, in the manufacture of sulphite of wood pulp.

Uses

All these solvents, either alone, or more often mixed, are used in making volatile lacquers, generally with various resinous bases; or in making lacquers with an oil base, which formerly were prepared by means of such drying oils as linseed, white wood, hemp and turpentine; or colours and varnishes to be applied by brush or spray; or Zapon lacquers, which are solutions of nitro-cellulose, camphorated pyroxyline, celluloid, or cellon, in suitable solvents, used for coating metal articles, aeroplane wings, and balloons; or anti-rust products with a base of asphalt, or pitch, dissolved preferably in benzene or phenol; or impregnating and adhesive materials; or solutions of india-rubber, resins, or celluloid; or preparing various adhesives in certain solvents. They are often known under the name of "cements" in the manufacture of rubber, oil cloth, or such clothing as boots and hats; for material for balloons and aeroplanes; of brushes; of accumulators; and of celluloid articles.

The necessity for thoroughly removing all traces of tar which are found on fleeces, especially those coming from Australia, has led manufacturers to replace the mechanical method, of pulling out the stained fibres with pincers, by a chemical method. A considerable number of products known under fancy names and generally of secret composition, have of recent years been put on the market. The wool is steeped in a more or less concentrated bath of solvent, or the stained part is treated by allowing the solvent to flow from a burette, as in the case of a sewing machine is oiled. These products, which during the last two or three years have caused much damage, are known under such names as "Tetralin", "Perpentol S", "Lanadin Lap" and "Poko". These solvents of which usually have a basis of trichloroethylene, chloride of ethylene (see article "Ethylene"), or chloro-hydrocarbons.
Solvents are further used for the extraction of fats from bones, waste meat and fish, and of oils from oleaginous grain and from oil cake made from oleaginous grain; for chemical washing and for cleaning and degreasing such metal articles as printing type and ink rolls, for which purpose derivatives of benzene and its homologues are used by preference, and the chloro-hydrocarbons of the fatty series.

From a practical point of view it seems important to point out that these solvents are put on the market under fancy names, so that it is very often impossible to know what product has been used as the solvent.

**Sources of Dangers**

(a) During the manufacture of solvents or products which contain them, the risk is comparatively slight, as the technical processes are generally carried out in apparatus either closed or under reduced pressure.

(b) During use, the volatilisation of solvents constitutes, on the other hand, the principal source of risk. There may be mentioned in the painting industry, the preparation of baths, and the lacquering processes, varnishing by dipping, and the use of the spray which is coming to replace brush work more and more. Fumes are given off from the baths, often at the ordinary temperature, and of course more powerfully at the temperatures employed in technical processes or under special conditions in a confined space. In painting with a spray, danger is caused by the cloud from the vaporising jet, which projects small extremely fine liquid particles in suspension into the air (see article "Painting").

The use of glues, cements, and products used for cleaning and for the extraction of fats, also exposes workmen to the action of poisonous fumes from solvents. There may be mentioned the serious injuries caused by using cements made with benzol in the manufacture of waterproof goods (see article "Benzene"); by using tar solvents in making woollen hats; and in making straw hats (see article "Straw").

**Toxic Effect**

It is only during the last few years that precise facts relating to the toxic properties of solvents have been available. This lack of accurate knowledge is explained by the common use of fancy trade names; by keeping secret the composition of the products used; by variations in composition of the same commercial product, either through change of appearance or of smell, or sometimes by variations in the toxic effect; by the use of constituents which are not always pure; or by the addition of accessory products, such as nitro-benzene, for instance, to impart a scent.

Generally speaking the toxic effect of solvents may be outlined as follows:

(1) The solvent, on reaching the blood stream, acts on the fats and lipoids of the body for which it shows a great affinity; in this way it disturbs the chemistry of the cells, for it removes the integrating substances analogous to the lecithins. This fact explains why the resulting organic lesions are more serious in tissues and organs which are the richest in fats and lecithins, and why solvents particularly exert a selective influence upon the central nervous system.

The toxic effect of solvents depends on the "coefficient of separation" which controls their separation in a mixture of water and substances analogous to fats; that is to say their toxic action is greater as their power of solubility in fats is greater, and less as their solubility in water is greater.

There is generally a close connection between the gravity of the damage and the changes in the nerve cells. This connection, however, for certain poisons, such as ether, chloroform, and alcohol, is not so direct; for the lesions are not permanent and "restitutio in integrum" may take place. In the
case of such other poisons as anhydrides and halogen derivatives, on the other hand, damage only occurs after a certain period and is from the first incurable owing to the formation of stable intra-cellular combinations.

Judging from experiments on animals, from the point of view of industrial hygiene there may be considered as being under suspicion all those solvents of which the fumes, while not causing narcosis, in comparatively weak concentrations such as 1 to 10 mg. per litre of air inhaled for one to three hours, induce after a "latent period" of apparent health, a progressive morbid condition of a narcotic type, and cause, owing to the process of the intoxication being irreversible, serious or fatal cases of poisoning (Bruckner).

Between these two types of solvents, one of which causes reversible and the other irreversible reactions, there exist whole series of intermediary solvents, concerning which toxicity can only be estimated by physiological tests permitting of the elimination of the most dangerous of them.

(2) Some solvents have a specific action on particular organs; thus the chloro-hydrocarbons of the fatty series act on the liver; carbon bisulphide acts on the central and peripheral nervous system; and methyl alcohol on the optic nerve.

The toxic action of tetracaine has been carefully studied in Germany by experts. They have found that it is scarcely toxic at all and that in animals it only causes nephritis after an administration of long duration. Similarly in tetracaine works and in factories where woollen hats are made and this chemical is used, in addition to trouble arising from the smell, only slight disturbances have been reported, such as headaches, vertigo, and localised pains in the kidney region. The urine may be brown or black, but this coloration is not consistent. But, if the tetracaine is in concentrated solution, it causes dermatitis with eczema and rhagades, and also nephritis, betrayed by the presence in the urine of hyaline casts, with epithelium from the upper urinary passages and blood. Analysis detects a product analogous to phenol.

What is of practical interest is the fact, emphasised by Gerbis, that this product which has a high boiling point, about 203°C., is easily conveyed by steam. This fact easily explains the serious injuries caused by the inhalation of Perpentol S, and of other products of tetracaine base, containing a very powerful odour, merely set up a feeling of malaise induced by the

Perpentol S, when taken separately, are scarcely toxic at all; but the complex product exerts a pronounced influence on the blood, the nervous system and kidneys. For this reason experts are searching for a product with a less toxic composition, but which offers the technical advantages of Perpentol S.

Special mention should be made here of chloroethylalcohol beta, which is a poison to the nervous system and more particularly to metabolism. Up to the present chloroethylalcohol has been regarded by German investigations, made by Koelsch (I. G. Fabrikenwerk, Ludwigshafen) as recently as 1927, in consequence of toxic effects which occurred in course of use, it has a high degree of toxicity. This fact has been proved by inhalation of its vapours and absorption through the skin in such animals as cats, guinea-pigs and rabbits, which died the same day or after a few days, according to the concentration used — from 0.002 mg. to 0.004 mg. per litre of air. The symptoms appear a definite time after exposure to the poison with vomiting, disturbances of the pupillary and defensive reactions, disorders of gait, and death which occurs from respiratory paralysis. Autopsies revealed localised irritation in the recesses of the respiratory passages, with fatty degeneration of the heart, liver, kidneys, and definite diminution in weight, showing disorders of metabolism. The experiments made at Ludwigshafen confirm those of Koelsch, and show that exposure to the poison, in more or less concentrated doses — from a minimum poisonous dose of 3.6 mg. per litre of air — has caused death, or, in its absence, such nervous disturbances and serious interferences with the metabolism that convalescence lasts weeks and months.

Finally, reference should be made to the specific irritating, suffocating action exerted by some solvents on the mucous membrane of the respiratory passages, with a repercussion on the heart and blood vessels; according to Brückner it is probably due to an irreversible reaction. But sometimes it is only a question of non-poisonous fumes, which merely exert an irritating effect on the mucous membranes of the eyes and upper respiratory passages.

Certain products produce an injurious effect on the skin by removing the fatty layer; reducers, which possess a very powerful odour, merely set up a feeling of malaise induced by the
SOLVENTS

nauseating effect caused by their disagreeable smell. A distinct smell pervading the atmosphere of a workshop is caused by 0.001 grm. of ethylic ether per cubic metre; by 0.09 grm. of acetate of amyl; or by 0.6 grm. of methyl alcohol.

The period of exposure plays an important part. The fumes of some solvents, even of those most commonly used, may, as a matter of fact, be dangerous when they are breathed for a short time in a highly concentrated form, and may then cause death by acute poisoning; while others, on the contrary, e.g. benzene, cause death by chronic poisoning, when they are breathed for a long period in low concentrations.

Individual susceptibility, of which clinical work has shown the great importance, must also be taken into account, the symptoms of poisoning varying for an equal exposure, according to the individual. Apart from idiosyncrasy, a predisposing part is played by states of depression, nervous affections, cachexia, cardiac lesions, such vascular trouble as arteriosclerosis, or such pulmonary conditions as emphysema, or disorders of the liver. Thus in fatal cases of poisoning by chloro-ethylalcohol beta autopsy on the victims has revealed the previous existence of more or less extensive organic lesions.

External conditions must also be taken into account. Thus temperature of the workplaces, increased temperature augments the volatility of the products, as does also the existence of large evaporating surfaces; technical processes may affect the mode of action of the poison, and the degree of poisoning; while the ventilation of the work-places is of course important.

SOLVENTS

Solvents may act either in the form of fumes — the most common form — or in the form of vapour, as when paint is applied by spraying.

The principal path of entry is by the respiratory passages, due to the inhalation of vapour or mist, which enables the poison to penetrate into the blood stream and, through its agency, into the general system.

But resorption by the skin plays a part which is far from negligible, for these solvents destroy the protecting fatty layer of the skin and diminish its suppleness.

STATISTICS

It is extremely difficult to get accurate statistics as to cases of poisoning by various solvents, in consequence of the multiplicity of the products used, of the uncertainty in their exact composition and of the numerous industries and operations in which they are employed. (See the articles referring to various products mentioned in the article on “Ethylene.”)

It is interesting to notice here the statistics reported by Koelsch on chloro-ethylalcohol beta in Germany.

No case has been reported during the manufacture of this product. All have been connected with its use: 3 cases, of which 2 were fatal, occurred in a paper works in 1923, while cleaning the cylinders of a machine with rags soaked in this liquid; 4 other cases, of which one was fatal, happened in 1925, in a linoleum factory, during the use of a quick drying coloured paste with a basis of chloroethylalcohol; 2 other cases appear to have occurred since elsewhere.

In 1925, 15 cases of poisoning by Perpentol S were reported from a woollen hat factory in Prussia.

PATHOLOGY

The pathology of the various solvents is almost identical; just indeed as is their general physiological action.

Solvents act first and foremost on the central nervous system, causing a state resembling drunkenness, with headache, somnolence, vertigo and staggering gait, loss of will power and of memory, clouding of the senses, hallucinations, precordial pains, insomnia, disordered vision, malaise and feebleness which may pass on to loss of consciousness. Sometimes acute mental disorders are observed, due chiefly to preparations of benzene and its homologues, and chloro-hydrocarbons of the fatty series. Fairly serious gastro-intestinal disorders have also been noted, with nausea, vomiting, diarrhoea and jaundice. In acute poisonings, caused by concentrated exposure to such toxic products as chloro-hydrocarbons, death may occur from respiratory paralysis, syncope and asphyxia. Except for concentrated exposures with rapidly fatal results, recovery is generally quick if the patient is moved at once to the open air. Nevertheless, cases fairly long in onset with fairly serious sequelae have been noted. Koelsch remarks upon the opposition shown by working women to giving up their work or changing their occupations.

The most varied clinical pictures may appear, depending on the quantity, the nature and impurities of the substances used.

The symptomatology takes on special aspects as the products exercise specific actions. Fatty degeneration of the liver results from chloro-hydrocarbons;
nervous disorders of central or peripheral origin from sulhide of carbon; incurable lesions of the optic nerve from methyl alcohol; renal symptoms from tetraline, with renal pains, black and pigmented urine having a special odour and containing casts and renal crystals.

Poisoning by chloroethylalcohol beta which rarely begins at the moment when the poison is absorbed, but generally some time after the termination of work, is characterised by localised lesions on the superficial mucous membranes and the deep respiratory passages. According to reported cases, the clinical picture presents the following type:

In an acute, rapid case of fatal poisoning which occurred during work, the onset was ushered in by a state of malaise, nausea and vomiting. The patient, after he had returned home, was taken with headache, slight mental confusion, and bilious vomiting, without fever or symptoms connected with the heart or respiratory apparatus. Sudden death occurred the next morning after a fainting attack. In another victim, the onset was also during work, with somnolence causing interruption of work, followed in the afternoon by dyspnoea. Death occurred in the evening from pulmonary and cerebral oedema. In subacute poisonings there is a varying period after the cessation of work, in the form of vomiting, vertigo, headache and weakness. In some cases, workers were able to return to work the next day; in others, recovery took place without sequelae, but after a long convalescence. Slight poisoning shows itself simply by local manifestations, with sensations of tingling and of burning at the eyes.

Products, such as tetraline and Perpentol S, used to clean tar marks from wool, have been the cause of stupor, insomnia and disturbed sleep; and in serious cases of nephritis and convulsions.

These solvents cause local lesions on the superficial mucous membranes of the conjunctiva and upper respiratory passages, especially in the case of aldehyde or ketones used as such, or found as impurities in the products employed.

They act also on the skin, provoking eczema, oedema, inflammatory reactions and rhabdoses, due either to the action of the poisons themselves or to intense defatting of the skin, which facilitates the entrance of bacteria and their attack on the sudoriparous glands.

Hygiene

The protective measures to be taken involve on the one hand the construction and arrangement of the workplaces, and on the other hand the use of the solvents.

Necessary measures should be taken to protect stores where solvents are kept against any risk of fire or explosion, as well as to make sure that the workers employed in this department of the factory are protected against all danger from the inhalation of poisonous vapours.

Dangerous processes should be carried on in places separated as much as possible from the other departments of the factory.

The receptacles used should only be of the hermetically sealed pattern. Rags soaked in solvents should be placed in closed boxes. Any liquid upset on the ground should be at once cleaned up and removed.

The escape of fumes and vapours should be prevented by adequate technical measures, such as exhaust ventilation and better regulation of spraying jets; where these measures are not possible, the fumes or vapours must be so diluted that their absorption, even if continued, cannot cause injury to the persons exposed. There is then need for the installation of a general system of ventilation or an adequate localised one.

All processes which generate vapours or steam should be carried on in spacious workplaces which are well ventilated. The actual processes should be carried on in hermetically sealed apparatus, or, in default of that, in apparatus covered in as much as possible and provided with some efficient system of local exhaust. Sometimes for that purpose, the natural draught of high chimneys is used, or jets of water or of steam; usually powerful aspiration is used, the mouths of the suction ducts being placed as close as possible to the source of the fumes.

The choice of apparatus to be used, its size, and the extent of the aspirating area depend on various factors, such as the rate of evaporation of the solvents used; the degree of their toxicity; variations in their concentrations in the air, according to the work, draughts and atmospheric conditions; the nature and density of the fumes which may be heavier or lighter than air; and the special technique to be observed.

Attention should be given to the entrance of air and to its heating, especially in winter, with a view to prevent-
When liquids with a basis of solvents are applied in confined spaces, such as tanks and boilers, or more especially when spray-guns are used, general measures of protection should be augmented by the use of protective appliances for each individual, such as respiratory masks, helmets, and goggles; but it must not be forgotten that such appliances are not willingly worn by workers and are only indicated for short periods of work. The production and accumulation of static electricity must be avoided by earthing the apparatus. (See articles "Benzene" and "Dust, Fumes and Smoke".)

Workmen should be prohibited from entering tanks or tubes which have held solvents, before such places have been carefully cleaned and completely freed of all fumes.

Absorption by the skin should be combated by providing for all requisite measures of personal cleanliness with baths, douches, and lavatories, so that personal factors tending to dermatitis may be eliminated. Lubricating the hands before and after work with lanoline or wool grease prevents eczema; this precaution renders useless the wearing of protecting gloves, which may, indeed, be dangerous and constitute a source of injury. It is, therefore, desirable that employers should arrange for this lubrication and supply the worker with the material required.

Improvement of the hygienic conditions in industries using solvents still raises numerous difficulties: there is the need for ascertaining the exact composition of the products used; disadvantages arise from present-day methods of work, and the manner in which the technique may regulate them; and problems of preventing injuries to the health of workers still await solution.

Workers should receive instruction by different methods — by lectures, leaflets, posters, and notices — as to the poisonous nature of the products they manipulate and the dangers they incur.

It is for this reason, that as regards chloroethylalcohol beta, some German factories have decided to restrict the sale to special and well-defined cases, while drawing in a special manner the attention of users either to the poisonous nature of the product, or to the precautionary measures to be taken. All these precautions should be effectively completed by medical examination on commencing work and periodically thereafter, enabling a choice of personnel to be made in accordance with constitution and physiology, and permitting of the exclusion of delicate subjects, as well as regular alternation of occupation for those exposed.
Soot

Soot is the product of incomplete combustion of the organic carbonated compounds produced by a smoky flame (coals, tars, mineral oils, resins, etc.).

In its natural state it settles throughout chimneys and hearths in the form of a blackish substance forming brownish, brilliant, fragile crusts or scale with an empyreumatic odour and a bitter taste, soluble in water which takes on a yellowish colouration. Soot contains carbon, empyreumatic substances, creosote, salts of ammonium and other special products, notably a yellow bitter oleaginous substance to which vermicide properties are attributed.

The formation of soot is dependent, on the one hand, on the properties of the combustion materials, and, on the other, on the type of construction of and manner of feeding the furnaces. Poor coals giving hardly any smoke produce very little soot. Faulty construction and badly disposed apertures in hearths, as well as defective charging (lack of air supply), which prevent complete combustion, favour the production of soot.

Soot is generally manufactured by the incomplete combustion of tar and tar oils which are caused to fall on to the hearth and burnt there with the smallest quantity of air possible. Cooled gases laden with particles of carbon are directed into precipitation chambers containing baffle plates or cloth screens on which the soot settles. The soot recovered is then sifted, washed with sulphuric acid or potash, dried and packed in barrels. The soot or "black" is finer the further the point at which it is collected is removed from the place of combustion.

According to the produce used there may be distinguished: oil soot, resin soot, lamp black, a very fine variety obtained by combustion of liquid or gaseous products in special lamps. Acetylene likewise gives a very black soot. In America soot is produced by burning directly petrol gas.

Soot is of course occasionally utilised as artificial manure. Manufactured soot (lamp black), unaffected by light or by ordinary chemical reagents and insoluble in all solvents, is used as a pigment in oil paints, varnishes, Chinese ink, printing ink, and in the preparation of certain pigments (bistre, for instance, etc.).

Sources of Risk

Sources of risk consist of exposure to soot dust and other irritant substances which it may contain (tars, phenols, creosotes, etc.), and which depend, as far as natural soot is concerned, principally on the kind of coal from which it originates: coals rich in sulphur or containing traces of arsenic to which an irritant effect is ascribed (see article "Tumours of Occupational Origin"). Besides soot, an important part is played by coal dust and perspiration, which exert harmful action on the lipoid substances of the skin, causing mitotic cellular subdivision (Koelsch). Chimneysweeps, blacksmiths, furnace and machine stokers, cleaners of hearths and furnaces, and less usually agricultural workers, gardeners, etc., may be enumerated amongst the occupational categories exposed to injuries connected with soot.

As regards chimneysweeps, it is essential to add as additional sources of injury exposure to inclemency of the weather, strain due to excessive effort, especially with the knees and elbows, and also the risk of accidents. Amongst workers engaged in the production of artificial soot, it is accordingly those who collect and pack it in barrels who are most exposed to risk.

Statistics

Available statistics are chiefly of English origin. According to the figures published by the Registrar-General for the
period 1921-1923 the mortality rate for chimneysweeps is above the average and the principal causes of death are cancer, phthisis, circulatory diseases and cirrhosis of the liver. The mortality rate for skin cancer, especially of the scrotum, is 11½ times that of the average.

This high cancer mortality rate already led English authorities to devote their attention to the subject, and from the end of last century such medical experts as Butlin, Ogle and Tatham have published figures to be found in British medical literature.

Investigations made in Europe (Austria, France and Germany) and in the United States have indicated that cancer is a very rare occurrence amongst chimneysweeps in these different countries, a fact which is attributed on the one hand to the varying nature of the soot dependant on the types of coal employed — and on the construction of the furnace chimneys used 1, and on the other hand to the habits of the chimneysweeps (wearing of working clothes, personal cleanliness). Richter considers that chimneysweeps' cancer has completely disappeared in Germany, and he attributes this to improved hygienic methods observed.

PATHOLOGY

The injuries encountered are chiefly connected with the action of soot dust, which has been thoroughly studied by Ascher in Germany, W. C. White in the United States, as well as by numerous committees engaged in the smoke abatement campaign.

Weyl considers that, despite the fact that chimneysweeps are of necessity exposed to the inclemency of the weather, especially as they work throughout the cold season, their occupation is nevertheless a relatively healthy one. According to Oliver, chimneysweeps suffer more than the average worker from acute respiratory affections: forms of rhino-pharyngitis and adenoids, forms of laryngitis, bronchial catarrh, inflammation of the lungs, pleurisy, etc., and especially tuberculosi. An enquiry conducted in 1927 by Hedborg amongst chimney-sweeps in Stockholm has shown that amongst 124 workers examined, or three-quarters of the total number, with an average length of employment of twenty-two years, there occurred 14 cases of pulmonary tuberculosis (3 active and 11 latent). This authority has found that while tuberculosis is of frequent occurrence, it shows a remarkable tendency to heal up or remain stationary, with the result that it is hardly possible in this connection to speak of the nefarious influence exerted by the occupation.

According to Schmidt, tuberculosis accounts for 60 per cent. of all cases of sickness, and 42 per cent. of all fatal cases occurring amongst German chimneysweeps.

On autopsy the lungs show blackish pigmentation due to particles of soot. Sternberg reports that stokers and chimneysweeps show this pigmentation, which is not accompanied by fibrosis. In his experiments on an animal, Arnold distinguished three kinds of pulmonary lesions due to the inhalation of soot: simple anthracosis, anthracotic melanosis of the lungs, and indurated anthracosis ("anthracosis simplex", "melanosis anthracotica pulmonum", and "anthracosis indurativa"), the latter only occurring as a result of the combined action of silica dust. Claisse and Josué, Lebenu, and Willis have never been able to produce fibrosis amongst animals by simple inhalation of soot.

It must be noted, on the other hand, that Cooke reported in 1930 a case of pneumoconiosis confirmed by post-mortem examination, as affecting a worker of thirty-five years of age who had been employed during the nine and a half years preceding death as a boiler and chimney cleaner.

Diseases of the heart and urinary system have been reported by Oliver; on the other hand, diseases of the digestive passage seem to be a rare occurrence.

There have likewise been reported chronic affections of the eyes (conjunctivitis) and of the middle ear (catarrh) due to the irritant action of soot dust, and, in the case of the eyes, also to the action of foreign bodies. Eczematous inflammation of the eyelids occurs likewise not infrequently amongst workers handling soot.

J. W. Thomas in 1930 met with a case of epithelial hyperplasia of the cornea affecting a furnace stoker aged fifty-two years, and found to be due to the penetration of dust from the combustible, which had set up persistent irritation even after a lapse of three years. In 1927 three small white masses were clearly visible on the one on the cornea, another on the internal limbus, and a third on the conjunctiva of the eyeball. Later on the conjunctival mass disappeared and two others coalesced to form a corneal mass, which developed finally into the formation of an excrescence for which excision was necessary (1930). The author considers that dust from the combustible, which contained 6 per...
cent. of pitch, had played a definite etiological part in the production of the tumour. Sixteen years earlier this worker had suffered from a wart on the face due to the action of pitch, and which had to be removed.

Lesions of the skin are the most frequent and are of greater importance. Under the action of soot the skin becomes thickened, hard and dry. Eczema affects the hands, legs and feet of those engaged in packing soot in barrels (Rambozsek).

Pichler in 1930 described a case of pigmentation of the skin affecting a chimney-sweep. Pigmentation is frequently situated on the hands and feet (ten times out of twenty), with linear scars, and small blue wounds with a blackish halo.

Cutaneous lesions do not often remain stationary at the stage of pigmentation or eczema, but undergo a malignant transformation causing Bowen's disease, dermatitis and true epithelioma, especially in the case of chimney-sweeps.

Chimneysweeps' cancer was described for the first time by Percival Pott in 1775 and studied, according to him, by numerous English authorities. On the basis of clinical observation, Pott distinguished cancer of the scrotum in English chimney-sweeps from a number of affections at that time designated under the name of cancer, and definitely ascribed its origin to soot — this being also later the opinion of Virchow — specifying clearly that the disease had its origin in the accumulation of soot in the folds of the scrotum. Spencer (1890) claimed to be able to demonstrate the presence of particles of soot in the cancer cells of chimney-sweeps.

Warts due to soot ("fuliginous warts") have been described in France by Selle (1787) and Alibert (1817); cases of cancer in Germany by Stöhr (Thesis of 1820: he refers to cases studied by Major and Michon); and by R. Köhler (1853); in Switzerland at the beginning of the nineteenth century by Jurine, of Geneva. Futterer collected 47 cases of chimney-sweeps' cancer, described in English and American literature in the period 1808 to 1854.

Chimneysweeps' cancer is generally situated on the external genital organs, most frequently on the lower part of the scrotum, and may rarely on the penis. In this case it chiefly affects the skin, whilst the gland and the prepuce do not seem to be affected except indirectly.

The outbreak occurs after a certain period of exposure to the action of soot, generally twenty to twenty-five years. There have been cited in this connection as quite exceptional lengths of employment periods of one to two years. Cancer preferably attacks subjects between forty and sixty years of age, though medical literature contains a reference to cases amongst younger individuals: 16 to 22 years (Stöhr); 15 years (Wadd); 8 years (Earle — at the time when "chimney boys" were employed in Great Britain as chimney-sweeps).

The disease may even break out after all cessation of contact with soot. Medical literature contains particulars of an instance in which workers who had left the occupation of chimney-sweep were affected after a lapse of twenty years.

The skin becomes dry, rough and pigmented, and later is covered with papilloma, which constitute a pre-cancerous stage. These papilloma may exist for years without suffering malignant transformation, and may grow in length, becoming horny and forming "skin corns," or they may remain quite small and even disappear, but in general they develop into a form of cancer, which, from the histological point of view, is a type of spinocellular carcinoma.

At the moment of malignant transformation the papilloma proliferate, become more salient, take deeper root and ulcerate in the centre (Butlin). In the absence of intervention the ulceration spreads, the edges become swollen and hardened, exuberant scirrhous formations grow on the surface, whilst fettid and highly irritant matter is discharged from the tumour (Earle). This stage is characterised by intense pruritus, which yields later to pain (Cooper). The patients become cachectic, lose weight, and die slowly or suddenly as the result of some intercurrent complication (Curling).

This form of cancer in its evolution may spread to the testicles, the spermatic cord, the inguinal glands, the abdomen and the intra-abdominal organs (Pott). Yet these forms of metastasis of relatively rare occurrence may nevertheless break out or continue their growth subsequent to ex- tirpation of the primary tumour.

More rarely cancer breaks out in the inguinal glands without the existence of scrotal tumour (Paget, Lawson).

The situation is therefore typical, though the disease may also be located on other parts of the body (face, hands, etc.). Whilst this form of cancer has been met with fairly frequently amongst members of chimney-sweeps' families, it may also occur in several occupations in which the handling of soot is involved.
Curling (1845) described a case of cancer of the hand affecting a gardener who strewed soot on plants for the destruction of parasites. Lawrence (1850) refers to a case of cancer of the tegmen tympani, and Cooper to a case of cancer of the cheek amongst workers engaged in carrying sacks of soot on their shoulders. Cusack removed a dangerous growth from the hand of a woman who had worked amongst soot. Curling has also described cases of papilloma on the toes amongst workers who packed soot in barrels barefooted.

Paget has likewise reported a case of cancer of the larynx affecting a chimney sweep, and was led to enquire whether this was purely a coincidence, or, on the other hand, whether there was a possibility that the soot inhaled had caused injury of the organ in question. Manouvrier (1876) has reported the occurrence amongst blast-furnace stokers of cancerous formations not only on the nose but also on the hands and face. In 1930 Bedford studied a case of multiple carcinoma affecting a smith aged forty-five and with a working experience of twenty years' duration. This worker, after the removal of a tumour from the lower lip, suffered from a further tumour on the scrotum subsequent to an eczematous condition which had lasted several months.

Early excision of the tissues affected does not protect the individuals in question from recurrences, which, however, do not appear in the cicatricial tissue but beside it, or at another point. These recurrences occur even when the patient has never been in contact with soot after the first attack. Curling cites the case of a chimney sweep who during a period of twenty-two years had been operated on five times and suffered from metastases of the inguinal glands. He likewise met with a case of a chimney sweep aged sixty-six who had had his finger amputated for cancer and who suffered from a cancerous papilloma on the other hand. He had previously been operated on for scrotal cancer thirty-five years earlier.

Besides the carcinogenic action of soot, mention should also be made of the predisposing effect of local irritation, and this explains certain occurrences at the point at which there is irritation of the skin: inguinal cancer at points of irritation due to wearing of an appliance for hernia (Rosser, 1886).

HYGIENE

Factories for the production of lamp black from distillation of coal, tar and bitumens in certain countries come within the list of scheduled establishments classified as dangerous or offensive trades, and are on this account committed to the observance of a certain number of measures concerning principally safety (construction of factories far from inhabited centres; construction in incombustible material with iron doors; separation of furnaces and boilers from lamp black rooms, and the application to boilers of all necessary devices for preventing liberation of disagreeable odours and harmful gases; the provision of high chimneys provided with metal trellis work; in the case of factories using resins and tars, compulsory mixing of the raw materials in boilers placed under hoods; construction of hearths separate from workrooms, etc.). These measures should be supplemented by measures of general hygiene and by those adequate for preventing raising of dust and smoke production (effective with withdrawal of these), especially during the extraction of lamp black from precipitation chambers. Precautionary measures against fire are likewise necessary; e.g. prohibition of access to certain workrooms with naked lights. Application of requisite measures for preventing all liberation of dust during bagging or barrelling of the soot is also necessary. Automatic apparatus provided with exhaust devices and means of recuperation should be adopted where possible, though such measures are at times not of ready application on account of the very fine state of subdivision of the soot.

During chimney sweeping, efforts should be made to diminish as far as possible or entirely eliminate all contact with soot. In Great Britain a recent reduction in the number of cases of chimney sweeps' cancer is attributed to the use of the "long brush", which involves less contact with the soot. Other types of apparatus for chimney sweeping and of withdrawal by exhaust adopted for various kinds of chimneys and boilers at the present time render the operations in question semi- or even entirely automatic.

These measures should be completed by measures of personal hygiene: wearing of working clothes, gloves, glasses and masks for protection against dust, but chiefly measures of cleanliness: provision of washing facilities, douche baths, etc.

As regards prophylaxis, periodical medical examination of workers coming in contact with soot is of primary importance. Abandoning the occupation in question may render the adult chimney sweep less subject to cancer,
but in no wise guarantees him against recurrence of this condition.

**Legislation**

Compulsory notification of cancer of the skin and cancerous tumours due to soot is provided for under French, Dutch and Polish legislation.

In Germany forms of chronic recurring dermatitis due to the action of soot entitle the worker to compensation in Great Britain and in Western Australia compensation is granted for cancer of the scrotum occurring amongst chimney sweeps; in Austria cancer of the skin due to soot; in the U.S.S.R. cancer of the skin. Compensation may also be claimed in the case of dermatitis or diseases due to dust, especially where chronic inflammation of the skin is concerned (U.S.S.R.), as well as injuries (ulcers) of the cornea due to the use of pitch, tar, bitumen, mineral oil, or "a compound, product or residue of one of these substances" (Great Britain).

**Sport (Hygiene and Physio-Pathology of)**

There is no divergence of opinion as to the great benefit derived from physical exercise, from the twofold point of view of the general mobilisation of the body and of the mental recreation it affords to those who do physical work.

Too often workers have to endure immobility or restricted mobilisation, unnatural postures from which may even result physical deformity or organic deterioration. Quite apart from various occupational deformations of the thorax or of the vertebral column, prolonged standing in itself causes in time circulatory disorders and a relative anaemia, due to stasis of blood in the legs and consequently diminution of blood in the rest of the body (Atzler and Herbili).

All these troubles and ill-effects are corrected by physical exercise. Its beneficial influence on the body is manifested by physical and physiological modifications, observed by many experts before and after the practice of sports. Thus, for instance, among physical modifications, Kaup and Grosse found that during training the person occupied in sport loses weight, but, on the other hand, he develops greater respiratory amplitude, greater vital capacity, an increase in chest measurement and in the circumference of the arms when outstretched, but especially when flexed, and also of the thighs.

As regards physiological modifications, during the rest before the exercise, they report, between the values taken at the beginning and the values taken during the training, a diminution in respiratory volume and the work of the heart. The difference between these values increased in a marked way when it was a question of a performance amounting to 320 kilogrammes per minute.

Under the influence of many and varied physical exercises, combined with adequate feeding, there occurs an increase in weight which has been attributed to an increase in muscular volume (Hersheimer). This development is more clearly demonstrated in the case of untrained youths, of slender build and of subnormal weight. This muscular hypertrophy is accompanied by an increase in muscular power; and it has been observed that this latter, after a training of twelve weeks, increased by 1,143 per cent. (Palmen).

Physical exercises may be classified as exercises for increasing the general strength of the local strength or skill (F. A. Schmidt). The first include heavy athletics; the second movements are limited to a restricted number of muscles, as in gymnastic exercises, boating or swimming; the last include exercise with the lance, quoits, and jumping over the bar, all of which require a well-developed and co-ordinated nervous system.

It is not without interest to consider the part played by the psychological conditions under which sports should be carried on, the aim and object of which are to provide recreation for the mind, capable of inspiring real interest and of developing initiative and emulation. The organisation of competitive sports is the best means of sustaining the aspirations of sport enthusiasts, by taking into account the instinctive tendencies which prompt them to strive for supremacy. The individual aspirations and untameable daring of youth find no outlet in the monotony of daily life, and it gladly turns to the counter-excitement of competitive sports, where each is free to strive openly with all the strength at his command (Ruhemann).

Finally, Gerbis (1931) recommends physical exercises practised during rest periods interpolated during the working day. He considers this a means for preventing the ills which work may cause, and of increasing output by eliminating fatigue.

**Physiological Facts**

The influence of sports on the body has been the subject of many enquiries, but by far the most numerous of these have devoted particular attention to the reactions of the cardiac muscle.
Whereas radiological examination has demonstrated an increase in the volume of the heart after exercise, there is divergence of opinion as to whether it is due to hypertrophy of the heart or a simple functional dilatation, and as to whether these modifications should be considered to be pathological or not. Clinical examination makes it possible to recognize this hypertrophy or distension; and the claim has been made that a parallelism exists between this condition and the intensity of the exercises (Sirl).

The increase in the volume of the heart in the case of persons in training is, in the same exercise, about 24 per cent. higher than that observed in the case of persons not in training (Kaup and Grosse), and it is more or less accentuated according to the type of the sport practised. Thus, the heart is found to be largest in those who go in for swimming; medium distance races come next; then, in order, long distance races, medium distance races, wrestling, swimming and athleticism; and finally, with the heart the least developed, boxers. The shape also varies according to the nature of the sport; the right side is more developed in boxers; the left side is more developed in skiers (Herxheimer). Yet this increase is not an absolutely invariable condition; for the dimensions of the heart have at times been found not to exceed the normal (athletes: L. Merklen, Abrahams). As a general rule, when the athletic effort is taking place, a diastolic dilatation occurs, which can be demonstrated radioscopically by amplification of the cardiac beats; it disappears rapidly when the effort is over (Bordet). In all these cases it is a question of adaptation to the new conditions necessitated by the exercise, and not of cardiac failure. A strained heart is an unusual injury in sports (L. Merklen); serious physical exhaustion, leading to grave mischief or death, is due to general toxaemia and not to symptoms which are characteristic of a strained heart, and which are simply those of acute hyposystolic or asystolic action (F. Heckel).

The rate of the cardiac delivery per minute, greatly increased during athletic activity, has been variously estimated by experts: from 2 to 5 litres delivery during sleep; 20 litres or even more during hours of violent exercise; from 4 to 6 litres (Krogh and Lindhard) or even 9 to 10 litres (Hendersen) during normal delivery to 40 litres during exercise (R. Herbst). This increase is facilitated by a greater reflux of venous blood to the heart during exercise, a higher degree of venous pressure, due chiefly to actual muscular movements, which compress the muscular veins and drive the blood towards the large veins and the heart (L. Merklen).

Deutsch, however, observes that the respiratory movements peculiar to a man who engages in athletics, and the need for blood in the periphery, would entail a diminution in the heart. The temporary or permanent dilatation, which, nevertheless, is observed, would appear to be merely a sign indicating that the diminution must often take place under difficulties.

The increase of work thrown upon the heart is also accompanied by an acceleration of the pulse; the mechanism of this invariable condition has not as yet been explained. The rate may reach 150 or even 200 pulsations a minute, and this may last some time; the return to normal, after certain exercise, may even take several days.

In the case of persons in training, by force of the effort, there is noted a characteristic increase in the maximum arterial pressure, whereas the minimum is comparatively stable. The rates rapidly reach a level which they maintain the whole time the exercise lasts and thus they constitute the scale of effort. When the exercise is over, these modifications disappear and the pressure rapidly returns to normal. In the case of persons not in training, after a temporary initial rise to a maximum, the cardiac muscle gives way and a fall in pressure takes place (Merklen).

The surface of the vascular network is seen to be increased by a dilatation and an increased permeability of the capillaries in the tissues which breathe; this increase may be as much as double or triple that of the normal surface; it entails a diminution in the absorption of oxygen on account of the increase in the rapidity of the flow (Kaup and Grosse).

The modifications of the heart have been compared with those that take place in the involuntary vegetative nervous system: predominance of vagotony in persons in training (Herxheimer, Schrenk, Deutsch and Kaup); manifested in the form of hypertrophy of the skeletal musculature, weak blood pressure, diminution in the pulse rate, respiratory arrhythmia, increased galvanic excitability and exaggeration of the reflexes. These symptoms are found in a mild form in most persons trained for sports. *The flabby heart which has sometimes been observed corresponds to the vagotonic heart. In the same way the alkaline reserves of
the blood come into the picture of vagolony. Pulmonary action is stimulated by engagement in sports. Even mild exercise may increase fourfold or fivefold the amount of air absorbed and the vital capacity. In wrestlers a descent of the lower limit of the lungs has also been observed, varying according to the duration and stress of the wrestling bout; it disappears at the end of twenty-four hours (Lampe, Weltz, Heirich and Straubel).

Modifications of the circumstance of the abdomen have also been described, especially in wrestlers inclined to abdominal adiposity.

Metabolism in the case of persons engaged in athletics has been the subject of numerous investigations, which have emphasised the fact that an increase in the consumption of energy occurs according to the nature of exercises. The value of the respiratory quotient may go up to 2 or over. But this increase is not a sign of actual combustion, but merely an indication of an ebb in the carbon dioxide (bicarbonate of soda of the blood), brought about by neutralisation of the lactic acid, the quantity of which is increased (Schenk). In the case of persons not in training, the acid reaction of the blood, in spite of the presence of phosphates, bicarbonates and neutralising albumoid substances, must be partly connected with the presence of mineral phosphoric acid, which is found in increased amount in the blood of those who engage in athletics.

In the case of trained persons the respiratory quotient comes nearer to unity, this condition has been explained by the capacity which the body acquires of burning up directly hydrates of carbon, so economising the glycogen of the liver. Thus there would seem to be a "resynthesis" of glycogen and a simplification of the intermediary metabolism (Kaup and Grosse). The neutralising substances of the blood are also increased in the case of trained persons; in this way maintenance of the equilibrium in the concentration of hydrogen ions — the pH — in the blood is secured.

All these reactions of the body are produced only when it is a question of exercises characterised by moderate rapidity and effort. The performance of an exhausting feat brings about serious dyspnoea with retention of lactic acid (Hill), as well as a change in the level of the blood pressure and in the intra-alveolar tension of carbon dioxide (Herxheimer), which lasts for some time after the cessation of exercise and imposes a convalescence rather than a simple rest on the body.

As regards the sugar in the blood, it may be affirmed, with individual variations, that the reducing capacity can be increased up to 0.250 ern. per cent. But from this figure the percentage of the other reducing substances, which may go as high as 15 per cent. of the rate indicated above, must be deducted (Schenk). The alkaline reserve of the blood becomes diminished even after half an hour of fatigue; however, the pH of the blood remains within normal limits (Cannaro and Merenda).

In the urine, in most of the cases, an increase of acidity with pH=5.1 to 6.1 after the exercise has been observed, as compared with pH=6.2 to 7.2 in the state of repose (Schenk). A fairly large quantity of lactic acid is present; no elimination of lactic acid occurs in a state of rest. Diminished elimination of the hippuric acid occurs. Non-oxidised purin (methylguanidine and adenine) increases. The presence and the proportion of these substances in the urine have been attributed to an insufficiency of oxygen with a consecutive slowing down of combustion (Kuist and Flossner).

A transitory albuminuria, and especially an orthostatic albuminuria (Brandeis), have been observed in persons who engage in athletics. Their urine may also contain leucocytes, red corpuscles, hyalin and granulated cylinders, epithelial cells, crystals of calcium oxalate and uric acid. All these figured elements mentioned above are found, not only when severe exercises are performed, but even in persons who go in for such moderate forms of sport as football, ball games and running.

As the expenditure of energy by the body is increased by the practice of sports, it is obvious that the losses must be made good by suitable feeding. For this reason, in spite of the fact that one result of training is a diminution in the expenditure of energy (Atrler, Herbst and Lehmann), special diets have been devised for those who go in for sports, quite different from the diets which are considered suitable for following a life of habitual occupational activity.

In the diet of those who engage in athletics an increased ration of albumen and fat predominates. The supplementary ration thus provided for is not approved by all authorities; in other diet formulae special stress is laid on the need for increasing above all else the ration of carbo-hydrates (Gordon).
A table drawn up by Lorentz helps us to realise the quantitative modifications designed for increasing the production of calories:

**Pathology**

Excessive exercise imposes severe strain and may cause various lesions. Muscular lesions in particular may result from an effort made by a person who is subjected to a prolonged tension. A sudden pain is the typical subjective sign; objectively there is an apparent discontinuity in the muscular outline, or merely a localised diminution or exaggeration in muscular resistance. Subcutaneous rupture of the triceps in the calf has been observed in tennis players and has been designated "tennis leg". Mosenthal has observed the tearing off of the small trochanter, and Löhre the tearing off of the anterior and superior iliac spine. Women do not often suffer from muscular lesions; whereas older men do so more frequently than others (Rosenburg). Among the complications of these lesions, atrophies, calcareous deposits or points of ossification in the muscular tissue have been described (Batzner). The joints may become affected with irregularities of the surfaces, with wear and detachment of the cartilages, with arthritic projections, with calcareous concretions, and with periosteal neoplasms. A typical deformity of the elbow joint has been described in the case of tennis players (tennis arm); and Lloyd Williams has described under the name of "boxer's thumb" a metacarpophalangeal subluxation found among those practising this sport. Again, cases of costal fracture following effort have been reported by Arnold, Dubs and Mandl; cases of spontaneous rupture of the knee in wrestlers (tibial tuberositis), a case of rupture of the anterior cruciate ligament (Bresler); a case of rupture of the axillary artery by W. Koch; and cases of hemothorax by Illebrand.

Excessive exercise at certain sports has also caused serious ocular lesions, especially in tennis players following a blow from a ball, when retinal haemorrhage may take place, followed by somewhat serious complications (Gérard, Baxter). Auricular lesions have been observed in this same class of athlete, consisting in cases of rupture of the eardrum, auricular haemorrhage and suppurring otitis (Baxter). Virchow (1863), Lakaki in Japan and Valentin (1905) have drawn attention to cases of haematoma of the right ear in wrestlers. A much more serious complication has been observed in tennis players and is analogous to that described by Stradiotti in 1908 in the case of acrobats.

Similar modifications may be noted on the bronzes and statues representing ancient Roman wrestlers, as well as on statues of Hercules, which is a proof that this condition did not escape the notice of the artists of the time. Fervers has observed a case of necrosis of the scrotum after a lesion caused by sport; Nadler a case of rupture of the small intestines; Castrin a case of rupture of the kidney in a football player.

Close observation of a group of athletes brought to light a large number of lesions which in most instances do not come to the notice of a doctor, either on account of their mildness or on account of fear of expense that would be incurred by their treatment. Out of 484 cases of wounds and minor accidents observed in the pupils of a school of physical culture, there were noted: 56 unimportant lesions, 11.5 per cent.; 304 slight, 63.5 per cent.; 117 medium, 20.2 per cent.; and 17 serious, 3 per cent.

Lesions classed as "unimportant" did not require any interruption of exercises. Slight lesions necessitated a rest of from ten to fifteen days; medium ones a rest of from fifteen to thirty days; and serious ones an interruption of exercises during a period of thirty days or more. The moment when the injured person could resume exercise without harm was considered to be the moment of the "recovery."
as far as the physical training aspect was concerned; but this did not always tally with clinical recovery. According to their localisation, the various lesions referred to were classified as follows: joints, 185 or 38 per cent.; muscles, 57 or 12 per cent.; tendons, 42 or 8.5 per cent.; bones 53 or 11 per cent.; foot, 56 or 11.5 per cent.; lesions accompanied by haemorrhage, 91 or 19 per cent.

In conclusion, serious lesions are very rare, but slight lesions are common and very often have results which later on prevent the continuation of physical exercise (O. Schmith).

According to data supplied by a German insurance company in 1925, 8,681 accidents were caused by various sports among 2,500,000 insured persons aged under nineteen years. The insurance company remarked that contrary to what happens during medical examination for compulsory military service where the examinee may do his best to put up a show of pathological symptoms — the man who goes in for sports may strive to conceal any defect which might debar him from engaging in the exercise on which he is intent.

Data referring to the physical constitution of athletes are not very numerous at the present time. By way of illustration, the anthropometric and clinical calculations which were made on 192 athletes by Untermüller are shown in tables I and II (page 930).

Other forms of cardiac weakness have been noted in young men (2 to 6.4 per cent.), varicoceles among gymnasts (6), varicose veins (2), inflammation of the apices (3), kyphosis in young men (1) and in gymnasts (3).

As regards the influence of sport on the body, it is essential first of all to distinguish between exercises for which strength and skill are essential, and those which require endurance or swiftness. Then again, it must be recalled that all sports are not equally suitable for all ages. Their effect on the development of the body, and primarily of the heart and lungs, is greatest between the ages of fourteen and nineteen. It is advisable to recommend chiefly open-air sports, and also to see that enough time is devoted to them to permit of adequate training. For exercises where swiftness is essential, the years between nineteen and thirty would seem to be indicated; whereas between thirty and forty the exercises requiring strength and endurance are considered the most beneficial for the body. After forty, quiet movements are recommended, e.g. walking, mountaineering and boating, since they conform best to the possibilities of the body.

An attempt has been made to classify types of athletes. Thus the persons of the asthenic type (Kretschmer) appear to be athletes with power of endurance, with a capacity for prolonged resistance. Athletes having average strength would appear to conform to the same type, but to be distinguished from the latter. On the other hand the “syk nicotine” type (Kretschmer) is only very rarely inclined to the practice of sports (Kohrausch). Gymnasts, wrestlers,

and runners correspond to the athletic type (Basch). As a matter of fact, this classification does not always correspond to the individual aptitudes, and frequently champions belong to one of the athletic categories for which their constitution would not appear to be an indication.

At all events, the doctor is bound to intervene in questions relating to sport, whether it be that relatives become alarmed and consult him, or whether athletic associations (clubs) decide to organise amongst themselves medical and physiological supervision, so that their members may be guided according to their physical aptitudes, and so sawed, as far as possible, from the effects, which may sometimes be disastrous, of excessive or foolish indulgence in sports (Merkien).

---

Starch Manufacture

The general term "starch" comprises a series of non-nitrogenous carbohydrate (C, H, O). It is made up of microscopic grains of special form found more or less abundantly in almost all vegetable cells.

The name "starch", however, is applied especially to the starchy matter in cereal grains (wheat, maize, oats, rice, etc.), and vegetables (chestnuts, etc.), while the name "leca" is applied to the same substance found in potatoes, manioc root, etc. All the same, these two names really refer to the same substance, differing only in the source, size and form of the grains.

Starch can be obtained industrially by grinding the grains of cereals after first having soaked them in water. During grinding a stream of water circulates over the grain and removes the starch, while the gluten accumulates and is collected on wire gauze, across which the grains of starch pass.

It can also be obtained by crushing the grain and allowing this to ferment for from fifteen to twenty days in five to six times its volume of water. As the result of fermentation, the gluten passes into solution, and by washings with water the starch is separated, collected and washed.

Other processes are based on direct chemical treatment of the cereals. Whatever the method, the starch collected is then dried in a stove and pulverised or broken up.

While rice yields 70-75 per cent. of starch and maize 65-67 per cent., wheat only yields 55-65 per cent.

Insoluble in cold water, starch swells in hot water without passing, strictly speaking, into solution and constitutes the well-known starch paste. The intense blue colour which starch gives with a dilute solution of iodine is very characteristic.

Starch is the first ingredient necessary for the manufacture of glucose and alcohol. It is used in dressing goods, in paper manufacture, hygienic powders, as an agglutinating material in colours, in pastes, in confectionery and pastry, etc.

Among sources of danger must be mentioned: dust raised by the grain, which is generally of poor quality or damaged (with, e.g., acari); starch dust, principally in stove drying; the steam and unpleasant smelling vapours, especially from the alkaline vats; the danger of fire or explosion from the starch, dust, etc.

Mention must be made, too, of the effect from inhalation of the starch dust in confectionery manufacture and the dermatitis resulting from pastes containing formalin or formaldehyde.

Ramazzini even had knowledge of cases of illness (headache, respiratory trouble, etc.) amongst starch makers where the work in question was carried on as a home industry. Thackrah reported on the same state of things in London, but enquiry by Arlidge was quite negative.

No statistics are available as to the health of the workers.

Preventive measures should take the line of closing openings on to main thoroughfares; insisting on concrete floors and walls cemented to a height of about 2 metres; on good general ventilation and exhaust ventilation locally applied where dust is given off; on provision of hoods over fermenting vats connected with ducts carrying gases and fumes to the boiler furnaces. Macerating tanks should be in the basement and have impermeable walls. Bolting, crushing and sieving should be done in closed apparatus. Residues should be removed daily, residuary water should not be allowed to run directly into streams, but should be
treated, e.g., on sewage farms; apparatus and machines creating noise should be isolated; all necessary measures must be taken to prevent fires and explosion from the starch dust.

**Stone Industry**

**Crude Materials**

The stone industry makes use of a considerable series of rocks which may be classified as hard or eruptive rocks, e.g., granite, basalt, and porphyry, and sedimentary or soft rocks, e.g., marble, alabaster, slate, sandstone, and lithographic stones.

The stone which is most widely used, but which is also the most dangerous to the health of stone-workers is sandstone (French, Gres; German, Sandstein; Italian, Pietra arenaria; Spanish, Piedra arenosa). All sandstones are sedimentary rocks, composed for the most part of quartz granules, varying in fineness, and held together by an agglutinating material, which may be argillaceous, silicious, or dolomitic; hence the names of silicious sandstone, calcareous, or dolomitic; hence an agglutinating material, which may be argillaceous, silicious, or dolomitic; hence the names of silicious sandstone, calcareous, or dolomitic; hence the names of silicious sandstone, calcareous, or dolomitic.

Silicious sandstone is the most difficult to work, but it is, on the other hand, the most resistant to weather. In practice the different kinds of stone are not distinguished according to their geological formation, but simply according to the locality in which they are found.

**Ganister** is a quartzite rock found in Great Britain; it is very hard and contains from 90 to 99 per cent. of silica; it is found under the coal measures. This quartzite does not melt even at high temperatures and is in consequence used for making bricks required for lining metallurgical furnaces and crucibles. The rock is generally obtained by blasting; the larger pieces are then broken by the hammer. The fragments are then placed in powerful crushing machines before being made into bricks. Much dust is liberated, particularly when large pieces are broken up by blows of the hammer.

**Buhrstone** is another very hard stone, perhaps the hardest of all known rocks; it is used in Great Britain for making millstones. This stone (which is found in France) is a variety of reddish-yellow flint.

**Grindstones** are made of calcareous or silicious sandstone or schist, the silicious variety being the most popular. There are soft, hard, and medium varieties. Eastern stones contain a kind of dolomite with the sand; the French contain mica; the American a kind of corundum.

**Lithographic stone** is composed of a special calcareous argillaceous material with traces of oxide of iron. It is very easy to polish.

Under the name of **marble** is included scientifically a variety of crystalline limestones with a characteristic granular appearance. Technically all varieties of granular and compact limestones which can be polished are included. The appearance and colour are very variable, depending on the nature and amount of heterogeneous substances present, such as metallic oxides, talc and fossil remains.

**Granite** is a crystalline rock, very abundant in nature, where it forms mountains; it is classed, as regards its dressing, among the hardest rocks. It is chiefly composed of a mixture of felspar, quartz and a coloured amalgam, which is generally mica or hornblend. In contrast to marble, granite is not affected by weather, but it is much more difficult to work. It generally polishes very easily.

**Alabaster** (French, Albatre; German, Alabaster; Italian and Spanish, Alabastro) is a limestone formed essentially of carbonate of calcium or sulphate of calcium.

**Slates** (French, Ardoises; German, Tafelschiffer; Italian, Ardesia; Spanish: Pizarra) are argillaceous schists, amorphous or of indistinct crystallisation, containing as impurities oxides of iron, lime or magnesia (see the articles "Alabaster" and "Slate").

**Lava** is a rock formed of a mixture of minerals, especially of silicates, thrown from volcanoes in a fluid or pasty state and then cooled and solidified on the outer slopes of the volcano as trachite, basalt, etc. Volcanic lava, chiefly used in the chemical industry, contains about 55 per cent. of silica.

**Serpentines or ophites** are formed of hydrated silicates of magnesia; they also contain iron. They can be easily polished and give a smooth homogeneous surface with a colour which recalls that of a serpent, hence the name.

**Porphyry** is a volcanic rock of a different kind containing crystals, quartz and felspar. Its colours are well known.

There must also be mentioned pebbles found in streams and rivers, of different sizes and shapes, but generally round. Pebbles may be found of varying composition and colour, of almost pure carbonates or of silica, and also of slate more or less rich in iron, manganese, etc.

**Industrial Operations**

The stone industry includes three principal groups of operations, the work (i) of quarrying or mining, (ii) of stone dressing, and (iii) of polishing.

Quarries are generally worked in the open; more rarely, like mines, they are underground. Open quarries are generally worked in ledges, either by
means of picks, wedges, or by spiral wire drills.

The blocks are often rough hewn and dressed on the site of the quarry. Underground work is similar to that in mines—explosives are used, while compressed air tools are coming more and more into use. (See articles "Mines", "Alabaster", and "Slate").

Stone-getting is carried out by labourers and quarrymen; the former remove the useless layer covering the stone which is being got, by means of pickaxes, spades, shovels, and occasionally explosives. The getting of the stone itself rests with the quarrymen. This occupation does not require what are called "skilled" workmen, but rather individuals having several years' experience and possessing strength. The danger is to a certain extent dependent on the kind of rock worked.

When the stone is dressed at ground level or at a slight height, the men work in a crouching position, which induces troubles of the circulation and of the muscles. The eyes are liable to accidents caused by particles of dust with sharp edges. Hernia is often caused by handling and lifting heavy stones. If stone is carried on the shoulder, tumours, such as fibrolipomata, may result. (See article "Alabaster." )

cement bricks.

When the stone is dressed at ground level or at a slight height, the men work in a crouching position, which induces troubles of the circulation and of the muscles. The eyes are liable to accidents caused by particles of dust with sharp edges. Hernia is often caused by handling and lifting heavy stones. If stone is carried on the shoulder, tumours, such as fibrolipomata, may result. (See article "Alabaster." )

The danger from dust is strictly in accord with the chemical composition of the stone. It has been repeatedly stated that the presence of silica in dust is the essential factor in the production of respiratory lesions. Middleton, for example, has been led by his observations to the opinion that the effect of dust liberated by grinding wheels, made of artificial abrasives, is less serious than the effect of dust from sandstone grinding wheels (see also article "Abrasives"). If the particles of dust are sufficiently fine, pointed and sharp, the respiratory apparatus is more affected, for the dust can then reach very far into the respiratory tree.

The work of modelling and carving for designs and lettering is done by hand or by compressed air tools.

DANGERS

Apart from accidents, due to falls, landslides of masses of rock, and the use of explosives, which are particularly frequent and often serious to quarrymen, the principal danger certainly is from the inhalation of dust. It may be said that manual labour and the use of old-fashioned tools, that is to say, the application of old methods, are more favourable than work by modern mechanical methods—if indeed the term "favourable" can be used in this connection.

Ramazzini long ago emphasised the danger arising from the inhalation of dust liberated during hewing, cutting and polishing marble and stone, to workmen in this industry, a large number of whom become asthmatical and tuberculous. Whereas it is true that certain operations can be carried out by wet methods, it is also true that other work, or certain kinds of stone, do not permit the use of such methods. Moreover, the ever-increasing use of compressed-air tools, which do not lend themselves to the use of wet methods, raises enormous quantities of dust. This danger is all the more serious in that the work is usually done in closed shops.

The danger from dust is strictly in accord with the chemical composition of the stone. It has been repeatedly stated that the presence of silica in dust is the essential factor in the production of respiratory lesions. Middleton, for example, has been led by his observations to the opinion that the effect of dust liberated by grinding wheels, made of artificial abrasives, is less serious than the effect of dust from sandstone grinding wheels (see also article "Abrasives"). If the particles of dust are sufficiently fine, pointed and sharp, the respiratory apparatus is more affected, for the dust can then reach very far into the respiratory tree.
Before the tubercle bacillus can come into play and aggravate the pneumoconiotic lesion, there doubtless exists among stone-workers a clinical pre-tuberculous period which is well defined and can certainly develop without tuberculous complications (see articles "Silicosis" and "Occupational Diseases: Respiratory System"). It is difficult to draw up a list of stones according to their danger to the respiratory tree; they vary too often from country to country, and even from district to district in the same country. Nevertheless, enquiries made in different centres prove that the morbidity and mortality rates are higher among workers on sandstone, ganister and granite than among workers on limestone and marble. The dust of "buhrstone" has a very injurious effect on the respiratory apparatus, and this fact explains the excessive mortality found in Great Britain among workers in this industry. The dust of ganister is also very injurious for the men. But, according to Collis and Smith (1917), mixing ganister with clay for making refractory bricks, diminishes the risk of tuberculosis among the workers exposed to the dust.

Dust may also cause irritation of the mucous membranes of the eyes, nose and mouth, of the auditory meatus, as well as the skin. We must also note disease arising from exposure to cold; from the inhalation of fumes and toxic vapours during the use of explosives for getting the stone; from awkward positions during work: but above all, from humidity which exists in certain mines or quarries. This last trouble is equally common in workshops where the stone is worked by wet processes during sawing, planing, and polishing at the same time. It is necessary also to take into account the possibility of infection from dust, which may serve as the vehicle for such germs as actinomycosis, and ankylostomiasis from dirty water, as well as the possibility of poisoning from the materials used in polishing, e.g. lead poisoning from putty powder and oxalic acid. Troubles, such as headaches, have been reported from the use of explosives.

Some experts have drawn attention to the troubles and lesions caused among stone-cutters by compressed-air tools. During an enquiry carried out in the United States (1917-1918) Hamilton found 181 stonemasons suffering from "dead finger" caused by these tools: among 15 sandstone masons, 3 cases; among 38 limestone masons, 34 cases; among 50 granite masons, 43 cases; among 78 marble masons, 44 cases. But the affection was not serious. The use of these tools has also been correlated with a high death-rate among granite cutters (Hay). The introduction of pneumatic tools into the granite yards at Aberdeen was made very rapidly, so that by 1905 almost all the workshops were furnished with them, and the death-rate among stone-cutters and masons over 21 years was as follows:

<table>
<thead>
<tr>
<th>Period</th>
<th>Tuberculosis</th>
<th>Other pulmonary diseases</th>
</tr>
</thead>
<tbody>
<tr>
<td>1895-1899</td>
<td>47</td>
<td>28</td>
</tr>
<tr>
<td>1900-1904</td>
<td>50</td>
<td>31</td>
</tr>
<tr>
<td>1905-1909</td>
<td>49</td>
<td>12</td>
</tr>
</tbody>
</table>

From 1895 to 1909 the mortality from pulmonary tuberculosis in the general population of Aberdeen was falling. During the period 1905-1909 fewer men were employed in the industry, and the reduction in deaths from other lung diseases indicates what should have occurred for tuberculosis.

Further, for the building section of the industry working in the open air, the proportion of all deaths due to phthisis was 25 per cent., while for the monumental section, working in closed sheds and so more exposed to dust, the proportion was 38 per cent. In fact research indicates that the danger is in proportion to the quantity of dust inhaled and to the length of time passed in the trade.

Statistics

An old enquiry made by Sommerfeld, which included 2,015 German stone-cutters, gives the following figures: 8.38 per cent. of hewers were tuberculous, 10.77 per cent. were suspected of tuberculosis, 8.15 average for the two); 17.97 per cent. were affected with respiratory diseases. Another enquiry, also quite old, that of Calwer, attributes to these workers an average of about 29 years for cutters, of 32 for polishers, and 38 for quarrymen. It must, however, be emphasised that there are inaccuracies in these figures, due to such factors as change of occupation in winter, interruption during military service, late entry into the work, etc.

Koelsch and Arnstein (1913) have made an investigation among 100 stone-cutters of Untermain (Bavaria), who were visited while at work in the workshops. Of 100 workmen examined, 23 were between 15 and 19 years, 29 between 20 and 29, 31 between 30 and 39, 13 between 40 and 49, and 5 above 50 years. Their social and hygienic conditions were bad; there was no efficient withdrawal of the dust; the workmen did not wear protecting goggles. Almost half (44) declared that their fathers had died of, or were ill with, respiratory diseases; and 41 of them that their fathers had been stone-
cutters as they were; 46 workmen complained of subjective troubles; 18 of cough with expectoration; 9 of thoracic pains. At the examination only 29 showed a completely normal condition of the respiratory system; the others all presented pulmonary lesions, 42 per cent. to a slight degree, 24 per cent. to a serious degree. In the three large stone-cutting works at Untermain, there were registered from 1900 to 1905, 139 deaths, which are classified as follows:

<table>
<thead>
<tr>
<th>Causes of death</th>
<th>Less than 20 years</th>
<th>From 21 to 30 years</th>
<th>From 31 to 40 years</th>
<th>From 41 to 50 years</th>
<th>Above 50 years</th>
<th>Total</th>
</tr>
</thead>
<tbody>
<tr>
<td>Tuberculosis</td>
<td>3</td>
<td>25</td>
<td>36</td>
<td>31</td>
<td>14</td>
<td>4</td>
</tr>
<tr>

<td>—</td>
<td>1</td>
<td>2</td>
<td>4</td>
<td>—</td>
<td>—</td>
</tr>
<tr>
<td>Other diseases</td>
<td>4</td>
<td>3</td>
<td>4</td>
<td>5</td>
<td>2</td>
<td>1</td>
</tr>
<tr>
<td>Total</td>
<td>7</td>
<td>29</td>
<td>42</td>
<td>40</td>
<td>16</td>
<td>5</td>
</tr>
</tbody>
</table>

This shows a total of 113 deaths from tuberculosis out of 159, that is to say, 81 per cent., or almost four out of five. The sickness rate per 100 sandstone-cutters was in 1909 13.6 cases, with 850 days of sickness per 100,000, that is to say, 81 per cent., or almost four out of five. In the United States the number of stone masons in 1918 exceeded 100,000, and, according to different authors, conditions of health were stated to be most serious for those who dress the surface of stone.

One set of figures compares the mortality from all causes for the centre of Barre and Bedford; it is as follows:

<table>
<thead>
<tr>
<th></th>
<th></th>
<th></th>
<th></th>
<th></th>
</tr>
</thead>
<tbody>
<tr>
<td>Below 30 years</td>
<td>22.98</td>
<td>7.64</td>
<td>28.39</td>
<td>4.05</td>
</tr>
<tr>
<td>30 to 49 years</td>
<td>65.35</td>
<td>46.23</td>
<td>52.43</td>
<td>47.18</td>
</tr>
<tr>
<td>50 years and over</td>
<td>11.69</td>
<td>46.13</td>
<td>19.18</td>
<td>48.77</td>
</tr>
<tr>
<td>Total</td>
<td>100.00</td>
<td>100.00</td>
<td>100.00</td>
<td>100.00</td>
</tr>
</tbody>
</table>

If the figures are examined according to the type of stone worked, very high records are found, particularly for pulmonary diseases. Thus, for example, for masons on limestone in the United States and Canada (1913-1917) the causes of death claimed the following rates per 100,000: infections, 58.0; pulmonary tuberculosis, 385.6; pneumonia, 104.3; other respiratory diseases, 75.4; heart disease, 191.1; digestive system, 127.6; violence, 208.7. The death-rate for the general male population will be given later. For the period 1905-1918 the mortality is presented as follows:

<table>
<thead>
<tr>
<th>Number of persons exposed to risk</th>
<th>Number of deaths per 1000</th>
<th>1905-1909</th>
<th>1910-1914</th>
<th>1915-1918</th>
</tr>
</thead>
<tbody>

1 Except for the last three months of 1918.

In Austria, Bass has carried out an examination of stone-cutters in Vienna, and in 45.1 per cent. he found pulmonary lesions, of which number 29 per cent. were tuberculous. Diseases of the vessels are also common, especially various conditions of the lower limbs. From 1893 to 1904, 50 per cent. of fatal cases were due to tuberculosis, and 58.5 per cent. to respiratory diseases. The average age of workers at death was 46 years.

Australia. — The enquiry of Badham and Assheton, carried out in 1924 in seven quarries of New South Wales, was based on a medical and radiological examination of 15 workmen employed in crushing at a basalt quarry and of 9 workers at a marble quarry. In this investigation the experts did not meet with any case of pneumonoconiosis. The dust of felspar can be very dangerous, but if it is moistened, it does not cause trouble.

Of the 15 men employed working on basalt, 9 complained of difficult respiration, but the clinical signs of dyspnoea were only found in two; two workmen complained of rinitis and catarrh; one of bronchitis. The experts are of the opinion that, except for the crushers, the dust of basalt and dolomite produced negligible effects as regards the production of pneumonoconiotic fibrosis. They consider, however, that prolonged work at crushing can lead to the formation of fibrosis, rhinitis, etc.

A statement, dealing with the period from 1919 to 1924, made by the New York branch of the International Association of Granite Cutters, on the health of stone-cutters, shows that out of 52 deaths, registered in the period, 36.5 per cent.
STONE INDUSTRY

were certified as due to tuberculosis and 17.3 to pneumonia. The Association claims that 98 per cent. of all granite cutters were their members.

A recent enquiry (1924) of the Division of Industrial Health of the Labour Department of the State of New York on the health of stone masons has brought out the following facts: the men were of good physical appearance, even above the average. They had a resistance above the average to sickness, although the number of deaths was relatively high and in spite of the large proportion of deaths from respiratory affections.

The examination of 67 granite cutters showed 37 (55 per cent.) with damaged lungs. The danger from dust is undoubtedly very serious in this occupation. Nevertheless, the investigator estimates that the installation of apparatus for withdrawing the dust by suction (of which he gives interesting details) can greatly diminish the dangers.

In Great Britain (according to Collins) the death-rate of limestone masons (1910-1912) is quite favourable; when compared with standard population, aged from 25 to 65 years, it showed comparative figures of 129 for pulmonary tuberculosis (142 in the whole male population), 6 for Abrod tuberculosis (compared with 2), 38 for bronchitis (compared with 36), 54 for pneumonia (compared with 67), and 12 for other respiratory diseases (compared with 14).

Workmen employed on ganister suffer from pneumoconiosis, and Birmingham gives the death-rate for 1,000 workmen as 42.3 for ganister getters, 179.8 for crushers, and 28.2 for makers of ganister bricks.

United States. — The figures relating to granite cutters are numerous. Those of Vermont for the period 1913-1918 show a death-rate of 1,044.3 per 100,000, and those of New England a death-rate from pulmonary tuberculosis of 962.3 per 100,000 in 1912-1913, and of 1,056.7 in 1915-1918. In the Southern States, where the work is done in the open air, the death-rate from tuberculosis is limited to 441.1 per 100,000. At Vermont for the period 1910-1914 (before the general introduction of pneumatic tools), the granite workers showed a death-rate of 771.1 from tuberculosis compared with 125 for the whole population (per 100,000).

In 1917 the death-rate from the same cause was 1,095.5 per 100,000 compared with 96.4 for the whole population, and for the granite cutters of the United States and Canada, the death-rate from all causes was 25.7 (1917) per 1,000 against a rate of 18.1 for the male population of New England. In that country during the period from 1913 to 1917 the death-rate from different causes was as follows: death-rate (per 100,000): infections 19.1; pulmonary tuberculosis 1,002.7; diseases of the heart 175.3; pneumonia 161.6; violent causes 74. For the district of Barre and for 12,930 persons exposed to the danger during the period from 1911 to 1917, the death-rate per 1,000 was 20.11 for all causes, 11.84 for pulmonary tuberculosis, and 2.76 for other respiratory diseases. If it is desired to take into account the death-rate for all causes and by age groups, the following figures are obtained:

<table>
<thead>
<tr>
<th>Age</th>

1 Except the last three months of the year 1918.

The death-rate is more serious for sandstone masons. For New England and for the period 1913-1917 the death-rate per 100,000 showed the following figures: 96 infections; 973.3 pulmonary tuberculosis; 144.2 diseases of the heart; 260.3 pneumonia; 204.3 other respiratory diseases; 132.1 violent causes. For all causes and for pulmonary tuberculosis compared with the whole number of persons exposed the figures are:

<table>

1 Except the last three months of the year 1918.

In Great Britain the death-rate from respiratory diseases among this group of workmen appears very high in compar-
son with the death-rate for the standard population. As a matter of fact, for the period 1908-1909, the following are the comparative figures: 415 for tuberculosis (compared with 142 for the standard population); 49 for pulmonary fibrosis (compared with 21; 116 for bronchitis (compared with 38); 120 for pneumonia (compared with 67); 26 for other respiratory diseases (compared with 14).

Barwise made an investigation extending over ten years in Derbyshire among sandstone workers. He found an excessive death-rate from pulmonary tuberculosis, which among quarrymen was 29 per cent., whilst the same disease caused only 4.6 per cent. of deaths among agriculturists. On this basis in calculating the death-rate from tuberculosis without taking age into account, he found a rate of 5 per 1,000 among quarrymen and masons, dressing and quarrying stone, compared with 0.72 for agriculturists. The deaths from tuberculosis among sandstone masons are ten times greater than among limestone workers.

Formerly in France a heavy sickness and death-rate was known among the masons (see further on). Most regards marble, there are no available statistics, although Bertillon has drawn attention to high death-rates in this occupational group in France, Italy, and Switzerland. The figures, however, are often mixed with those concerning stone masons (see further on).

As regards stone, statistics are fairly numerous. In the State of Ohio, for example, in 1909 the death-rate from tuberculosis was calculated to be 29 per cent.; in the State of Massachusetts for the town of Quincy, during a period of 16 years and with a total of 343 deaths, there was a percentage of 41.4 caused by pulmonary tuberculosis, 12 from other respiratory diseases, 12.8 from diseases of the heart, 7 from violent causes. The average duration of life was, however, rather high: 47.8 years. But it should be noted that a sick workman may change his occupation for another, which is not so unhealthy and is less fatiguing, while remaining registered under the former occupation at his death; this falsifies statistics.

According to the Prudential Insurance Company of New York, the number of deaths from tuberculosis, among the cutters, planers and polishers of marble, is very high, reaching 40 per cent. of all deaths in the age group of 25 to 34 years and 34.4 in the group 35-44.

While this source of information shows us a relatively low death-rate from all causes for the age groups below 25 years, but higher for those above 25 years, it also reveals that the rate from pulmonary tuberculosis is excessive, for that rate is 5.41 per 1,000 for marble and stone-cutters compared with 2.65 for the industrial group, and 1.66 for that of commerce.

According to the census report (1908-1909) supplied by the Statistical Department of the United States showing 1,657 deaths from all causes among stone masons, 509, or 30.7 per cent., were due to pulmonary tuberculosis, which showed a percentage of all deaths of 43.5 for the age group 25 to 34 years, of 44.1 for the group 35-44, and of 41.6 for the group 45-54. Statistics of the Prudential Insurance Company for the period 1897 to 1914, when compared with the death-rate from tuberculosis among the male population in the registration States, give for marble and stone masons a percentage of 53.1 at ages 25-34, against 30.5 for the whole population; of 44.4 at ages 35-44 against 23.4; of 39 at ages 45-54 against 14.7; and of 26.7 at ages 55-64 against 7.7. An all-round percentage for all workmen aged 35 and upwards amounted to 13.9 as against 33.6 for stone masons.

In Great Britain the statistics used not to show stone masons separately, but included them under "quarrymen employed in working stone and slate" which diminished the heavy pulmonary tuberculosis rate. Nevertheless, investigations by experts have emphasised the excessive mortality from tuberculosis and respiratory diseases in this occupational group.

In 1900-1902 these statistics showed a comparative mortality from phthisis of 190 as against 186 for the whole male population between ages 25 to 65.

The average age at death of granite cutters, masons and polishers at Aberdeen during the period 1910-1919 was 48 years for cutters who died of tuberculosis, 61 for those who died of respiratory diseases other than tuberculosis, 62 for those dying of diseases of the circulatory and nervous systems, and 56 for all causes of death.

In Holland the death-rate of stone and marble cutters during the period 1908-1911 was as follows:

<table>

Close collaboration between the public health services for combating tuberculosis,
those of the factory inspection department and the tuberculosis clinics made possible a radiographic examination in 1923 of 274 stone-cutters out of a total of 963 above 18 years who had occasion to visit the doctor. During this visit, attention was given to various factors which can play a part in health conditions of the workman, as well as to the danger of the occupation in general.

Of the 963 cutters 114 were aged from 20 to 25 years, 151 from 25 to 30, 308 from 31 to 40, 190 from 41 to 45, 108 from 46 to 50, 80 from 51 to 55, 57 from 56 to 60 years. Classification according to the number of years of work resulted as follows: 36 for less than 5 years, 65 from 6 to 10 years, 222 from 11 to 20 years, 324 from 21 to 30 years, 164 from 31 to 40, 150 from 41 to 50, 80 from 51 to 55, 57 from 56 to 60 years and one for 67 years.

The occupation of stone-cutter appears to have been carried on by many consecutive generations. The enquiry seems to show besides that men of poor physique do not choose this occupation. The majority of workmen examined felt in perfect health. Many of them, however, after questioning, coughed from time to time, but without expectorating. This is why there were but few opportunities for detecting tuberculosis by examination of the sputum. In 28 cases where this examination was possible, in only 6 was the tubercle bacillus found. By questioning the men it was brought out that this infection existed 8 times among grandparents, 66 among parents, 85 among brothers and sisters, 8 times among the wives, and 45 times among the children of stone-cutters.

The greater part of the workmen work exclusively at freestone (571), very few at sandstone and chiefly freestone (241); 102 worked at other stones, such as marble and granite. The masons bring home a piece of stone home with him to finish, and it also happens that a mason may take a piece of stone home with him to finish, but the economic advantage is annulled by the danger which arises to health.

The workshops are generally well arranged hygienically and give the impression that much has been done in this respect, thanks to the law, for stone-cutters.

As regards the consumption of alcoholic drinks, it seems to have much diminished during the last 10 to 25 years. Young workmen are usually abstainers, or small consumers of alcohol. The same may be said regarding the habits of smoking or chewing.

Very few masons wear respirators, and many do not even wear goggles.

The clinical examination was supplemented by a radiographic examination. It enabled a positive diagnosis as regards pulmonary lesions to be made in 135 cases which had clinically been found negative.

The use of X-rays for detecting pulmonary lesions among stone masons has proved the necessity of arranging a medical examination for adults. This enquiry has also resulted in organising conferences in the various departments of the Dutch Federation of Stone Cutters by experts and medical inspectors, in order to make known to those concerned the occupational risks and the best means for preventing them.

In Switzerland, according to the Health Insurance Office, for men in the building trade at Zurich for the period 1900-1911, the sickness rate of stone-cutters recorded at the Office was as follows:
When this rate of sickness extending over twelve years is compared with that for certain other groups of workmen, the stone-cutters are found to present a sickness rate of 41 per cent. against 30 per cent. for locksmiths.

The Swiss Association of Stone Workers return, for the years 1903-1911, a total of 3,889 members, shown in return, for the years 1903-1911, a total of 3,889 members, shown in the statistics with an average of 22.6 per cent. of sickness of an average duration of 39 days for each case. The diseases of the respiratory system numbered 44 per cent., of sickness extending with an average of 22.6 per cent., of sickness of an average duration of 39 days for each case. The diseases of the respiratory system numbered 44 per cent., of sickness extending

An investigation organised by the National Tuberculosis Association of the United States (1919) showed that in the districts where marble was worked the death-rate from tuberculosis was lower than in other districts, and the same held good for districts where slate and talc are obtained.

The same conclusions can be drawn from English death-rates. According to those for 1919-1921 the comparative figures for deaths from respiratory diseases compared with figures for deaths of the standard population, were as follows:

<table>
<thead>
<tr>
<th>Material worked</th>
<th>Deaths</th>
<th>Death-rate per 100,000</th>
</tr>
</thead>
<tbody>
<tr>
<td>Slate</td>
<td>93</td>
<td>111.3</td>
</tr>
<tr>

Mathew Hay has shown that at Aberdeen the death rate from tuberculosis among granite workers is at least three times higher than the average rate for young men of 21 years and rises to almost 6.2 per 1,000 at all ages. Collis found that granite-cutters who work in closed workshops show a smaller chest expansion and more respiratory trouble than do men working in the open air. According to the same writer, the death-rate from pulmonary tuberculosis due to different kinds of stone is as follows:

<table>
<thead>
<tr>
<th>Material worked</th>
<th>Deaths</th>
<th>Death-rate per 100,000</th>
</tr>
</thead>
<tbody>

</tbody>
</table>
Death-rates per 1,000 living: coalminers 1.0; masons (limestone) 1.4; miners (iron) 1.5; miners (lead) 3.9; granite cutters 6.2; masons (sandstone) 16.7; ganister-work 22.3.

**Pathology**

Generally speaking, stonemasons have a superior physique, which would lead one to expect them to offer a greater resistance to disease. But statistics show that, on the contrary, these workers are unusually prone to respiratory diseases and to tuberculosis in particular. Although autopsies have not been made which would enable the quantity of silica dust contained in the respiratory tree to be determined, and although the nature of the dust inhaled calls for further scientific research, yet the available figures show that the danger lies particularly in the quantity of silica present in the dust inhaled. An American enquiry of recent date (1922) shows that for all the stone-cutting centres of the United States, the deaths due to tuberculosis and to non-tuberculous respiratory diseases (bronchitis, pneumonia, asthma) among granite workers have been increasing, whereas there has been a general diminution for adult males of the rest of the population.

The wearing down of steel tools which is quite common in the case of certain varieties of stone, such as ganister and quartz, gives rise to metallic dust, which also plays a certain part in the production of respiratory diseases.

It is obvious that among these workers, diseases of the respiratory system occupy the first place: rhinitis, pharyngitis, bronchitis, pneumonia and especially the pneumoconiotic form improperly called "silicosis" which is frequently complicated by tuberculosis. This is a matter which urgently calls for the attention of experts, for very often the diagnosis of phthisis is made in the case of lesions which are non-tuberculous. (See articles "Tuberculosis", "Diseases of the Respiratory System", "Dust", etc.) As long ago as 1913 Sleeswijk, of Delft, expressed himself very strongly against the readiness with which the dogma was accepted that "dust equals tuberculosis amongst stone cutters", and he desired that this dogma should be submitted to the severest criticism. It is necessary to examine carefully the patients concerned and to make a very conscientious differential diagnosis. He recalls, for example, that Elias in his thesis, 1909, on stone-masons reported that among 104 masons of 21 to 50 years, 38 showed on examination, symptoms of pulmonary lesions (tuberculous), or were suspected of having such; but that only in the case of two out of 24, who had been recognised as tuberculous, were bacilli found in their sputum.

As the result of an enquiry in the Elbsandstein district, Domann (1925) considered that the lungs of stonemasons show characteristic lesions which should not be mistaken, as is often the case, for pulmonary tuberculosis. Examination by X-rays can help the differential diagnosis, but Domann admits that there still remain in this matter some very obscure points.

Every clinical effort, by examination of sputum, radiography, and where necessary observation in hospital, should be made to arrive at a true diagnosis with a view to adequate and early intervention. The Medical Silicosis Bureau of South Africa, the Mines Department of the United States, the Medical Inspection Department of Holland, the official and private agencies of Germany and Italy, a technical committee formed on the suggestion of the Minister of Commerce of New South Wales, 1925, etc., have undertaken, or are about to undertake, a series of general investigations into the action of mineral dust on the respiratory system, making particular use of radiography.

Among these investigations mention may be made of that undertaken in Italy by C. Bianchi (1928) on the frequency of tuberculosis among Carrara marble workers, and that undertaken in the United States (1929) in the granite industry, in which the workers are exposed to dusts very rich in silica. The latter enquiry has brought out the close relationship between exposure to dust and state of health. The constant presence of silicosis with special radiological characteristics; manifest susceptibility to tuberculosis, generally appearing after twenty years' work; lesions almost invariably at the base of the lung and terminating fatally; the relationship between duration of exposure to dust, and the tuberculosis incidence and fatality rates; the relationship between tuberculosis morbidity and duration of employment of pneumatic tools; the high incidence of diseases other than tuberculosis.

In Great Britain an enquiry by Sutherland, Bryson and Keating (1929) on granite brought out the incidence of silicosis among the granite workers. Of the 494 examined, 290 were suffering
from fibrosis. Radiography showed that among 211 workers there were 36 clear cases of silicosis. Another report of 1929 by Sutherland and Bryson deals with cases of silicosis found among sandstone workers (buildings under construction, quarries). These authors examined 454 workers, including 266 by radiography, and found fibrosis, probably silicotic, among 112, chiefly those aged between forty-five and forty-four years.

In France, Heim de Balsac, Agasse-Lafont and Feil (1930) drew attention to occupational pneumoconiosis among sandstone paving workers (hewers and quarriers).

Digestive troubles are also common, due in part to the large quantity of drink taken by the workmen, to be explained in part by dryness of the throat from dust. Work in wet workshops, especially those for polishing, causes forms of rheumatism which are often accompanied by laryngitis and tracheitis. An irritant effect at the back of the mouth is also caused by the materials used in polishing, such, for example, as oxalic acid.

Accidents to the eyes are very frequent, due to fragments from the tools, spicules of stone and other foreign bodies. The conjunctiva and cornea are very often the seat of injuries and ulcers, which may become complicated in consequence of infection. Bass found at Vienna that 48 per cent. of young workmen and 78 per cent. of old had been victims of eye accidents.

Nerve troubles have been reported among masons making use of compressed-air tools. One cannot, however, regard them as special occupational diseases. Southard and Salomon have reported a case of cramp in a granite cutter (see article "Pneumatic Hammers").

A rare and interesting case of paralysis of the left vocal cord following upon pleuro-pericardo-mediastinitis in a patient suffering from pneumoconiosis was described in 1931 by Lacroix and Wild.

Among the stone-breakers and crushers callosities of the hand are noticed, set up by the pressure exerted by the tools; according to Bramwell, a scleroderma caused by the handling of chisels in cold weather seems to be quite frequent, as well as lesions of the palm caused by limestone and lime. The hands are dry, hard, and swollen; the skin scales and peels; the nails become brittle, thin and are streaked along the length of the nail; the interdigital skin is very inflamed and shows incrustations on a level with the articulations. The dust may also cause eczema of the external ear and of the auditory meatus, and even irritation of the tympanic cavity.

The lesions of the hand and fingers, especially of the index, may become infected and complicated by whitlow and phlegmon.

Very painful lesions are caused by lime and oxalic acid.

Figures from the above sources also show a great frequency of accidents among stone-workers: it is sufficient to mention blasting, falls of masses of rock, transportation, breaking and crushing by hand, in order to understand the cause of this frequency. Hernias, ruptures of muscles, and lumbago are fairly common results of the exertions demanded by work on stone.

**Hygiene**

The organisation of work in stone quarries and mines should take into account the measures laid down for coal mines, in all that concerns, for example, work in galleries, drilling, the use of explosives, ventilation, lighting, and the removal of water. Accident prevention during the raising and removal of blocks of stone demands very particular attention, for very often the moving of stone from the face to the exit of the quarry or mine calls for great force and is dangerous work.

Stone may be worked either in the open air or in workshops. In the first case the workman should be protected against the injurious action of wind, of draughts and bad weather (Germany, Denmark). German legislation also provides measures for quarry workers, who are to be protected against the action of the sun, either by roofs, or by sheds closed on three sides. These measures are also adopted by Holland.

The workshops should have a smooth impermeable floor, which should be washed down each day on the conclusion of work; if the work is done wet, provision must be made for draining away the water (Denmark). The height of the workshop is not allowed to be less than 10 feet in Denmark and 11 feet in Holland; in Holland floor space is also called for sufficient to provide each worker with not less than 20 cubic metres of air, which must be renewed; there must also be good lighting and adequate cleanliness of the workshops (Denmark, Holland). Provision of spittoons, respirators and goggles is also
laid down by legislation both for quarrymen and for those employed in the workshops. In Danish and Dutch legislation it is besides laid down that work on silica stones shall be done wet, and that each man shall be at least 1½ metres from the next; and in Holland 2 metres when working on sandstone.

The German legislation also provides that when sandstone is being worked, there should be a distance of at least 2 metres between each banker. The raising of dust, as well as the spraying of slush from apparatus and machinery, must be suppressed as much as possible.

The workmen employed in carving stone with compressed-air tools should be protected against dust by a helmet covering the whole head, into which air enters under pressure. In Holland measures are taken to prevent dust caused by work on stone with compressed-air tools from spreading about, but it should be removed by adequate means.

Every quarry and every workshop ought to be provided with cloakrooms and overalls, which should be waterproof (if the work is done by a wet process), lavatories in sufficient number (1 for 5 workers), towels for each person (to be changed each week) (Denmark, Holland), drinking water, canteen with necessary means for keeping and warming the food brought by the workmen; closets, etc.

German legislation provides for the installation, at the quarries, of rest rooms (Aufenthaltszimmer) lighted, with a level floor, warmed in winter, with sitting accommodation for the workers.

The moistening of blocks of stone, especially during very hot weather, if there are no technical objections, is also laid down for sandstone in Germany and Holland. Moreover, similar measures must be taken for other kinds of stone. In dry weather the floors of the workshops (Holland) must also be kept wet.

It is desirable to provide adjustable bankers for the workmen so that the stone blocks can be placed at the most convenient height for work and the workmen need not get into uncomfortable positions.

Whenever occasion permits it, wet methods should be used for crushing and polishing; when they cannot be employed, then the best means must be adopted to catch the dust at the place where it is generated and to evacuate it from the workshop.

Research work was carried out in the United States in 1930 to determine the best methods of collecting the dusts arising when granite is worked with the surfacing machine or pneumatic tools (which give off the most dust) (Hatch, Drinker, Choate).

It is the workmen's duty to take the greatest possible care with regard to their food and personal hygiene, in order to insure good conditions of resistance against infection by tuberculosis; it is equally the duty of the employers to provide for healthy conditions in closed workshops. Enquiries made in different countries show that in the centres concerned there is no accurate appreciation of the seriousness of the danger from dust to the health of workmen in general, and in particular to stone masons. That is why the Dutch Government has decided upon the following rules: one shift to three hours and a half, followed by a rest of at least half an hour. The Commission of enquiry of the United States suggests for granite workers, time for recreation and holidays from time to time long enough to increase their resistance to disease.

In Denmark it is compulsory to post up the Regulations laid down by the Government.

The Industrial Arbitration Court of New South Wales (Sydney) fixed, in November 1925, forty hours' work a week for sandstone quarrymen. The arbitrator based his decision on the statistical documents put in evidence, which proved the unhealthiness of quarrymen's work.

The Health Service of Ohio published in 1914 the following recommendations:

Employers should co-operate one with another to fight against the frequency of pneumonia and tuberculosis by observation of the following measures: engage only men of good physique especially in the case of young workmen; instruct workmen on the occupational risk of their work; institute periodical medical examinations; only carry out machine planing and sawing by a moist process, using mineral oil; clean workshops daily; provide openings in the walls at a level with the floor, or rather at about 1 metre in order that the dust, which is rather heavy, may not rise in the atmosphere; install where possible local suction apparatus, especially in the case of machine work.

LEGISLATION

Women are excluded from work in stone quarries in Germany and Greece; women of less than 18 years are, however, admitted to some processes with the sanction of the administrative authority and for a six-hour day's work. They are absolutely excluded from any carrying work.
workmen possesses a valid stone-cutter's card. This card is issued on request by the burgomaster, when he has received from the applicant the completion of his fourteenth year, provided that the workman possesses a valid stone-cutter's card. The Regulations also lay down measures, for preventing the liberation of dust from elevators and sieves, for the care of the floors of workshops, and for the use of respirators in stone-cutting workshops.

The following affections found among stone-cutters are subject to compulsory notification in Holland: silicosis and tuberculosis, silicous dermatitis, silicous rhinitis, silicous ophthalmitis, and silicous conjunctivitis. The English Regulations of 1919 for refractory materials provide that stone-cutting by hand shall be done in the open air, and that crushing and grinding must be done in machines provided with adequate means for the removal of dust, or done by a wet process or in closed apparatus. The Regulations also lay down measures, for preventing the liberation of dust from elevators and sieves, for the care of the floors of workshops, and for the use of respirators in stone-cutting workshops.

The first general examination of adult stone-cutters took place in 1923.

Straw

Straw is composed of the stalks and ends of certain cereals (wheat, rice, barley, rye, oats, etc.) which have ripened and dried, that is to say, the plants have died in a natural manner. As a type of straw may be taken straw made from grain or from wheat. In fact, the term "straw" usually designates straw got from wheat, whilst for other kinds the plant of origin is specified, for instance, rice straw, barley straw, oat straw, etc. It should also be recorded that the world production of wheat straw exceeds alone and by a good deal that of all other types.

Data concerning the pathology of workmen handling wheat straw being included in operations connected with straw in general, efforts will here be confined to dealing principally with pathological manifestations due to wheat straw either in the agricultural industry or in industrial establishments.

The harvesting of wheat dried in the sun occurs in the hot months and is effected by means of a small hand sickle and less frequently with a large scythe. In certain regions (Northern Europe, France Flanders), the Flemish scythe is used. Elsewhere, where the nature of the ground makes it possible and in the case of extensive fields, reaping machines are used. The cut grain is gathered in sheaves and undergoes final ripening. Thereafter the sheaves are transported to a threshing floor for threshing, which has the effect of freeing the grain from seeds and ears. This operation is done by hand or by the help of animals or by machinery. Threshing furnishes, on the one hand, grain and, on the other, straw and chaff (composed of fragments of stalks, ears and waste foreign matter) — secondary products, but nevertheless of great economic value.

PATHOLOGY

In the Agricultural Industry

During harvesting and threshing operations the workers are exposed to a series of occupational pathological manifestations represented by accidents (use of scythes, reaping machines or mechanical threshing machines), to sunstroke and heatstroke, and to fevers caused by continued exhaustion on prolonged working days commencing at dawn and finishing at dusk with very short rest intervals during the day. At times even the Sunday rest is not observed, for once the grain is ripe the harvest may not be deferred in order to avoid the loss of a certain amount of grain. As characteristic occupational injuries connected with the harvest there should be recalled certain forms of teno-synovitis, often affecting harvesters using the sickle. At times there is a painful swelling, characterised by crepitation situated at the exterior side of the pulse and the lower third of the right forearm and affecting the sheathes of the abductor muscles of the thumb (Palizzari). In other cases there is noted acute synovitis of the wrist and extensor sheath of the left hand (Bonazzi). In the first case the lesion is due to the repeated and prolonged passage of the hand from a state of hemipronation to hemisupination, whilst the thumb in a state of prehension manipulating the sickle accomplishes considerable effort. In the second case the harvester cuts the stalks with the sickle, which he holds in his right hand, and gathers them into sheaves with the left hand, thus
accomplishing an almost circular abduction movement of all the upper limbs, the forearm being slightly bent back on the arm. In consequence of this movement, repeated during several hours, the hand effects movements of prehension and flexion on the forearm, and it is precisely these movements which give rise to forms of acute synovitis of the pulse and of the extensor tendons of the fingers of the left hand.

These forms of inflammation, most usually serous and easily healed (severe cases are very rare), affect in general weak subjects during the first days of the harvest, that is to say, while they still lack practice.

Another injury, characteristic of harvesters and of distinctly traumatic origin consists in small wounds of the cornea and sclerotic, caused by ears of cereals (wheat, rye, etc.). Abrasions of this kind frequently set up profound ulceration and sometimes even, in the case of local infection, the much-feared serpiginous ulcer, which is often followed by hypopion.
