Thresholding, whether manual or mechanical, raises large quantities of organic and inorganic dust. The workers who work threshing machines and who travel with these machines from one field to another or from one farm to another are engaged on these operations over a period of several weeks and often contract acute forms of bronchial catarrh (generally without fever) as a consequence of the inhalation of irritant dusts. Where it is a case of persons subject to chronic bronchial catarrh and, in addition, to emphysema and asthma (recurring bronchial asthma), such injuries aggravate the effect of the conditions and the patient often falls a victim to serious asthmatic attacks. On this account, work connected with threshing and similar operations should be prohibited for all workers showing predisposition to forms of bronchial and asthmatic catarrh.

Straw forms a part of cattle fodder, but it is chiefly used in combination with chaff for animal bedding in stables and byres. When the straw is stored or has to be transported it is commonly couch'd up in bales, which are bound together with wire. Compression of straw is effected by the aid of special machines worked by hand or mechanically. Wherever threshing machines, compressors or other machines involving the use of solid or liquid combustion agents are used, the presence of toxic fumes must be reckoned with (especially carbon monoxide), if such operations be

affected in badly ventilated places, etc. These machines, and particularly the threshing machines, are likewise the cause of accidents, sometimes of a very serious order. Amongst the workers engaged on threshing machines, those most exposed are the workers who load these machines.

Straw and chaff are frequently a source of infection, at times very serious, for man as well as for animals. Characteristic diseases connected with wheat which may be transmitted to man include different parasitical infections of a cryptocomic nature: rust disease of plants caused by fungi of the Uredineae group; by a fungus of the Ustilaginaceae group, etc. The latter, however, is rather a possible theory than a practical occurrence. In fact, whilst certain of these causes may give rise to disease in man (for instance the so-called "wheat itch" or pruriginous dermatitis due to Acarus tritici, known also as Poediculoides ventricosus), grains disseminated in the chaff and in the straw is usually too sparse to be greatly feared as transmitting agents of infection.

On the other hand, the straw and the chaff are much more frequently the vehicle of diseases common to stall animals and to man. This is true of certain fungi which live on vegetable refuse, a type of which is the actinomycoses (see article "Actinomycosis").

Straw is a very dusty substance which often, when piled up in damp places and even when exposed to the air, develops mould and may transmit to man diseases caused by moulds (Aspergillus fumigatus and Niger). The spores may be inhaled at the moment of removing contaminated bedding. This disease is not uncommon amongst cattle. Amongst men, the Aspergillus fumigatus may even be found in the lungs (Pneumomycosis aspergillicana), whilst the Niger has only caused certain growths affecting the walls of the exterior auditory meatus or the Membrane tympani.

Straw used for bedding or for clean-lind mangers and drinking troughs and even the animals themselves may transmit foot-and-mouth disease, vaccine, tuberculosis, swine fever, erysipelas, glanders, rhages, anthrax, etc. (see these articles and also the article "Infection").

As regards the agricultural industry, there should not be overlooked the use of straw for animal fodder, necessitating the use of machinery (chopping machines), which often give rise to deep wounds, sometimes even involving amputation of part of the upper limbs.
In the Manufacturing Industry

Straw is used as a protective material in the packing of fragile objects, for covering chairs and armchairs, for the manufacture of baskets and mats and especially for that of hats, and also in the manufacture of certain kinds of paper.

At the present time, efforts have succeeded in producing a substance known as "maizolithe" with straw as a basis and this substance seems to give excellent results as an insulating medium and in the manufacture of small objects. The straw is reduced to small pieces, treated with caustic soda, washed, transformed into a gel, boiled and dried.

Straw also serves for the preparation of a special kind of carbon utilised in the manufacture of powders and explosives (Hengst powder or Hengstite); it is also used in the manufacture of wood-shavings, wood-cotton, wood-wool, etc.

In the packing industry, as in other branches of industry in which straw is used, it is not an uncommon thing to meet with small wounds situated on the hands of the worker, wounds which may become directly infected. Gaston and Bolzer have described two cases of whitlows due to sporotrichosis occurring amongst workmen engaged on stuffing with straw.

The straw hat industry and the artistic manipulation of straw for hats comprise various operations and manipulation of the straw, which are of interest even if consideration is confined merely to hat manufacture as executed in Italy, Switzerland, Germany, China, Japan, etc. For hat-making different types of wheat straw are used — in Italy, especially the variety known as *Triticum aestivum* Linn. The following observations all refer to Italy, for as a result of certain comparisons with hat manufacture in other countries it is found that the Italian industry and the technology which it produces are more or less the same for workers in all districts where straw is plaited either by itself or mixed with hair, silk, etc.

Straw for hats, after having been treated, is gathered in sheaves and exposed to the sun for drying, then subjected to bleaching (dew and sunshine, the harvest taking place after the first spring heat), and finally it is picked. This operation consists in detaching from the stalk the part which is situated above the last knotty exccrcence and which carries the ear. The worker engaged in this operation seizes with the right hand one or several stalks of straw at a time whilst with the left she holds the sheaf of straw on her knees. This work gives rise to forms of occupational cramp, sometimes painful and sometimes spastic, and always affecting the right arm. Picking is an operation which creates relatively little dust unless the straw, and especially the offshoots, contain a certain amount of dried earth. The straws are passed through a perforated plate to separate out the thick straws from the finer ones. Thereafter they are cut in two, the upper part, namely that which carries the ear, being the finer ("point"), whilst the lower part is much thicker ("stalk").

The straws are first subjected to bleaching by means of sulphurous fumes, then plaited by hand in such a way as to produce flat plaits of some millimetres in thickness and several metres long, the fineness of which varies according as to whether they have been made with the tips of straws or the stalks of the straw and in accordance also with the kind of straw used. Hats are made from this plaited straw which is sewn by hand or by machinery. The work of plaiting the straw is a fine, methodical and continuous operation resembling, as regards precision and rhythm, machine work. This precise, rhythmic operation often causes a form of occupational cramp which is at times bilateral and most frequently affects the right arm. Painful forms accompanied by paresthesia and more rarely spastic in character have been met with, affecting the fingers, the wrist joint and even the right forearm (Giglioli, Pieraccini). The picking and plaiting of straw may cause characteristic callosities situated on the hands and on the volar surface at the point where the straws exercise greater pressure, and likewise deformities on the fingers, especially on the distal parts of the index and on the left middle finger (Martinuzzi).

When in hat-making the straw plaits are sewn by hand into concentric and superimposed rings, the woman worker (these operations are always done by women) is obliged from time to time to stretch the straw with a view to flattening the straw material, or, in other words, to pull it out. This operation causes the formation of large callosities, intense wearing away of the nails and even deformations of the phalanges. The pressure exerted in the course of drawing out the hat on the radial side of the thenar eminence and on the side of the metacarpal phalangial joint of the right thumb...
causes inflammation of the tendon sheaths of one of the abductors or extensors of the thumb, thus giving rise to the condition designated in Italy as "spring finger". This condition is, however, sometimes caused by the extensor muscles of the left thumb as a result of the facts above described but of repeated efforts (with the thumb flexed) which the workers engaged in plaiting exercise during the pulling out of the hat. Amongst persons who sew the hats by hand there has at times been observed the occurrence of occupational spams.

For bleaching hats, they are passed through solutions of various substances (acid bisulphite of potassium and sodium, liable to liberate irritant sulphur fumes) and they are thereafter placed in a closed chamber where they are exposed to sulphur fumes.

In the case of a worker engaged in removing straw from bottles and scraping with his nails mouldy straw which has stuck to these, Dreuw noted the formation around the nails of a friable mass which had even caused injury to the fingers. Microscopic examination showed the presence of hyphomycetes recalling very closely trichophyton.

The reports of the German factory inspectors for 1920 contain references to cases of conjunctivitis due to solvents, and in 1927 there were noted toxic manifestations among workers engaged in the manufacture of straw hats for women who used a product known as "Z varnish", which was replaced, after prohibition, by other kinds of varnish, which, unfortunately, possess similar harmful properties. The symptoms were as follows: headache, watering of the eyes, vomiting, nervous trouble, attacks of syncope; and locally, exanthema, dermatitis and sub-cutaneous cellulitis.

Caustic soda used for washing the straw with a view to the preparation of "half stuff" has also caused cutaneous troubles amongst workers coming into contact with the caustic solution.

Hygiene

The hygienic measures which it is desirable to apply are particularly connected with the use of reaping and binding machines which cut the grain and tie the sheaves; protection of forage from moulds by adequate storing in covered places subsequent to ripening and drying, etc.

In certain cases bleaching by sulphur may be advantageously replaced by bleaching with peroxide of hydrogen (see article "Bleaching"), which would constitute considerable progres from the hygienic aspect.

The protection of the worker handling straw, however, is always connected with the agricultural industry. Mechanical work, provided that safety is effectively guaranteed, shortens the duration of the work, which is often very trying, and reduces the number of workers occupied and the daily fatigue involved.

In Japan, boys under fifteen and girls under twenty-one years of age are excluded from dusty operations connected with straw.

Strontium

Strontium (symbol Sr) is an alkaline-earth metal the properties of which resemble those of two other elements belonging to the same group: barium and calcium. It is found in the natural state in the form of carbonates and sulphates, almost invariably mixed with barium and calcium ores, and in small quantities in certain mineral waters and in sea water. The metal is obtained by electrolysis of molten chloride of strontium. It has a silvery white or yellowish colour, melts at 800° C., and commences volatilisation at about 950° C. Amongst its compounds the most important are the bromide, the carbonate, the chloride and the nitrate, etc.

The various compounds of strontium are utilised in the sugar industry and in the manufacture of Bengal lights. From the point of view of industrial hygiene, the various compounds are considered as harmless (Lehmann and Löwy).
Salts of strontium possess properties similar to those of barium compounds. On the digestive system they exercise a fairly slight toxic effect, having a purgative action. Injected into the veins, the toxic action is manifest, since strontium constitutes a poison of the heart. According to experiments effectuated by Rahuteau, salts of strontium abolish muscular contractility. Nevertheless, lesions attributable to the various compounds of strontium are but little known.

Sandri (1931), by methodical research effected on animals (hens), has studied the effect of a titrated suspension of carbonate of strontium administered per os and capable of occasioning phenomena of motor paralysis. The study dealt with the peripheral reticulum of the nerve cells (ganglion cells of the anterior column of the spinal marrow).

**Studios (Cinema)**

**Pathology**

Amongst the occupational diseases to which cinema artistes are exposed may be distinguished two types of affections: first, those common to actors on the stage in general, and secondly, those particularly connected with studio life.

The first type has been studied in the article devoted to "artistes". It may be recalled here that amongst cinema artistes, skin affections due to make-up should not be overlooked, more especially on account of the very extensive quantities of cosmetics, etc., which are used.

Alcoholism and epilepsy constitute contra-indications for the occupation of cinema artistes. Dreyfus (1892) demands that candidates should be certified as immune from either of these. The same authority examines candidates for work of this kind in testing presence of mind by the forefinger test.

Affections specially connected with studio work have in consequence of the development of the cinematograph industry, been made the object of special study by eye and skin specialists. The most typical form of cutaneous lesion is represented by what is known as electric "sunstroke". The patient suffers from swelling of the face and especially of the eyelids, which are reddened and affected with an intense pricking sensation. The lesion develops fairly rapidly and soon there occurs desquamation of the epidermis followed by a brownish pigmentation which is more or less persistent.

Lesions of the eye are more serious. The lesion is characterised by a latent period during which the sufferer complains of a trying sensation of pricking similar to that caused by pricking with a needle or by the presence of grains of sand in the eyes. This sensation increases later, becomes persistent, and finally gives way to dull pain. The conjunctivae are red and at times raised by inflammatory infiltration. There is abundant secretion. The eyelids become sticky and small crusts form along the edge of the eyelashes. This blepharitis is accompanied by palpebral spasm, photophobia, watering of the eyes and asthenopia.

Chappe described in 1920 before the French Congress on Ophthalmology cases of conjunctivitis due to the action of light amongst cinema artistes.

Adam reported in 1922 amongst artistes in German studios a large number of cases of conjunctivitis which very closely recalled follicular conjunctivitis. In 1922 similarly, Reichert, of Berlin, found amongst people engaged as "supers", or "crowd artistes" in the studio, a whole series of slight irritations of the conjunctiva, and among artistes a form of acute catarrh with blepharospasm, oedematous inflammation of the globe, hyperaemia of the iris, all symptoms being accompanied by violent ocular pain. He found serious lesions similar to those caused by sunlight and by reflected light from snow. These cases follow in general a fairly mild evolution, but there has at times been noted as sequelae changes in the macula with scotoma and vacciniform hydroa of the eye (case of Friede, 1921).

In 1924 Sedan noted in two cases corneal complications (forms of keratitis). Though serious symptoms are rare, the possibility of lesions of the internal eye must be reckoned with, especially in the case of predisposed subjects and those presenting notably certain effects of refraction (myopia, etc.). In one of the cases described by Sedan, the artiste had suffered from attacks similar to the initial attack for a period of five years, though he had completely given up the cinema from the first appearance of the lesion (Sedan, 1929).

In an Odessa studio, Rabinovitch (1927) noted cases of photophobia caused by ultra-violet rays. It was chiefly a case of erosions and of opacity of the cornea, the lesions being
localised at those points on which the light struck vertically.

Hoorgina (1929) examined 205 cinema workers (mechanics engaged in the maintenance of the lighting equipment, actors, directors and assistants) and found numerous hypertrophy of the conjunctiva with a tendency to disappear as a result of interruption of the work. He attributes these lesions to the action of luminous radiations and remarks that the latter may cause even superficial forms of keratitis, notably amongst new and inexperienced actors.

All the cutaneous and ocular lesions are due to the same cause: the excessively bright lighting to which artists working in a studio are exposed. Work in bright sunlight is, moreover, not without danger either. The very powerful arc lamps, incandescent lamps filled with gas, and mercury vapour lamps used in the scenarios for providing “sunlight” effects are well known. It is their luminous and blinding intensity and in particular their richness in ultra-violet rays which provoke the affections, at times fairly serious, referred to above. This problem has for several years received the attention of specialists: Verhoeff and L. Bell- (1921), Elvy, Bossu, Comandon, Polack (1923), as well as the various publications issued by the Illuminating Engineering Society (United States, Great Britain), the American Academy of Art, the Society of Motion Picture Engineers. These studies have drawn attention to the danger for the human system, and in particular for the eye, involved by radiations from certain luminous sources. Doubtless there should not be overlooked that heat in which the artists are at times obliged to work and of which the lamps in question are sometimes the cause; heat which gives rise to headache and a sensation of oppression which only disappears in the open air. Yet the danger comes chiefly from the blinding glare of the luminous source and from the infra-red, blue and ultra-violet rays emitted by it.

The eye possesses, it is true, means of defence against luminous traumatism, amongst which figure in the foreground movement of the retinal pigments and the contraction of the pupils.

On the other hand, the ultra-violet rays are absorbed by the cornea and the crystalline lens, which reacts by giving rise to painful transient symptoms.

Where, however, the luminous source is very intense or exposure to it very long, very serious lesions may be produced. The limit of brilliance of and contrast which the human eye can stand varies, moreover, in different individuals.

It is certain that a certain amount of tolerance can be acquired, and that amongst scene-shifters, electricians and studio veterans there are many who can withstand much more rays than neophytes the intense glare from the lighting projectors. This faculty of adaptation does not, however, prevent the organ of sight from becoming frequently attacked by the above-mentioned lesions which necessitate the adoption of definite means of prevention.

**Prophylaxis**

Prevention of these affections is a complex problem. The demands made by photographic and cinematographic technique are often in contradiction to the steps necessitated in order to effect the provision of adequate protection for the eyes of the artistes. The lens used for taking pictures requires a certain quality of light and the exclusion of all radiations except those without danger to the eyes of the artistes is not possible from the technical point of view. On the other hand, artistic effects sought in making certain films necessitate big changes in the intensity of the light and at times lighting placed at a short distance from the face when it is necessary to register fine shades of expression. It is known that any lighting source or reflecting surface having a brilliance exceeding 7 Lambert (about 22 lux per sq. cm.) causes ocular pain. It would be advisable, therefore, as soon as this limit is exceeded to take measures calculated to counteract the effects of undue brilliance. These measures consist in the use of diffusing globes (indirect or semi-indirect systems); in the arrangement of the lamps and projectors, etc., in the upper part and on the walls of the studio; and in the removal of objects with brilliant surfaces from the field of vision of the artistes. It is possible likewise to take precautions with a view to avoiding the sudden switching on of light and rapid changes in intensity. In the case of very intense lighting being necessary, it should not be used except during a very short period and artistes should not be subjected to it except at sufficiently long intervals.

The prevention of lesions due to radiations with great refrangibility is more difficult. While it is relatively simple to deal with liberation of ultra-violet rays, it is not equally so in the case of violet and blue rays which, as has been seen, likewise present a certain danger for the sight.
As regards ultra-violet rays, the glass tubes of the lamps used render harmless radiation in consequence of its absorption. The same is true of the powerful arc lamps unless in the case of a naked light being used. They should therefore be provided with a glass globe to absorb ultra-violet radiations.

In this manner it is possible to prevent serious retarded symptoms, to be feared in the case of cinema artistes (Vigouroux, 1928).

Unfortunately, ultra-violet rays are not the only harmful rays, and the globes referred to do not succeed in retaining the violet and blue rays which suffice to give rise to ocular lesions. The only means of dealing effectively with the danger from harmful radiations would be to intercept between the lighting source and the eyes of the artistes a screen of yellow glass. In this way it would be possible to obtain a light free from harmful radiations. In practice, however, this is difficult since the ordinary film is not sensitive to light sifted through the yellow screen, and it would not be possible in order to counteract this effect either to prolong the time of exposure or to intensify further the lighting. There is therefore a single means of dealing with the problem: that is to modify the film (Polack). The problem to be solved therefore consists in discovering a panchromatic emulsion possessing, besides adequate stability and faculty of conservation, a rapidity almost eight times greater than that of the present panchromatic film. This problem would not seem to be impossible of solution. There are already known processes of hyper-sensitivity which increase considerably the rapidity of the emulsion. Up to the present time they still possess the defect of rendering the film subject to spontaneous alteration and thus reducing the period of its conservation to a point which is inadequate.

The importance of the risk run by artistes during the shooting of films led the German Federal Health Office to issue (1928) a warning leaflet dealing with protection of the eyes of those exposed to the violent luminous radiations in studios. In this leaflet, those affected are informed as to the effect of the ultra-violet rays and of the intense lighting on the eyes, as well as of effective means of protection. General hygiene in the studio does not differ in any particular from the hygiene of workshops intended for any kind of human labour.

As regards modern methods of lighting in studios, reference should be made to the paper by W. A. Villiers and to the discussion to which it gave rise in the English Lighting Association (18 February 1930), and also to that by Cabet (Bulletin de la Société française des électriciens, November 1930).

Particular attention should be devoted to ventilation in lighting and shooting rooms.

Bellon has already drawn attention (1922) to the question of ventilation in operators' boxes, the air renewal in these places constituting an almost more urgent necessity at present in consequence of the technique of the talking films, where the operators are isolated in cages, so to speak, with soundproof walls, unless in rare cases, where they are situated in a room adjoining the studio — which arrangement would naturally be ideal, but is unfortunately very often difficult to carry into effect.

**LEGISLATION**

Social legislation relative to the cinema industry adopted in the different countries — Austria, France, Germany, Italy, United States (California and New York) — deals only with the protection of children, regulating the age of admission and the length of the working day.

**BIBLIOGRAPHY**

The bibliography available on this subject is fairly extensive: cf. the quarterly publication of the International Labour Office: Bibliography of Industrial Hygiene.

Submarines

The quite special conditions applying to men on undersea craft and submarines have opened up an entirely new and extremely interesting chapter in the realm of naval hygiene. Medical literature on this subject is comparatively scanty and is almost exclusively Italian; the contributions of other countries, e.g. Great Britain, the United States and Japan, are very limited. This fact may be explained both by the difficulties of experimental research on the question, and by the need for keeping secret the internal equipment of these vessels.

Undersea craft, in the original sense, being henceforward abolished, naval construction at the present time is confined to submersible torpedo-boats or
*submarines* only, that is to say, vessels which travel on the surface, but are able at any moment to dive to such a depth as to make themselves invisible and invulnerable.

Without going into the technical details of construction, it is only to mention here that the largest submarines can dive to a depth of 120 metres. The number of men carried may be sixty or more. The interior form of the various types is very nearly the same; it is only the methods used for diving which differ widely.

The dive is achieved by automatically filling special compartments with seawater, which enters through openings in the external hull and the double bottom, which are provided with valves. The return to the surface is normally carried out by expelling the water from the compartments by means of rotary pumps driven by electric motors. In exceptional circumstances compressed air is introduced. These operations take place very quickly, in two to three minutes. The duration of the immersion may be prolonged to even more than twenty-four hours.

Navigation below the surface is silent, the electric motors running without noise. Exterior vision is almost nil; but it is assured by periscope when the vessel is partially submerged.

As far as the interior structure of submarines is concerned, it need only be recalled that the compartments connect with each other, and that in certain types (e.g. Laurentia) a passage exists in the space between the two hulls which enables a man to pass from bow to stern without going through the battery compartment. This is a very good arrangement, for if, by some accident, seawater penetrates into the battery compartment and comes into contact with the sulphuric acid, chlorine is liberated, which renders the air irrespirable.

The crew's quarters are situated in the central compartments, and, at least in the more modern types, a certain degree of comfort is provided. As far as the kitchens are concerned, electric cooking does not use up oxygen from the surrounding air. Originally sewage was removed by means of non-odorous containers, which were, however, the source of various unpleasant conditions. The construction of lavatories with a double valve and pump, which drives out the faeces by means of a jet of compressed air, represents a very important advance.

The average cubic space per individual is, on certain submarines, round about 15 cub. metres, with, however, considerable variations between one compartment and another, from a minimum of 6.5 cub. metres to a maximum of 48. Although these values are greater than those for ordinary vessels, they, nevertheless, suffice only for a total submersion of a few hours' duration. The average cubic space is calculated on the supposition that the compartments communicate with each other. Naturally it varies when the doors are closed.

Propulsion is effected either by internal-combustion engines, with liquid fuel, or by steam turbines when the vessel is on the surface or partially submerged, and by electric motors for navigation below the surface. The internal-combustion engines have the advantage of heating the surrounding medium less than the turbines. It is true that turbines can be placed in a special compartment and can be provided with fans. The internal-combustion engines, by driving the dynamo, can also charge up the batteries of accumulators which supply power to the electric motors for navigation during submersion. The direct current motors are driven by accumulators containing sulphuric acid or an alkaline solution. The accumulators are hermetically sealed so as to prevent the escape of the electrolyte or the liberation of gases formed as the electric power is generated.

The Edison alkaline accumulators used on American underwater craft do away with the use of sulphuric acid and so eliminate the liberation of sulphur dioxide or chlorine gases, which render the air irrespirable. They take up considerably less space, and require less maintenance. However, from the technical point of view, they are inferior to the sulphuric acid type.

Compressed air at 150 to 180 atmospheres pressure is stored in steel drums.

**Sources of Danger**

**Changes in the air of the vessel during submersion.** — From the hygienic point of view, a submarine is of particular interest when it is travelling completely submerged; under these conditions it forms a hermetically sealed space, immersed in, and completely surrounded by, a large liquid stratum, which separates it from the outer air.

The causes of change in the internal atmosphere are chiefly due to the functions of organic life of man, the effects of which are peculiar to submarines because of the hermetic sealing of the space. There must be taken into account the pollution of air brought about by the biological functions of man (see article "Air of the Work-room").

Combustible liquid may foul the air, either by the small quantities of vaporised fuel which leak through joints and valves and mingle with the atmosphere, or by such poisonous products of combustion as carbon dioxide, steam, nitric oxide, which changes into a hyponitrite, nitrous acid, nitric acid, methane and acetylene, varying with the quantity and quality of the fuel used. This vitiation of the air must especially be taken into consideration when submersion has taken place immediately after stopping the engines when there has not been time to ensure a sufficient
change of air. The working of the electric motors also affects the air; but, as the accumulators are hermetically sealed, the gases generated — hydrogen, sulphuretted hydrogen and sulphur dioxide — cannot penetrate into the compartment. Finally, lubrication with heavy mineral oils, containing more or less considerable quantities of light oils having their boiling point below 200° C., leads to the generation of poisonous products.

Furthermore, a rise of temperature occurs by reason of the operation of the internal-combustion engines, of which a considerable part of the calories produced is radiated into the compartment. In the case of electric motors, about 17 per cent. of the average power furnished is transformed into heat energy. This radiation is greater when the accumulators are fully charged. The rise of temperature is, however, lessened by the operation of fans, provided that submersion does not follow quickly after stopping the engines.

Secondary causes of chemical and physical pollution of the air are: artificial lighting, varnishes which in oxidising withdraw oxygen from the air, the escape of compressed air from increase in pressure, and the stirring up of dust by the movement of the motors.

After several hours of submersion, a peculiar smell, irritating to the mucous membranes, due to sulphur dioxide and hydro-carbides from the motors, becomes noticeable.

The physical and chemical alterations of the air in submarines have been studied experimentally by Belli and his collaborators; the results obtained may be summarised as follows:

Concerning the physical state of the air the temperature is, to begin with, 2-3° C. above the outside air; it equalises itself after a time with the temperature of the water outside. In general, it may be said that the temperature keeps within limits which are tolerable for life. In temperate seas during the cold weather, it is rather cool, but the crew protect themselves easily with clothing and electric heating. In summer, the temperature sometimes exceeds 30° C. and may become trying by reason of the high degree of humidity which accompanies it.

The relative humidity may touch 90 per cent. or more. In some places saturation is reached. During submersion, aqueous vapour accumulates in the air, and, little by little, it increases the humidity, both relative and absolute. Naturally, saturation is quickly reached in winter, on account of the low temperature, with a relatively low degree of vapour pressure. In summer, because of temperatures exceeding 30° C., the excessive humidity of the air causes a disagreeable sensation, which is accentuated after a certain period of submersion.

Barometric pressure is 10 to 30 mm. above that outside, with variations which are a little irregular. Its increase is due to the liberation of hydrogen and other gases generated in the operation of the accumulators, and especially to the escape of compressed air.

The chemical changes are far more important than the physical changes and are characterised by a decrease in oxygen and an increase in carbon dioxide.

The reduction in the percentage of the oxygen is greater than that due to the consumption of this gas by the vital processes of the men — organic combustion — for part of the oxygen obviously goes to serve other oxidations of the hydrocarbides of the motors. In a submersion of normal duration the amount of oxygen remains sufficient for breathing. Belli and Olivi found that after six hours of submersion the minimum percentage was 18; because of successive renewals of the air — still during submersion — there was an increase to 19 per cent. which was maintained throughout the whole time of observation, i.e. eighteen hours. It is plain, therefore, that they were far above that minimum percentage below which asphyxiation is produced, 3.5 per cent.

In a British submarine where the volume of air per person was 4.25 cubic metres, and where the crew numbered sixteen, estimates made after twenty hours of submersion gave 16.37 per cent. of oxygen (Shaw and Gérad).

The proportion of carbon dioxide varies according to the activity of the persons present; like the reduction of oxygen, the increase of dioxide is greater than that occasioned by the vital activities of the human organism. According to Belli and his collaborators, this increase appears to be gradual, and at the end of six hours to reach 31 parts in 1,000. By renewing the air every five hours it was possible to obtain a concentration varying between 13 and 17 parts in 1,000 after each renewal. The amount rose rapidly to 31, and after twenty-four hours reached 37.2. But no serious phenomena of poisoning have been reported.

In an English submarine, after twenty-six hours of submersion, the concentration of CO₂ had reached 9.4 per 1,000 without either objective or subjective troubles being noticed among
the sixteen men. It was by no means the same when a fresh experiment was tried during which no measures were taken to lessen the amount of carbon dioxide.

Hydrogen is physiologically an unimportant gas, which is liberated from the accumulators during charging; but it may become dangerous, for in given proportions it can form an explosive mixture with the air.

Sulphur dioxide is an unbreathable gas which exercises a vigorous action on the human body when it is inhaled. For rabbits its harmful action starts at 0.05 per cent. It becomes fatal at about the end of 4 hours at 0.24 per cent. A maximum content of 0.314 grm. per cub. metre of air has been found in submarines at the end of twenty hours. This amount, although small, is sufficient when added to that of other gases to explain a feeling of suffocation. For rabbits its harmful action starts at 0.1449 grm. per cub. metre of air; this small quantity is liberated by the electric motors.

Chlorine is generally absent, but it may be given off occasionally should the sea-water penetrate into the accumulators; in this case, it may be the cause of very serious accidents.

Even at the beginning of submersion, hydrocarbides may be detected. The small amount of 0.1449 grm. per cub. metre has been found, which is due to products from the evaporation of naphtha rather than lubricating oil.

Carbon monoxide, ammonia, nitrous and nitric oxides are always absent.

On the other hand, arsine and arsine, hydrogen may occasionally be present, as a result of abnormal reaction in the accumulators. Two instances of general asphyxiation have been noted on Italian submarines. The electric accumulators were blamed as they were not hermetically sealed, and also the ventilation hole in the container was in direct contact with the living room atmosphere. The lead plates were enclosed in sheaths of asbestos so as to prevent the lead oxide crystals which form on the positive plates from precipitating. Now the asbestos contained arsenic, whence originated the arsine and arsine, hydrogen which was given off into the air during the operation of the accumulators. Similar cases have been observed in France after two immersions each of eighteen hours, and in Great Britain, where cases of asphyxiation have been caused by the use of lead plates contaminated with arsenic. The gaseous discharge occurs particularly during the charging of the accumulators. To prevent such accidents it is necessary to use plates of lead, free from arsenic, and sulphuric acid which does not contain more than 0.0008 per cent. of it by weight. Moreover, vigorous ventilation of the accumulators must be assured during charging and for one hour after the completion of this operation.

Apart from these exceptional cases of asphyxia, the crews of Italian submarines have never experienced much trouble, except for headaches, mental stupor, and, exceptionally, forms of lethargy after many hours under water.

Physio-Pathology

Theoretically, air conditions differ in the various compartments; in practice, these differences tend to disappear, for the communications allow the air to mix, and the only real difference is that between the highest and lowest parts, owing to carbon dioxide being heavier than air.

Tests of the exact extent of these changes would be very useful for warning the crew of any threatening danger. This would be all the more useful seeing that the sense of smell — which is of use elsewhere — no longer responds in these atmospheric conditions, after some time has been spent breathing air contaminated with gases exerting different reactions.

Such small animals as mice and guinea-pigs were formerly used on board to detect the presence of carbon monoxide; but they are no longer used at present, for it is recognised that there is no need to fear this danger on submarines. Nor is the lighted candle of value; for even in an atmosphere harmful to man there always remains sufficient oxygen to feed the flame.

The maximum limit of concentration of carbon dioxide, fixed at 1 part in 1,000 in city areas, is quickly reached — in half an hour — in submarines during submersion. If one accepted a test of this nature, it would be necessary to raise the limit to 15 in 1,000, which corresponds to about half the maximum quantity — 50 parts per 1,000 — recorded in several tests, and perfectly well tolerated. Automatic apparatus (Drager, Ausell, etc.) may be used for indicating the content-limit of carbon dioxide in the air, e.g. when the content reached is 15 parts in 1,000.

On the other hand, it is unnecessary to equip submarines with apparatus for indicating the amount of oxygen, because, although the air may be rendered irredeemable by carbon dioxide, there is still sufficient oxygen for breathing.

In submarines totally submerged there is no question of being able to
use the outside air. Thus it is always the same air which passes several times through the lungs; a veritable rumination of the atmosphere. Consequently it is necessary to restore the chemical constituents of the air present in the vessel.

While it is comparatively easy to introduce fresh oxygen, it is more difficult to rid the air of harmful gases, such as carbon dioxide, hydrocarbides, and sulphur dioxide. In face of the difficulty of purification, action is limited in practice to absorbing the carbon dioxide, and introducing oxygen, which is used in the compressed state (see article "Air of the Workroom").

The cleansing of the atmosphere does not give pure air in sufficient quantity, so complete renewal of the interior atmosphere must be sought after. Strictly speaking, this renewal is particularly possible, or, to be more accurate, what is affected is dilution of the harmful substances; in short, it is ventilation on a reduced scale. For this purpose compressed air is used which, in a given quantity, replaces an equal quantity of vitiated air which is driven out by the pressure. This imitation of the chemical composition, and at the same time the hygrometric state of the air.

In order to avoid unnecessary sources of air pollution, electric lighting is used, and it is indispensable at depths exceeding 12 metres. Because of the low height of the compartments, the lights are placed on a level with the eyes; hence, owing to glare, they cause eye troubles. Frosted glass lamps lessen, but do not eliminate, this disadvantage. Indirect lighting should, therefore, be adopted. To diminish surface glare, the walls and ceilings must not be highly polished.

In determining a suitably healthy diet, the crew may be considered as being subject to a moderate amount of work. The problems which arise are mainly concerned with the preparation and preservation of food. In the first place, electric cooking must not use up much power. In consequence, the food should be in forms which allow of easy preparation. But cooking leads to the generation of steam, which increases the humidity of the air. The preservation of the food also is in itself difficult, fresh food being very rapidly decomposed by the gases, the temperature and the humidity. Dried foods also are soon rendered useless. For this reason tinned foods are resorted to, which, however, present two objections: loss in food value and a sensation of emptiness in the stomach. But, after the first day, the appetite flags, and the feeding is even too abundant. A loathing for tinned foods develops, especially for vegetables, hence recourse to a diet which is over-rich and nitrogenous. However, these drawbacks are not serious considering the short duration of this diet. The use of alcoholic liquor is a debatable question. It has been observed that, in Italy, Marsala is more popular than wine. Its moderate use, especially in winter, has been recommended as being more satisfactory than other drinks and stimulants.

From the pathological point of view, attention should be drawn to a state of extreme nervous tension among the personnel. Hence arises the necessity for selecting the men for the service (see article "Compressed Air Work"). During the first few days phenomena analogous to those occurring among divers may develop, i.e. a sensation of acute distress, dizziness, buzzing in the ears and nausea, which, however, rapidly disappear. During submersion and after work, the men have an irresistible need for sleep. Sleep is necessary; for this reason men not on duty are ordered to keep resting, and only to move about when unavoidable.

The study of the chief functions of organic life in submarines has been pursued by Belli, Olivi and Motegi on persons who have been submerged for twenty-four hours. The blood did not show modifications which were either remarkable or persistent in its figured elements or in its haemoglobin content. Spectroscopic examination did not reveal any indication due to the presence in the air of carbon monoxide, dioxide or sulphuretted hydrogen. Breathing increased in frequency and in amplitude; carbon dioxide reached 16 litres an hour. The pulse corresponded with the respiratory changes, and showed symptoms analogous to those of fatigue. However, experience gained during the war has established that permanent injuries occur; thus an increase of blood pressure was found in a large percentage of submarine ratings; these troubles had decreased noticeably six months after the armistice in 1918 (Great Britain).

So far as metabolism is concerned, the researches of Belli and Olivi, apart from a few individual differences, go to prove that it is not influenced by the composition of the air inhaled, and that the balances, thermal, nitrogen, mineral and carbon, are not altered.

No statistics of sickness exist. However, the various occupational troubles to which the crew of submarines are frequently exposed are as follows:
Poisoning by naphtha owing to liberation of gas from the reservoirs during combustion; and by arsine retted hydro¬gen in the blood of 30 men asphyxiated by this gas during the war on board submarines. Dudley noted (1916) a large reduction in the number of red corpuscles, and a normal or slightly reduced number of leucocytes. The presence of arsenic in the urine, the hair and the nails was due to the fact that arsenic was an impurity in the sulphuric acid of the accumulators. With the acid eliminated, fresh cases of poisoning occurred; it was then found that the lead plates of the accumulators contained 0.2 per cent. arsenic. Ear trouble arises from inequalities of pressure. Respiratory affections may result from inadequate ventilation and the inhalation of irritating gases. Dermatitis may be due to naphtha, etc. Conjunctivitis is due to exposure to gases and vapours (McDowell, 1917). Various nervous troubles occur, such as claustrophobia.

But the characteristic occupational disease of the personnel of submarines is represented by asthenopia due to the use of the periscope. The ocular troubles are caused by one-eyed vision, which calls for an effort of accommodation, and is carried out in an inconvenient position. To these factors may be added inefficient and imperfect functioning of the instrument, due to faults in construction and focussing errors, defective illumination and, finally, the visual defects of the observer. The sun, when high up above the horizon, produces a strong, luminous intensity, which affects the sight, and protection of the eye with red or orange glass is essential.

In order to reduce these visual troubles to a minimum, normal vision among the personnel must be a condition of service; a comfortable position must be arranged opposite the eye-piece; and the eye must be protected from the glare of adjacent lights; the lenses must be without spherical or chromatic flaws; and, in order to prevent ocular fatigue, the observer must not be allowed to close the inactive eye. There exists at the present time a special device which allows the inactive eye to be kept at rest, and at the same time protects both eyes from the harmful effect of adjacent lights.

Finally, it should be sufficient to keep in mind the following additional dangers: the impossibility of coming to the surface again after any accident to machinery; gas explosion due to hydrocarbides and air, and to oxygen and hydrogen given off from the accumulators; the cutting off of reservoirs of compressed air; and collisions.

Prof. C. M. Belli (Naples).

**Sugar (Sugar-Refining Industry)**

Crystallised sugar, described by chemists as "saccharose," is extracted from a certain number of vegetables or plants growing either in warm climates or in temperate zones, as sugar cane, sugar maple, several kinds of palms, beetroot, etc.

**Beet Sugar**

Beetroot is cultivated principally in Europe. The root is gathered from the end of September to November, then treated locally in factories which have increased so much in importance that 3 to 4 million roots can easily be dealt with in a day. This manufacture is carried out in Austria, Belgium, in the north of France, Hungary, Italy, Holland, Prussia, Saxony, in the south-west of Russia and now in Great Britain.

**Industrial Processes**

The manufacture of beet sugar comprises:

- The reception, weighing and washing of the beets;
- Extraction of the juice;
Defecation; Clarification; Evaporation and crystallisation.

These operations are carried out immediately after the collection of the beets which are treated rapidly in order to lose as little as possible of the sugar contained in the root of the plant. When the stock of beets gathered over an area more or less widespread around the factory becomes exhausted the manufacture properly so-called ceases. This represents two or three months' activity for the factory, the period being called a "campaign".

The sugar leaving the factories is called crystallised sugar. It can be used as it is, but generally it is remelted and refined to be more saleable either as loaf sugar or in pieces. This is effected in other factories called refineries which work all the year round.

Washing the beets. — The reception of the beets takes place either in a railway siding or by a canal or river quay. They are received in such numbers as to provide the necessary complement, and no more, of roots that can be treated without involving much storage in heaps, cellars or silos. Communicating with the beet bin or cellar is the hydraulic carrier which, in its simplest form, consists of a canal in which the water travels in a direction opposite to that of the roots. In the course of this circulation they undergo a preliminary cleaning by which they lose part of the earth clinging to them and some of the leaves and rootlets. The canal ends in the washing machine proper, consisting of an apparatus known under the name of beet washer, which is also provided with a stone catcher.

The washing water constitutes an important part of the residuary effluent from a sugar factory.

Extraction of the juice. — On leaving the washer the beet is sliced into very fine flakes called "slices" or "chips (cossettes)", which are automatically led into cylindrical cast-iron vessels arranged vertically the one beside the other or in a circle. These vessels communicate with each other in such a way that the sugar in the slices is extracted methodically. The pure water at about 80° C. enters the cylinder containing the slices that have already been subjected to the solvent action of waters less and less charged with sugar, while the richest water enters into contact with the fresh slices.

The process of dissolving the sugar contained in the slices is called "diffusion" and the whole series of apparatus in which it takes place is called a "battery". A re-heater is attached to each battery with the object of giving to the water, increasingly rich in sugar, a temperature facilitating exhaustion of the slices. The cylinders of the re-heater are connected by tubes provided with valves. Manholes allow of introduction of fresh slices above the cylinders and their removal from below.

The slices are thus brought nine times into contact with water free from sugar and the juice, having passed through these diffusers supplied with fresh slices, is ready for defecation.

According as the batteries are arranged the progress of the process of diffusion may be different, but the principle is the same: exhausting the slices, by water less and less rich. Displacement of the liquid more and more richly charged with sugar is assured by hydrostatic pressure.

In some of the annexes of sugar factories called "juiceries" the equipment consists of only a washer, a beet slicer and a diffusion battery. The juice so obtained, to which a little limewater is added, is sent to the central factory through an underground channel. These "juiceries" increase the area and capacity of the sugar factories and obviate transport difficulties.

Defecation. — The juice leaving the diffusion battery contains not only sugar, but also nitrogenous and mineral matters that require to be eliminated before concentration of the liquor to extract the sugar. This process is effected by means of milk of lime and precipitation of the lime by carbonic acid gas. This is known as defecation.

The way in which the lime is added and its treatment by carbonic acid may be different. It may be added either separately or simultaneously, the latter being the more usual of the two methods.

In the lower portion of the tank used for defecation are openings by which the carbonic acid enters, forced in by a gas pump and a steam coil intended to heat the juice in course of rectification. The carbonic acid gas tank has a hood for carrying off the gas and vapour given off during the process. Defecation comprises generally two successive operations.

In the first carbonation the juice in the tank with the milk of lime added is brought to a temperature of about 30° C. On introduction of the carbonic
acid gas bubbles immediately give rise to an abundant frothing which is kept down by means of wood shavings or of a steam blower, or by pouring a greasy liquid on the surface. The temperature is raised to 60° or 70°, the production of carbonic acid gas being continued at the same time. When the process is considered to be finished the addition of gas is stopped and the juice is boiled for some minutes. The cloudy liquid thus obtained is pumped into a settling tank to be decanted. The solid particles made up of the carbonate of lime and holding some foreign matter collect at the bottom of the tank. The juice passes on to the second carbonation, while the deposit goes to the filter presses.

The second carbonation is done in the same way as the first, but carbonic acid gas is passed in until the whole of the lime is precipitated. The juice is carried to the boil. The separation takes place in a settling tank. The deposit passes to the filter presses and the juice to be clarified.

Preparation of the lime and carbonic acid. — The lime used for defecation is always prepared in the factory, using a lime as pure as possible, and for heating the furnace washed coke containing neither sulphur or sulphide is employed. The lime solftn is surmounted by a dome connected with a cast iron duct along which carbonic acid gas is sucked by a pump and forced into the defecation tanks. Before reaching the tanks it is purified and cooled in a gas washing apparatus in compartments.

Filter presses. — Whatever the method employed for defecation, the formation of deposit holding considerable quantities of sugar is attained. And it is the same with the scum. Both are sent to filter presses in order to extract from them the juice they contained and this is returned to slake the lime for defecation. The cake is used as manure.

Pulp. — The pulp is made up of the exhausted slices. Generally it is sold to farmers for cattle food and can be kept in silos.

Clarification. — After defecation, sometimes the juice still contains some foreign organic matter, and substances turning a brown colour on contact with air. Use has been made of a certain number of substances for clarification such as oxalic acid, phosphoric acid, sulphurous anhydride and animal black. Of all these, however, only sulphurous anhydride is still used, and that only occasionally, in the processes of defecation because of improved methods of carbonation and defecation.

Sulphurous anhydride not only precipitates the proteid matters and hinders secondary fermentations, but it prevents very largely the change of colours on contact with air, and ensures the fluidity of the juice. Its use depends on a number of factors which it is not necessary to go into here.

Evaporation. — The clarified and filtered juice must be concentrated in order to effect crystallisation of the sugar. It is first converted into syrup by evaporation of about half of its water; then after a fresh clarification it is again concentrated to the point where crystallisation occurs.

The process is carried out by means of evaporation under a vacuum in apparatus generally consisting of three vertical vacuum pans placed near one another and in communication. In the first evaporator the atmospheric pressure is reduced one quarter, and the steam which escapes during the evaporation serves to heat the juice contained in the second evaporator where the concentration continues, thanks to a still higher reduction in the pressure. At last the juice passes into the third evaporator, where the concentration is achieved by a boiler set up by the steam which has escaped from the second evaporator and by a still higher diminution of the pressure. On leaving the last evaporator the juice records from 25° to 26° B. It is syrup.

Boiling. — This process, which has for its object the transformation of the syrup into a thick liquid, in which crystals of sugar can form, is called boiling. It is carried out in vacuum pans of a particular pattern. When the syrup has reached the desired degree of concentration, it is removed from the vacuum pan and a part of the mass on cooling crystallises out. This is "boiling to string proof". Generally the process is so managed that crystallisation takes place in the vacuum pan itself; this is "boiling to grain".

When the boiling is finished the pan is emptied and cleaned by a steam jet. The mass is led into crystallisers.

Centrifugation. — It is not possible to extract in a single operation all the sugar contained in the syrup. The mass placed in the centrifugals yields first a part of its sugar (first product).
The syrup thus obtained is sent to be reboiled and a fresh quantity of sugar is obtained called second product. In this case the apparatus for crystallising is rather different from those used for the first boiling. They have to be kept in a place where the temperature remains from 35 to 40° C.

The syrup coming from this second operation, again boiled and crystallised in the same warm place, yields sugar spoken of as the third product. The crystallisation for this third operation being very much slower, the centrifugation cannot take place until four or five months after the boiling.

The syrup withdrawn from this last centrifugation contains all the foreign matter which the processes of purification have not been able to remove, and they are highly coloured. They constitute the molasses.

In large modern sugar factories the proportion of sugar extracted from the first centrifugation has been greatly increased, so much so as, if not to abolish completely the second stages, at any rate the third.

Treatment of the molasses.—The molasses after centrifugation still contain important quantities of sugar which can be utilised in three separate ways: (1) mixed with forage it makes a rich cattle food; (2) sent to undergo fermentation for the production of alcohol; or (3) treated in such a way as to extract the sugar which it contains. It is this last process which is carried out in special establishments, technically independent of the sugar factories and known under the name of "desugaration factories".

The separation of this sugar contained in the molasses can be done in three ways, all three based on the property possessed by sugar of combining with alkaline earths to constitute distinct salts — sucrate of lime, sucrate of strontium and sucrate of barium, which are soluble, and from them the sugar is easily obtained by precipitating the base. The process with barium, yielding a product of great purity, is only used in Canada and Italy where the oxide of barium is procurable at a non-prohibitive price; that with strontium has been given up as too expensive, but that with sucrate of lime is employed to-day, especially in the United States, as the best method of separating part of the sugar in the molasses.

On leaving the vacuum pan the boiled mass is sent to the mixer and then to the centrifuges, where the centrifuged mass is "clear"ed " in 4 to 6 minutes (i.e. washed with a stream of water) and freed of the molasses impregnating it.

This clearing with water is followed by a clearing with steam, its object being to finish the cleaning of the crystals and to dry them.

By the alternating processes of clearing, centrifugation, boiling and crystallisation, products of the first, second and third order are obtained.

The industry limits itself in general to the production of sugar of the first product and is diminishing considerably work in the centrifuging room, which is very trying because of the heat and humidity.

**Cane Sugar**

The manufacture of sugar from cane differs only slightly from that of beet sugar except in regard to the extraction of the juice. The raw material consists of the stalk of a plant growing in the hottest climates of the globe; it requires, therefore, to be treated as rapidly as possible to avoid loss of sugar. This treatment takes place by crushing and expression in mills where the canes are crushed by fluted cylinders. The juice resulting from this first operation is called sugar juice. It is treated, like the beet juice, by lime to take out the impurities which are similar, though not of exactly the same nature. After carbonatation comes evaporation and crystallisation, just as in the case of beet sugar. The dangers from ill-guarded machinery are the same, as are also the hygienic measures necessary, such as cleanliness and ventilation.

**Maple Sugar, Date Palm, Sorgum Grass**

Industrially speaking, the preparation of maple sugar, palm sugar or sorgum grass sugar has very little importance.

**Sugar Refining**

Cane sugar and beet sugar leave the factory in the form of crystals which do not generally as such come on the market. They require to be refined, that is, purified afresh and changed into an amorphous crystalline mass which is subsequently sold in pieces. For refining, the same processes are

---

1 It should be remembered in this connexion that ankylostomiasis is very widespread among those employed in the cultivation of sugar cane at Porto Rico, in British Guiana, and especially in Dutch Guiana. The malady also occurs among the cultivators of sugar and tea in Natal.
workrooms are low and natural light-develop vertically rather than horizontally. Establishments, they have had to situated in towns and are very important. Some underwent rapid development — some in ports, others in large centres of population or near the place of manufacture.

As the majority of these factories are situated in towns and are very important establishments, they have had to develop vertically rather than horizontally. The result has been that the workshops are low and natural lighting is poor, obstructed as it is by neighbouring buildings.

The crystallised sugar is melted, clarified, filtered, boiled and submitted to crystallisation as in the sugar factories, but with some difference. A characteristic feature of the processes is the moist heat in which they have to be carried on, not only in winter, but also in summer. Molasses are, as in the factories, the residue of the manufacture and are utilised as has been already described.

After melting, the sugar is subjected to a first process of filtration to intercept the insoluble portions consisting of the debris of cellulose, and fibres mixed with the crystals on their removal from the wrappings. Another filtration takes place through granular animal charcoal. The use of this substance, made sometimes in the refinery, deserves quite special attention because it raises a thick black cloud in the room which prevents one seeing because it raises a thick black cloud in the room which prevents one seeing. According to Wilson (1920), the work of filling the filters with animal charcoal is work so dirty and unpleasant that the workmen only do it because they are well paid. On entering the chamber they cover their head with sacking and work under very unpleasant conditions and in the dark. Some English refineries have adopted mechanical means allowing the distribution of the animal charcoal to be regulated and making entry by workmen unnecessary. In some cases the filtration is worked from below upwards instead of from above downwards; the liquid is thus distributed more regularly. The revivification of the animal black is a source of vapours and bad-smelling and injurious gas, as it is first treated with hydrochloric acid, and, if necessary, with a hot solution of soda. The wet black mass is allowed to ferment (an alcoholic fermentation occurs first, then an acid and finally a putrescent); it is then washed with water, treated with steam and dried by calcining it in special furnaces.

The boiled syrup may be cooled in moulds either conical (loaves) or parallelepipeds (plaques). The shapes cut up into bits (sawing) in the well-known shape of small parallelepipeds are placed in boxes. The sugary dust is agglomerated by means of sugar syrup and broken afresh. (For candy sugar, see article “Confectioners and Pastrycooks”.)

Dangers

Among the injurious factors are the high temperatures prevailing in the different parts of the factory, the high degree of humidity, the number of substances used or given off in the different processes either in the form of gas (carbon dioxide, sulphurous anhydride, hydrogen sulphide, fumes of hydrochloric acid, evil smelling gases, etc.) or as dust (lime, strontium, sugar, etc.).

Statistics do not show the manufacture to be particularly unhealthy or dangerous; but that perhaps is owing less to the relatively small number of specific accidents or effect on the health observed than to the fact that it is an industry only in operation, except as regards certain departments, for a short time.

The workmen employed in washing the beet are exposed to the weather. It would be well if the washery were under cover. The principal accident to be feared is the fall of a workman into the beet washer along which the beet is conveyed by an Archimedean screw, or the accidental starting of the washer and stone catcher when a workman is busy inside. It might be thought that such accidents would be rare because they are easily avoidable, and similarly those which might happen when workmen are engaged on or are cleaning the elevators and travelling bands while they are in motion, but one of the chief dangers in the industry results from the fact that, no special knowledge being required, the workmen are generally agricultural labourers, employed by the factory during the autumn months, at a time when other work on the land, the plucking of beet excepted, is slack.
Such people are little accustomed to machinery and are naturally more liable to fall victims to accidents. The overcrowding, too, of that part of the works where the beet is received, the constant vehicular movement, motor and horse-driven, and the insufficiency of lighting at night must also be taken into account.

The extraction of sugar by diffusion does not create any special dangers except for the workmen whose duty it is to clean out the diffusers, because while opening up the apparatus they may be exposed to inhalation of gas given off during the operation (hydrogen, carbon dioxide, and occasionally other gases). Another danger to inattentive and unskilled workers exists in the machinery. There is also the danger of burns from steam or from the hot pipes present in all the workrooms. Finally, after the stoppage of the diffusion, there is an accumulation of carbonic acid gas in the apparatus and the foreman of the battery must be careful to clean the diffusers out frequently.

Accidents in carbonatation are due to the workmen entering the tanks to repair or clean them without taking care beforehand to see that the taps and valves admitting gas or steam are properly closed; or without having ascertained whether any carbonic acid gas remains behind at the bottom of the tank.

Mention also has been made of explosions caused by approaching the apparatus for evaporating or for the third product with a naked flame after cleaning them. It is known that in spite of carbonatation carefully carried out some lime always remains in the juice in the form of organic salts. During evaporation the salts become deposited on the internal walls of the apparatus which require to be frequently cleaned. For cleaning an acid is used liberating fumes which, mixed with air, may form an explosive mixture. Causes of poisoning are ammonia, ammonium cyanide, chlorine, alcohol vapours, etc. Similarly there is danger to the workmen employed at the lime kilns because of the carbon dioxide escaping at leakages and accumulating inside the apparatus and certain furnaces (see article "Lime"). The same remarks apply to the workrooms where clarification by sulphurous anhydride takes place. In the room for the third product and the evaporators, the temperature and relative humidity are high, but it is in the centrifugalising room and the room containing the evaporating pans that this heat and humidity reach temperatures that have long attracted the attention of hygienists (see article "Hot and Moist Air"). These rooms are veritable thermostats, the object being not to allow the temperature of the boiling mass to fall too rapidly and get below 40° C. Consequently their unhealthiness is due to the following conditions: as little renewal of the air as possible; very high temperature; high degree of humidity; unpleasant smell; an atmosphere rich in micro-organisms.

The danger of infection is especially one closely related to the presence of micro-organisms in the air, which find in such an atmosphere the best conditions for their development.

Safety and health precautions in the refineries may be summed up in the same way as has been done for the factories. Control of the heat, however, is even more difficult than in the latter as can readily be understood after what has just been said; the ceilings are generally low and work is continuous throughout the year. Temperatures of 25°, 30°, and 35° C. and even higher are recorded in the rooms where clarification, centrifuging and crystallisation are done, with a relative humidity of 80° to 90° per cent. On the other hand, in the smaller workrooms there is risk of explosion when the dust comes into contact with a naked flame.

Finally, as the refineries must have quantities of crystallised sugar so as to be fully employed and must get them when they can, some have very large warehouses where sacks of sugar are piled one on top of the other to a great height. Handling these sacks not unfrequently causes serious accidents either from falling sacks or mishandling of the lifting machinery employed.

Pathology

The statistics of the Leipzig Local Sick Insurance funds show the morbidity of the sugar industry to be very high. The number of sick days is 69 per cent, higher than the average; accidents and respiratory diseases are two and a half times higher than the normal, and diseases of the digestive tract 30 per cent, higher, while rheumatism shows a percentage of 70 per cent, above the average. These figures, however, refer to a relatively small number of persons (40-50) and Lehmann is of opinion that the high morbidity noted might be explained by the fact that the manufacture of sugar is limited to unskilled persons and is carried out during the cold season of
the year. In refineries working the whole year round conditions are considerably better. A similar condition has been noted in other countries (France, Italy, Russia, etc.).

The high temperature is the cause of headache, heat stroke, intense thirst, and sometimes fainting. The workman drinks huge quantities of water and becomes the victim of digestive ailments. These very high temperatures may be avoided thanks to the installation of adequate systems of ventilation.

Saizeff (1927) found, at the end of a sugar season, rheumatism (24 per cent.), furonculosis (20 per cent.), acute bronchitis and other illnesses due to chills; and Chafanow (1927) loss of weight through evaporation of water due to high temperatures. Malaise and high temperature are present also in the process of clearing, especially if centrifugals and mixers are installed in the same room. They favour naturally the contraction of chills, rheumatism and respiratory affections.

On the subject of if and how sugar dust acts on the respiratory tract opinion is divided. Some writers (French) think that 10 per cent. of the refiners are subject to tuberculosis, while the majority take the view that it has no specific action in the lungs. There are no two opinions as to its effect on the teeth (see later).

According to certain Italian writers, tuberculosis is said to be only slightly prevalent among refiners working under good conditions. Evidently one cannot generalise about such a point as local conditions in different countries vary so much.

A certain number of accidents from the centrifuge have been reported, involving fracture of the outer casing owing to faulty charging or excessive speed. But what characterises the rooms in which the centrifugals are placed from the point of view of hygiene is a dermatosis attacking all the uncovered parts of the skin, fingers (especially the borders of the nails), hands, forearms, face and neck. The workmen who go down with naked limbs into the molasses tanks are attacked on the arms and legs. The splashes from the boiling sugar get into the cracks on the skin and induce an exudation of serum. Secondary infection follows and the lesions become pustular. Often the dermatosis is favoured by contact with pants saturated with syrup. Those who are employed on sugar in a viscous state, on the molasses of the second product in sugar factories, in centrifuging, or boiling are especially liable. Oliver long ago described a lymphangitis accompanied by discomfort and boils.

The infection seems to be produced at places where the hair follicles are conspicuous; the dry viscous mass when removed pulls out the hairs and pathogenic organisms gain entrance. The malady commences with slight fever, preceded by shivering and feeling of weakness. The healthy skin shows a localised infiltration which, after a few days, takes on all the characters of a very painful boil. Lymphangitis and inflammation of the glands are present and unless lanced the boil bursts of itself with escape of a quantity of pus. Healing is very slow. Sometimes the boils are multiple and they can even unite and cause a condition of cellulitis.

This lesion affects two-thirds of refinery workers employed in the crystallisation of the products of the second product and especially those engaged on it for the first time. Curiously enough, this affection tends to become less and less frequent after the first year and only attacks those working in successive "campaigns".

Gardenghi has shown that the micro-organisms which cause the infection (staphylococcus pyogenes albus, and sometimes aureus also) can be found in the boiled masses in the crystallising vats. The conditions of the medium naturally favour their development and Gardenghi is of opinion that the non-sugar elements contained in the secondary substances make the skin very susceptible to the action of the pyogenic organism in facilitating and exaggerating their effects. The heat and humidity also play an important part, because they tend to macerate the skin and so favour the action of the micro-organisms.

Nevertheless, cases of lymphangitis not only in the factories, but also in the refineries are becoming rarer and rarer.

The Medical Inspector of Factories for Great Britain, in his report for the year 1922, has some interesting observations on a dermatosis peculiar to refineries. Thus, in two factories employing more than 4,000 persons 12 cases had been noted in five years. The parts affected were the hands in 8 cases, the hands and arms in 1, arms and face in 2, both legs in 1. Duration of employment before the malady appeared varied — in 2 cases it was six months, in a week only. 1 at the end of one year, 2 between one and two years, 2 between two and five
years, 2 after five years, and 1 after 34 years. The dermatitis shows itself generally in the interdigital spaces as a scaly rash and extends from there to the back of the hand. Later these scales weep, but the affection rarely looks like a genuine eczema.

The statistics published by the British authorities of food-poisoning contain the following figures for dermatitis reported during the period 1928-1930: cases due to sugar, 187; cases among confectioners, 93; cases among sugar refiners, 37.

In refineries attention must similarly be paid to sugar breaking. All the time the workmen are coming into contact with lumps of powdered sugar and some of the latter must get into the air. Contact with the lumps, it has been found, abrades the epidermis of the finger-tips, which becomes extremely sensitive to the pricks from the sharp points of the crystals. This lesion is also very common among sawyers and packers of sugar.

Although it is difficult to show that sugar has a specific action on the skin the facts stated give support to the view. Bridge considers that the sugar itself plays a role in producing the condition. Once affected, a second attack easily follows on contact with sugar. In some factories workmen who have had two attacks are transferred to other work. This danger, which is really not very formidable, can easily be combated by attention to cleanliness (washing accommodation, baths, etc.).

Deposition of sugar on the teeth and gums, unless removed by frequent cleaning, favours fermentation processes and loss of the teeth. Dental caries often shows itself after 1, 2, or 3 years; in those who observe good dental hygiene after 4 to 11 years, and in those who have a very good set of teeth in 10 to 14 years. According to observations of Koelsch and Misch among persons of 40 years of age employed in sugar factories, only 6.7 per cent. sound teeth out of 32 were found. Kuhnert, in 1901, stated that among all persons of 25 to 28 years of age coming into contact with sugar only 40 per cent. of the teeth were sound, while the percentage fell to 21.2 for persons of 40 years of age. Friedländer (1921) considers that the caries can only be caused by the sugar dust and not by sugar consumed as food. Examination of 1,208 persons whose mean age was 34, and who had been for 14 years on an average in contact with sugar, enabled him to say that (out of a potential total of 38,121) the teeth in 43.3 per cent. of the cases were sound, in 3.5 stopped and in 53.3 per cent. defective (and of these 41.8 had been extracted, 10 fallen out and 7.2 were carious).

Gerbis in 1923 was able to examine 300 men in sugar factories. The cases with earliest development were those of a man aged 51 employed for 8 months in crushing sugar and a girl working for 5 months in the section for fondants. Generally caries begins about a year after commencing work, whilst tartar appears within a few months. Caries and loss of the incisors were noted by Gerbis in 6.5 per cent. of persons within less than a year’s employment, in 25.5 per cent. between 1 and 3 years, in 46.8 per cent. between 3 to 10 years and in 25.42 per cent. after more than 10 years. In the last group 44.58 per cent. had a denture either completely ruined or lost. Not one had an intact set.

Watré (1927) considers, in the light of his experience, that the dental lesions appear after six years’ work and that sugar dust acts mechanically by causing gingivitis.

In 1921 eye troubles (conjunctivitis, superficial keratitis) due to the pollution of the washing waters by sulphur-etched hydrogen were found in 1921 in the best-washing department of a Dutch sugar factory.

Thiele (1928) also found keratitis, which he ascribed to sulphur-etched hydrogen, in three sugar-factory workers.

Three cases of poisoning, of which two were fatal, in a sucrose works employing the baryta process were ascribed (Leclercq and Vallée, 1926) to the gases given off by the electric furnaces for the regeneration of barium carbonate and containing carbon monoxide, amines, hydrocyanic acid, ammonium cyanide, various hydro-carbons, etc. Jacobi (1927) reported three cases of carbon monoxide poisoning.

Saizeff (1927) found in sucrose works caustic burns on the hands and conjunctivitis due to lime dust. The workers who were unaffected at the beginning of the season were all suffering from conjunctivitis at the end (two months later).

Hygiene

The most important measure is to see that the floor is impermeable and smooth and channelled so as to allow the water to run off. The walls and ceilings should be impermeable and frequently washed; cleanliness should be meticulous, and accumulation of matter capable of fermenting should be prohibited. Apparatus should be arranged on a careful plan and precau-
tions should be taken to prevent the escape of gas and steam from furnaces, tanks and evaporators. The chimney stack should be a high one. Manual labour should be, as far as possible, replaced by automatic machinery.

In very hot and humid places work should be done mechanically as far as possible; there should be artificial electric lighting and alternation of employment so as to limit the length of time spent in these rooms; a place for refreshment, which might usefully be placed near by, should be provided, separation of the centrifuge rooms with localised ventilation of each one; ample air space; propulsion of dry hot air; energetic extraction of the hot saturated air; fireproof covering of the steam pipes; removal of the mixers from the centrifugal as which should, if necessary, be provided with constant cleaning should be effected with hot dry air by mixing beforehand saturated with superheated steam. From the hygienic point of view, clarification by water is much to be preferred to that by steam (and from the economic point of view also).

The water from condensations should be considered animal blood regenerated by mechanical means. If this is not practicable, the filters should be charged in such a way as not to expose the workers to its inhalation.

The immediate surroundings of the lime kilns and the sides of the piping leading the carbonic acid gas to the tanks should be arranged so that they can be watched easily and no one should be allowed near them except workmen whose duty it is to look after the furnace. The same remarks apply to the sulphiting plant.

The cleaning of the boilers, tanks and vessels in which gas might accumulate should only be undertaken after ensuring complete ventilation and under the direction of a foreman.

Measures for the temporary storing, transport, and disposal of residues of all kinds should be adopted. Sugar factories use enormous quantities of water in the different processes. Thus 1,000 quintals of beet require about 700 or 800 cubic metres of water.

The water from washing the diffusers, pulp presses, and, in less degree, that from washing the beet, is very liable to ferment. The former contain about 5 parts per 1,000 of organic matter in suspension and 6 to 8 per 1,000 in solution as well as 3 per 1,000 of sugar. These fermentable waters give off a very disagreeable smell and statutory provision is made in all countries to prevent their passage into streams. The condensing water is relatively free from risk and still less so the washing water.

The problem of the purification of these waters has always been a matter of great difficulty and they cannot all be treated in one and the same way, as regard has to be paid to the kind and quantity of the water coming from the different sections of the factory.

Chemical treatment (with lime, oxide or sulphate of iron) is expensive and insufficient; mechanical filtration only represents a partial solution of the problem.

Biological treatment, preceded by filtration and aeration, gives good results, but eliminates only 40-70 per cent. of the organic matters. The problem of complete purification of the sugary waters therefore still awaits solution. (See also report of the British Ministry of Agriculture and Fisheries, published in 1928.)

Separate treatment of the residuary waters of the different departments can be tried. Thus, e.g., clarification of the waters for washing and extraction of the juice, containing earth, roots and debris of beet, sugar, and salts, can be effected by sedimentation and repeated filtration over sand and cinders. The substances contained in the water can also be decomposed by reagents such as chloride of iron, alum, permanganate of potassium, with production of water capable of being sent again to the factory.

The waters from treatment by charcoal containing ferments, alkalis, albuminous matters, etc., can be filtered through wood charcoal and treated by acid magnesium, phosphate and a basic iron salt. The best results, however, are those from biological treatment combined with some other process, either mechanical or chemical.

For personal hygiene see that article.

Lymphangitis has disappeared wherever the workmen are able to avoid frequent handling of the viscous sugary masses, and where douche baths and means of personal cleanliness have been provided. Where it has shown itself, frequent washing with antiseptic lotion suffices to ameliorate the condition. Strong workmen with healthy skins whose sweat glands function normally but not to excess should be selected, and those with heart disease and alcoholic subjects excluded. Lastly, it should be added that in many of the sugar factories in country districts some of the workers are strangers to the district and occupy sheds. Such sheds must be kept clean and in good sanitary condition.
SUGAR. — 964

Special Regulations have been issued in Germany (24 Nov. 1911) on the employment of women and young persons in sugar factories and refineries in Austria (28 Aug. 1911, No. 142), in Yugoslavia (25 Oct. 1921, as to health and safety measures in such undertakings), in Belgium (Royal Order of 4 October 1923 concerning the physical purification of the residuary waters), and in Czechoslovakia.

Regulations issued by the Austrian Ministry of Commerce lay down the measures for the prevention of accidents during the reception and washing of beetroot (paras. 2 and 3), diffusion (para. 4), carbonatation and evaporation (para. 5). In this paragraph are laid down the measures necessary for preventing accidents in the cleaning of evaporators with vertical pipes and adoption of means for closing the pipes for steam, carbon dioxide, and juices, is required. Para. 6 deals with the prevention of accidents from centrifuge machines; para. 7 with the breaking of sugar (press guards, circular saws, etc.); para. 8 with the preparation of the lime (perfect tightness of the apparatus, exhaust ventilation for the removal of dust, etc., are required); para. 9 with steam apparatus. Dangerous operations are dealt with in para. 10 (which prohibits descent into tanks or vessels which might contain injurious gases before the absence of such gas has been ascertained; if it is not absent they must be ventilated by washing with water or steam or by blowing air in, etc.). Directions are given for arranging the piles of sacks in stores. Cleaning and repairing the apparatus is dealt with in paras. 11; making the lime in para. 12 (in addition to accident prevention it prohibits the use of the store from which the lime is withdrawn as a sleeping place). The work of diffusion and evaporation are the subject of para. 13 (prohibiting descent into the molasses tanks, carbonatating, evaporating apparatus, especially after they have been cleared with boiling acids; and prescribes constant supervision of the workman employed in cleaning operations). Paras. 14 and 15 treat of the centrifugals and the construction of the ceilings; para. 16 of welfare (sanitary conveniences arranged so that the workers have not to be subjected to great changes of temperature in going to them); drinking water, rest room, washing accommodation, baths, overalls and foot-wear, cloakroom, etc. Protection devices for workers tending, the kilns are described in para. 17. First-aid provision is laid down in paras. 18 and 19, with selection of personal (exclusion of epileptics, deaf persons, the subjects of fainting fits, vertigo and cramp, etc.).

These measures are required also in Yugoslavia (loc. cit. sections 295-313) and in Czechoslovakia (the same as the Austrian Regulations of 1911).

The Netherlands requires notification of dermatitis (eczema) and synovitis of the joints and tendon sheaths and subcutaneous tissue in persons employed in sugar factories and refineries, and of conjunctivitis in beet sugar factories.

Legislation in New Brunswick awards compensation for all illness, the result of infection set up by work with sugar, and in Mexico, for dermatitis among sugar cane gatherers. Great Britain has scheduled among diseases to be treated as accidents for purposes of compensation any dermatitis or ulceration of the skin due to dust and liquids.

Queensland Workers' Accommodation Act, 1925. — Any person engaged in work for the employer (in plantations, sugar factories) shall be given sufficient and comfortable accommodation by the employer free of charge. Such accommodation shall include a bedroom, dining-room, drinking water, shower-baths, etc.

**Sulphate of Soda**
*(Sodium Sulphate)*

**MANUFACTURE**

The manufacture of sodium sulphate (Na₂SO₄) has lost much of its former importance since the Solvay process for the production of soda has taken the place of the Leblanc. Actually its industrial use is limited to the manufacture of glass and, secondarily, that of sodium sulphide. Purified and hydrated it is used as a medicine under the name of Glauber's salts.

The principal process in the manufacture of sodium sulphate is based on the reaction, when hot, of sulphuric acid on sodium chloride.

The reaction takes place in two stages in a special muffle furnace divided into two parts: the pan, which is a large chamber with very thick walls, and the muffle furnace, with its floor constructed of refractory material.

The furnace is charged with common salt and raised to a high temperature, and into it is directed, by a pipe running along the roof of the furnace, the necessary quantity of sulphuric acid at an average temperature of 58° B. and carried to a temperature of near 100° C.

The mixture of sulphuric acid and chloride of sodium is stirred in the pan by means of long iron rakes. When the mass is in a pasty condition, it is pushed through a sliding door into the muffle furnace, where the further reaction is finished.

On leaving the muffle furnace the neutral sulphate of soda is withdrawn, cooled and carried into the storehouse.

While the process is going on, considerable quantities of hydrochloric acid vapours are given off. These gases are carried separately from the pan and muffle furnace into cooling apparatus where they are condensed.

To effect this condensation, two systems are in vogue: the first consists in acid resisting towers packed inside with porous fragments through which the gases rise to be met by a rain of water coming from above. The other process consists in batteries of stoneware Woulfe bottles half filled with water through which the gas bubbles.

A manufacturing process much less in vogue is to use the gas given off in the roasting of pyrites.

The gases, with steam added, pass from above downwards on to the sodium chloride arranged in cast-iron pipes. The HCl solution thus obtained then undergoes suitable precipitation and condensation.

**SOURCES OF DANGER**

Work at the pan and calciner is made peculiarly irksome by reason of the excessive heat given out from the furnaces. And the work of rabbling the mass in the pan, shoving it into the calciner, and finally withdrawing it is rough in the extreme.

The principal nuisance, however, with which we are concerned comes from the escape of gas (see the article "Chlorine") from the furnaces, muffle furnaces, pans, and discharge piping. At the pans the escape is especially pronounced during charging and rabbling the mass subjected to the reaction. It is much richer in hydrochloric acid fumes than that emanating from the second hearth of the furnace, but in the latter the high temperature reached allows sulphuric acid fumes and certain chlorine derivatives of iron and arsenical compounds (arsenious anhydride and arseniurated hydrogen gas) to be given off. They constitute a further risk because of their toxicity. (See the article "Arsenic").

Whenever the charge is withdrawn from the muffle furnace, the sulphate of soda, on cooling, gives off vapour and gases (mostly hydrochloric acid fumes). Analyses made by the Factory Department in Belgium demonstrate that, in the course of cooling, the sulphate of soda undergoes a loss of 0.018 per cent, calculated as hydrochloric acid.

A further nuisance in the manufacture occurs, if effective preventive measures are not taken, from the escape into the surrounding atmosphere of considerable quantities of chlorine gas which has escaped condensation. The destruction thus caused to the vegetation is often considerable and the nuisance created may sometimes make itself felt in an extremely disagreeable manner to the people living in the neighbourhood.

**STATISTICS**

See article "Alkalis".

**HYGIENE**

Mechanical furnaces are in use carrying out the processes of mixing the sodium chloride with sulphuric acid
and rabbling right up to the completion of the reaction. The Mactear furnace is an example based on the action of cast-iron stirrers in mixing automatically the mass subjected to their action.

This removes an important part of the work for the persons employed, because not only is rabbling by pans made unnecessary, but charging and discharging are greatly facilitated. These mechanical means, however, do not eliminate the chlorine emanations, so that the greatest care is necessary in installation, proper maintenance and working of the exhaust ventilation, especially of the hoods above the furnace doors. Escape from joints and fissures in the piping is frequent owing to the high temperature of the gases as they leave the furnaces; they also need constant supervision and frequent luting.

Condensation and cooling of the hydrochloric acid necessitate suitable apparatus if damage to the personnel of the factory and persons living nearby are to be avoided. Cooling, which is effected separately for the gas coming from the pans and from the muffle furnace, takes place, to a slight extent, while the gases pass along in the piping and much more in the thick walled acid-resisting tanks provided with bafflers inside. These tanks (called "douches") are sometimes kept moistened with a little water, which helps to absorb the sulphuric acid vapour without absorbing too much of the hydrochloric acid gas. This latter gas passes then to be condensed in one or other of the two methods already described. As an instance of complete condensation, after cooling, an account in detail of the steps in the process as carried out in works using the tower system is given below.

The hydrochloric acid vapour coming from the cooling tanks is directed into two "scrubbers" constructed of lava and filled with lumps of coke. They come into contact with a spray of water and the gases are thus cooled and wetted, and so condensed for a second time if account is taken of the preliminary cooling carried out in the cooling tanks.

From the scrubbers the hydrochloric acid gases, always kept distinct from their origin, are directed in two groups towards the condensing columns, constructed of lava, 2.20 metres wide and 12.50 metres high. These columns are filled with lumps of coke and a water spray falls constantly on them from above.

The cooled and moistened gases meet this stream of water, take it up greedily and pass into solution of a strength of 16.8° B.

The gases which escape condensation are collected at the upper end of each of the columns, and are carried by stoneware pipes to the bottom of two columns 8.50 metres high, and 1.90 metres wide. These are similarly filled with coke and are subjected to an abundant spray of water; the hydrochloric acid vapours are practically all dissolved; the acidulated water collected at the bottom of the apparatus is only 0.1° B.

These very dilute liquids pass into a drain, where they are mixed with large quantities of water coming from other parts of the factory; they are still further diluted and then mixed with a solution of chloride of lime, which completely neutralises them before their discharge into the river. Finally, traces of hydrochloric acid vapours which may escape from the upper part of the last columns are led into a final chamber analogous to the cooling tanks already described, where they come into contact with a last supply of water and are then discharged into the factory chimney. The quantity of chlorine detected in the smoke drawn from the bottom of the chimney yields, on an average of ten tests, 0.680 grm. of gaseous hydrochloric acid per cubic metre of smoke.

The normal functioning of such a condensing system necessarily depends on the use of a sufficient supply of water to absorb the gases. In certain circumstances there may be important economical advantage in discharging into the atmosphere much hydrochloric acid vapour. In order to prevent such action, which may lead to considerable damage to the neighbourhood, it is advisable to place seals on the water mains in order to prevent any diminution in the amount of the water supply. Further, to make inspection easy, meters with seals attached should be affixed to the water mains.

This double recommendation is of use also in the case where condensation is effected by means of batteries of Woulfe bottles through which the gas is made to bubble.

**Legislation**

Women are excluded from the manufacture of soda salts and sulphate of soda in Argentina, France (where acid vapours are given off), and Switzerland. In Belgium young persons under 16 years of age are prohibited from employment in factories for the manufacture of artificial soda by decomposition of the sulphate, caustic
Soda by means of crude, artificial soda and sulphate of soda. In Spain, lads under 16 years of age and women and girls under 21 are excluded from factories where sulphate of soda is made and in places where acid vapours are given off, from factories where sulphate of soda is made by means of the chloride, and from factories also of sulphide of sodium. In Switzerland and France young persons of less than 18 years are excluded from the manufacture of sulphate of soda by the decomposition of common salt by sulphuric acid and from factories where acid gases are given off. In Italy, boys under 15 and women and girls under 21 years are excluded from the manufacture of sodium salts by means of sulphuric acid, etc.

Invalidity caused by sodium sulphide is treated for compensation purposes in Switzerland as though it were an accident. For hydrochloric acid, etc., see the corresponding articles.

Dr. D. Gilbert
( Brussels).

Sulphur

Sulphur Mines

In Sicily sulphur is found in more or less deep-seated deposits (100-300 metres in depth) of varying richness, and consisting of crystallised or agglomerated sulphur mixed in varying amounts with other calcareous or marlaceous substances of sedimentary origin, which form the gangue. On this mixture depends the richness of the ore utilisable (from 14 to 60 per cent. for industrial purposes).

The first operation in prospecting for sulphur, and which is of no particular importance for the purposes of this article, consists in taking soundings and in excavation effected in regions which geologically would imply the presence of the mineral.

Such excavations consist in the opening up of horizontal galleries or galleries with an incline of 40° provided with the necessary equipment and where a certain depth is reached, with adequate ventilation, which is furnished by means of piping in wood or masonry running along the galleries.

When water is encountered in course of the work it has to be removed by pumping; but where it is present in too great quantities digging is simply abandoned.

Another danger is represented by the presence of fire damp or sulphuretted hydrogen likely to give rise to serious accidents in the case of a sudden liberation. Once a fairly rich deposit has been struck, working on a serious scale is commenced: hewing of the ore in the galleries, extraction and transport from the mine to the nearest station.

Extraction

The deposit of sulphur is attacked as far as possible along its whole extent with the double purpose of extracting the sulphur and proceeding with the opening up and eventual development of the mine.

There may therefore possibly exist various working levels separated from each other by deep intervals of 10 metres or so. The work proceeds by exhausting the product, in attacking the rock at various levels from below upwards and filling up the empty spaces as they are found by material brought from outside.

The workers engaged in hewing employ different methods, according to the nature of the rock.

In general, dynamite is used, but with a view to eluding legislative safety provisions the workers at times use a white powder which they themselves prepare with potassium chlorate, flour and sawdust, and which exposes them to very grave danger. The blasting holes are prepared and loaded by the pikemen. At a fixed hour the men who light the fuses, provided with protective apparatus against smoke and explosive gases, set the explosion in train and control its effects.

Once this operation is completed, the pikemen return to the working face and break into pieces the loosened material and prepare it for transport.

In small undertakings the pikemen do both the charging of the blasting holes and the lighting of the fuse.

When the rock is very friable or the ore very rich in sulphur, the hewing is done by hand by means of a pick.

The pick used is usually prism-shaped and very large; it weighs 5 to 7 kg. and is sharpened only on one side. At the base of the prism there is a hole through which a wooden handle is inserted.

Manipulation of the pick involves a shoulder movement, which requires a certain skill and also demands considerable muscular effort.

Continual repetition of these movements leads to emphysema and pneumoconiosis, which are in fact of very frequent incidence amongst pikemen, who are
also exposed to numerous forms of microtraumatism from flying stones, which become detached in great numbers at each blow of the pick on account of the great friability of the rock, thus creating a risk of eye injury, not a rare occurrence. A technopathy of relatively frequent incidence occurring amongst these workers and connected with the use of the pick and the crowbar, which weighs about 10 kg., is a form of dry tenosynovitis, almost invariably localised in the muscle sheaths of the forearm.

The gravest dangers to which workers of this category are exposed are connected with accidental falls of rock, the effects of which extend from simple contusions to complete crushing. Accidents of this kind may affect the hewers when mine explosions occur before or after the moment anticipated. Accidents of this kind are, however, almost always due to lack of care.

Transport of the material got is effected in three stages: (1) from the rock face to the trucks in the transport galleries; (2) from these galleries to the outside, that is to say, to the pit entrance; (3) from the pit entrance to the place of discharge near the foundries. Wherever possible a system of Decauville rails are laid up to the working face and loading of the trucks is effected directly from the heap of hewn material. When loading galleries are situated at a lower level, loading is carried out by means of hoppers.

In other cases, the transport of the ore is effected by porters — known in Sicily as carusi — who carry the material on their backs but only for very short distances, since it is in the interests of the industry to reduce as far as possible the carrying of loads on the back, which is a very costly system. These porters are of various ages, some of them forty years of age or over. At all events, the youngest are always over the age demanded by law, i.e. over fourteen years of age. The weight of the loads carried varies, naturally according to the age and strength of the worker, from 20 to 80 kg. Amongst porters, especially adults, hernia is frequently encountered and likewise deviations of the spinal column (kyphosis and scoliosis). Apart from accidents to which all the workers in the mines are exposed, the porters often suffer from traumatic lesions, due to material which has fallen from the load they are carrying or from that of their comrades.

The trucks, after being loaded, are pushed by hand to the stations, where trains are formed; these latter are then drawn by mules to the shaft cage, which brings them to the surface. The work of the truckmen involves effort required for pushing the trucks, weighing 1,500 kg., an effort which is increased when the mine galleries are not absolutely level or when, as is very often the case, the ground is damp and soft.

Cases of hernia are common amongst these workers, as well as accidents due to collisions of the trucks when riding on these, and when perchance the trucks leave the rails or overturn.

Traumatic lesions amongst porters are fairly rare, and still rarer in mines where the workers carry the material on their back from the working face to the unloading station at the surface, i.e. in small mines of little importance and of relatively slight depth, which are, on the whole, of little interest from the point of view of production. The trucks on their arrival at the surface are received by the workers, and sent for discharge to the neighbourhood of the foundries. This latter stage of transport may be effected by the workers themselves or by animal haulage, or again by mechanical means, more usually when the level of discharge is higher than that of the entrance to the pit.

The work of truck-men at the surface is similar to that of their comrades in the pit, but it has the advantage of being carried out in the open.

Treatment of the Sulphur

The last phase of manipulation is carried out at the surface, where the mineral is submitted to the action of heat (smelting) in order to free the sulphur from the gangue which surrounds it. This operation is effected in Gill furnaces and in so-called calcheroni (Sicily).

The furnaces are composed of a number of small compartments made of masonry, which may communicate with each other in order that a part at least of the heat produced in the first compartment may be utilised in the others. Loading of these does not involve any manipulation apart from filling the furnaces with the ore when these are lit.

The calcheroni are, on the other hand, vast receptacles constructed of masonry having a circular form, and from 15 to 20 metres in diameter, open at the top and with a hearth, which is constructed with a very strong incline on one side. The charging with ore is effected in a certain order up to the level of the upper edge of the masonry,
the ore which is added thereafter taking on a conical form. The whole is then covered with a layer of foundry residue having a thickness of 10 cm., with a view to preventing contact with the air and allowing only a few holes through which the mass can be fired by means of faggots. In the furnaces above described, as well as in the calcheroni, the agent of combustion which effects smelting is the sulphur itself. A large part of the mineral is therefore lost by transformation into SO₃, which forms a more or less abundant smoke, which becomes disseminated above the mine.

As smelting takes place, the liquid sulphur is recovered from the hearth of the furnace or calcheroni at the foot of the slope, which ends in a special discharge aperture known as the dead space. This aperture is protected by a wall of lesser thickness, and when smelting commences, lasting four to eight days in the case of Gill furnaces and eight to twenty in that of the calcheroni, according to their size, discharge holes for the molten sulphur are effected by means of an iron bar. After smelting has terminated the other workers, scarcaratori (Sicily), after having completely broken down the discharge aperture, loosen and break with a pick the residue (ginesi), which is loaded on to trucks and thrown on to heaps at some distance, being without further value.

For ore which is rich and has a high sulphur content, a combustion process involving the use of coal is resorted to. The ores, which are placed on special trucks with grids, are introduced into cylindrical boilers, the lids of which are bolted on. Steam at a pressure of 4-5 atmospheres, that is to say, a temperature of about 150° C., sufficient to separate the sulphur from the gangue, is passed into the boiler into the centre of the ore. The molten sulphur flows through a hole in a trough, from which it is directed into moulds by means of large ladles.

After this process the ore is not completely exhausted and the residue still contains about 15 per cent. of sulphur. This residue is recovered and submitted to further treatment in Gill furnaces. All the smelting operations are effected under the supervision of workers known as arditori (Sicily), who are subjected during the whole time to the injurious action of sulphur fumes. These cause chronic and extensive bronchial catarrh, with resulting pulmonary emphysema. Amongst old workers cases of atelectasis and pathological derangement of the pulmonary circulation are still met with.

Respiratory lesions are of earlier occurrence and are more usual amongst the scarcaratori, whose work is effected in surroundings charged with hot and bitter dust rich in acid gases from the sulphur, which are liberated during combustion (SO₂ and SO₃).

The transport to the stations of the sulphur melted into block is effected by various means: loaded on donkeys, lorries, carts or again by mechanical means (tramways or overhead rails). Each mine comprises a certain number of auxiliary plants, amongst which an important place is occupied by machinery destined for the production and utilisation of power necessary for the different stages of manufacture.

At the present time, except in rare instances where steam is still used, the mines generally generate the electricity necessary in the thermic stations by means of motors activated by poor gas, heavy oils or naphtha.

Running a mine requires further the assistance of mechanics, electricians, machine-minders, blacksmiths, boilermakers, furnacemen, foundry workers, carpenters, woodworkers, etc., whose work is effected not only at the surface but also in the mine. Mines therefore constitute a highly complicated organisation, to the successful and harmonious working of which numerous categories of workers contribute in various ways and under exposure to various risks, amongst which may be mentioned, as of first importance, account of the risks to which they are continually exposed, timberers — those workers called on to effect their work at the most dangerous points of the galleries and engaged in reinforcing the galleries and workplaces with a view to preventing falls of rock, and securing safety for their comrades engaged in hewing and transport.

**Sources of Danger**

Mining conditions have a predominant characteristic connected with the nature of the ore mined with which the workers are continually brought into contact, in the present instance sulphur. Distinction must further be made between outside work and work in the mine proper, since in the latter special working conditions are encountered.

The temperature in the mine galleries is dependent on a number of factors and principally on the nature of the deposit, on the abundance of ventilation and on the humidity rate.
Underground lighting is always artificial. Use is made of lamps with a free acetylene flame, electric lighting being installed, however, in the transport galleries of certain mines. In very special cases safety lamps are used.

No ocular technopathy like nystagmus has been observed.

Ventilation of mines is almost always effected naturally: the air penetrates into the pits and descending galleries, circulates through all the underground ways and returns to the outside through special piping designated riflessi (Sicily). In very extensive mines there may be several entries for air and several riflessi. Cases of artificial ventilation are rare, but are utilised in certain sections of mines and more frequently at the working face where it is deep and distant and therefore not situated in the path of air circulation.

Even where ventilation is abundant the air of the galleries is exposed to numerous causes of vitiation, e.g. the gaseous derivatives of the sulphur. Amongst these should be mentioned: (a) sulphur dioxide formed during explosions and continuously during combustion of sulphur particles in suspension in the atmosphere which come in contact with the flames of the lamps; (b) sulphuretted hydrogen, which is mixed with the water in the deposit and from which it may easily be liberated; at times it is encountered in pre-existent pockets and it appears to be also produced during processes of maceration and putrefaction of organic substances (wooden supports, refuse) which take place in the subsoil itself; (c) carbon dioxide produced by human respiration, by combustion of acetylene or oil lamps and during explosions. Amongst the derivatives of carbon there are present in large quantities numerous hydrocarbides, amongst which should be mentioned firedamp, which the workers in Sicily call 'antimony', and which is encountered particularly in very deep mines or mines having argilaceous gangue. This gas is sometimes sufficiently abundant to warrant extraction by special piping, at the end of which it remains continually lit like a gas jet.

In the air of the mines and particularly in the dry zones there is found in abundant suspension a type of dust formed during hewing of the ore and all subsequent manipulation during loading of the trucks and during transport. This dust is of the same nature as the ore and likewise the gangue, and is composed of particles

Absolutely dry mines constitute a veritable exception. There is generally a more or less considerable quantity of water which has a twofold origin: by infiltration from the outside through the various geological strata, and secondly the water from the deposit itself, which is, where it is of a calcareous nature, completely immersed in a watery mass more or less considerable in quantity.

Removal of water is one of the most urgent problems in these mines. In certain cases where the formation of the ground permits of it, special galleries are opened to allow of the water running off towards the outside, but as that is not always possible, recourse is had to extraction by means of pumps working without interruption. The flooring of the mine is therefore almost always wet and covered with mud which soils the feet and legs of the workers and often also their hands. This circumstance explains the presence of conditions favourable to the development and propagation of the ankylostoma, and damage is likewise caused by the solution in the water of a derivative of sulphur which Mottura describes as acid sulphate of iron, alumina, and lime, extremely caustic, and liable in strong concentrations to give rise to forms of dermatitis, sometimes even amounting to actual chemical burns.
of lime, clay and silica mixed with particles of sulphur. The latter, by reason of the crystalline form of the product, have rough surfaces and very sharp angles. These characteristics of the air of the galleries become accentuated as greater depths and greater distances from the entrance are reached.

### Pathology

The technopathies from which workers in sulphur mines suffer are dependent on the nature of the ore and on the action which it is capable of exerting in regard to the various chemical states of the system. It is for this reason that respiratory lesions abound. These reactions are due to penetration at each inspiration of a quantity of air containing in variable proportions acid gases from the sulphur and dust. This involves the combined irritant action of the gases with the traumatic action of the dust.

Subsequent to a chronic catarrhal condition, emphysema sets in, consisting in atelectasis and in very advanced cases of pleurisy. Circulatory troubles which never again recovers its former normal state.

Autopsies effected have proved the existence of cases of pneumoconiosis, amongst which predominate anthracosis due to a deposit of particles of carbon formed chiefly during combustion of the lamps. There is more rarely found deposits of sulphur dust designated by Giordano as "theapneumoconiosis".

The data collected in the course of visits made by doctors belonging to the Sicilian Association for the Pre-
vention of Industrial Accidents proved that about 50 per cent. of the workers in these mines suffer from chronic respiratory affections.

Another pathological manifestation consists in a certain degree of anaemia, quite independent of any other precise and specific cause (ankylostomiasis, malaria), but which would appear to be caused by the harmful action of the acid gases of the sulphur and sulphurous products on the red blood cells. This feature is very obvious amongst workers who work continually in mines or parts of mines where the presence of sulphuretted hydrogen is more marked.

Hernia has been met with in the case of about 25 per cent. of the workers.

Eye diseases are confined to chronic forms of conjunctivitis caused and favoured by the irritant action of dusts and gases amongst which a chief place is occupied by sulphuretted hydrogen. These symptoms affect about 20 per cent. of the workers.

Cases of deformation of the thorax and vertebral column (scolioses, lordoses: about 8 per cent. of the workers) are of rarer occurrence. These cases are diminishing now that transport on the worker's back is being replaced by mechanical transport and with the coming into force of the law prohibiting underground work for boys under fourteen years of age.

As regards infectious diseases, it must be stated that tuberculosis is a very rare occurrence amongst sulphur workers, either in visceral or in surgical forms. Cammarata (1923) found skin reaction to tuberculosis positive in a proportion of 95 per cent. amongst thirty sulphur miners.

Malaria is very widespread, and it may be said that a third of the workers have suffered from this disease for a more or less considerable period. The mines are always situated in unhealthy regions. It has further been noted that the anophelles mosquito may, under certain conditions, live and propagate in the mine galleries, thus increasing the possibility of contagion.

Ankylostomiasis is equally very extensive. Very few of the mines, two or three only, are free of it. However, it is a case of individuals suffering not so much from true anaemia as constituting carriers of the germs which are present in a fairly high percentage.

Whilst special reasons exert their effect in favouring the biological capacity of the parasites and at the same time attenuate individual resist-
by bridging short gaps (see article "Dust").

Accidents due to smoke tend to diminish in mines on account of the adoption of adequate means of defence (masks and oxygen apparatus).

Mine explosions may give rise to accidents, but are almost always due to imprudence on the part of the worker. Their effects may be very grave and often the sight is affected.

Inhalations, happily fairly infrequent, of sulphuretted hydrogen are always the consequence of sudden escapes of this gas and give rise to very acute poisoning which almost always ends fatally. In the less serious cases the symptoms disappear very slowly and usually leave poverty of the blood, which is hard to modify even after long delay.

Inhalations of firedamp (called "swallowing antimony" by the workers) may also cause serious cases of poisoning, but the greatest danger resides in combustion of gas and in explosion, since at that moment the flame from the explosion may envelop those workers which it encounters, with consequences rendered still more serious by the fact that the workers work naked or almost naked, thus offering vast surfaces to burns which affect also the mucous membrane of the mouth and the upper respiratory passages.

In certain cases where the volume of the gas is considerable, the galleries act like the tube of a cannon, within which the explosion projects and crushes against the walls the workers found therein.

Accidents due to firedamp therefore affect a large number of workers and are fatal on account of the extent of the burns. Death generally occurs six or seven days after the accident, being due to septicemia with nephritis or peritonitis in the final stages.

**HYGIENE**

In Sicily the mineowners are compelled to belong to the Sicilian Association for the Prevention of Industrial Accidents, which has organised first-aid posts in the mines, certain of which have doctors and nurses in attendance and others only nurses. This association pays for treatment of the victims

**Fig. 152. — An elderly sulphur carrier (Caruso).**
until complete recovery; it calls on the local consulting physicians for treatment for ordinary cases and sends to hospitals or convalescent homes the badly wounded or those having need of special care.

The association has served as a basis for the application of other branches of assistance, principally in the campaign against malaria and ankylostomiasis, a campaign in which the Public Health Department participates very effectively.

All the first-aid posts and all the consulting physicians in the communes are engaged in various ways and in accordance with the possibilities in the anti-malaria campaign, since during the whole year the curative treatment of the diseased is carried on, and during the epidemic season the prophylactic treatment of healthy individuals, as well as defence by means of "small-scale" health measures. It has been found that the extension of these means has resulted in arresting and even completely eliminating malaria in certain mines.

In the campaign against ankylostomiasis those measures are adopted which appear necessary and opportune from time to time. At Caltanissetta a hospital has been erected in which workers from all mines showing definite symptoms of anaemia are treated. Whenever small centres of diffusion become manifest, cleaning up and rendering healthy of the mine is engaged in, detection of the parasite being assured by microscopic examination of the excreta, examination of carriers and finally their disinfection while at work by means of daily thymol treatment combined with disinfection of the underground workings by application of milk of lime prepared on the spot.

The association has been able to constitute a special fund destined for thorough care of cases of hernia, which, on their own request or on that of the doctors concerned, are sent to a hospital, where they undergo adequate surgical treatment. In the principal mines rescue posts are attached to the first-aid posts furnished with accident apparatus, masks for fumes and smoke, electric safety lamps and lamps for measuring firedamp, safety belts, portable telephones and all other apparatus necessary for effecting rescue work or for the execution of work rendered especially dangerous by the presence of irrespirable gases.

This special service works in connection with a central rescue post at Caltanissetta, installed under the aus-

LEGISLATION

In Italy: Act of 30 May 1903, No. 184; Regulations of January 1907, No. 152, dealing with the regulation of mines, quarries and peat pits; Regulations of 3 December 1908, No. 787, on the service of rescue posts for workers in the sulphur mines of Sicily; Regulations of 3 July 1921, No. 1190, on the safety service of workers occupied in sulphur mines in Sicily. As regards work of women and children, the general measures issued for the regulation of work in mines are applicable. Boys under fifteen and women under twenty-one are excluded from grinding and refining of sulphur.

Dr. I. di Giovanni
(Caltanisetta, Sicily).

Sulphur and its Compounds

Sulphur, symbol S, is found in its native state under different forms: in crystals, in a compact amorphous mass, in stalactites, or in pelvulent layers. It is generally extracted from sulphur mines (see above), but in American cokeworks recuperation in a colloidal form of the sulphur contained in the gas has been effected.

In the pure state, sulphur is an element which is yellowish in colour and crystallises in two forms: rhombic and monoclinic. It is practically odourless and insipid; it melts between 114° C. and 115° C. (rhombic sulphur) and 119° C. (monoclinic sulphur). At this temperature it assumes the aspect of a yellow mobile liquid, which towards 250° C. becomes consistent and viscous and of a reddish-brown colour. It re-assumes a fluid form above 300° C. and boils at 445° C., giving off orange-red fumes.

It burns easily in air with an azure flame, liberating an irritant odour of sulphur dioxide. It is insoluble in water, slightly soluble in alcohol, ether and benzine and readily soluble in carbon disulphide.

Sulphur is used in the preparation of sulphuric acid, sulphurous acid, sul-
phites and hyposulphites, carbon disulphide, cinnabar, mosaic gold, artificial ultramarine, and organic sulphur colouring agents; it is likewise employed in vulcanising rubber and gutta-percha, for bleaching (wool, straw, etc.), in preparing cements, in the manufacture of matches, wicks, and inflammable powder, for coating wine or beer casks, etc. It is recommended for impregnation of wood with a view to its conservation, long the manufacture of compressed articles with a basis of cement, wood, cotton, or coke dust. Sulphur enters also into the composition of hardened and waterproofed papers and into that of certain plastic products (plastiline: 23 per cent. of sulphur). In agriculture sulphur is employed for dusting vines, fruit trees, vegetables, etc. Finally, numerous pharmaceutical products have a sulphur basis: ointments, pastes, etc.

Pulverised, sublimated or precipitated sulphur exerts an irritant action on the skin, which in the case of certain predisposed individuals may take the form of eczema (Hesse). In practice, however, affections of this kind are relatively rare. The mechanical action of sulphur on the ocular conjunctivae of agricultural workers, for example, has long been known. Eulenburg (1881) considered that sulphur was capable of causing even a very violent form of the above. Yet whilst Piconveri (quoted by Hirsch) is said to have noted a fairly high number of cases of conjunctivitis caused by sulphur — a fact which was confirmed by Burruano in 1906 — Hirsch (1910) does not claim to have noted any special form of conjunctivitis amongst the miners in the Rhineland.

Amongst the compounds of sulphur may be rapidly summarised sulphate of soda (see that article), sulphate of quinine (see article "Quinine"), and sulphate of nickel (see article "Nickel"); sulphide of ammonia utilised in artistic bronzing (Collis); sulphate of arsenic (see article "Arsenic"), etc., all of which may exert a violent action on the skin, mucous membranes, nails, hair and skin. This action is still more marked in the case of sodium sulphide, which causes erythema, papular and pustulous dermatitis and even ulcerations, at times deep-seated. According to Prosser White, it is more irritant than the chromates. Sulphide of potassium and sodium is very alkaline and causes very serious dermatitis and ulcerations amongst washerwomen who use hot solutions. Sulphide of calcium is also a skin irritant. Sulphate of soda is likewise a skin irritant and may cause dermatis and superficial ulceration. Prosser White has described lesions of this kind amongst women workers engaged in cotton dyeing. Bisulphate of soda, used in the cloth printing and bleaching industry, may also cause cutaneous ulceration amongst workers engaged in attending the colouring baths. Nevertheless, in such cases there must be taken into consideration the joint action of other ingredients utilised in preparing the said baths (lyes, soaps, sulphurous acid, sulphuric acid, etc.).

There should be recorded finally sulphur colouring agents (see article "Dyes"), used in alkaline solutions (carbonate of soda, sodium sulphide), which cause irritation of the skin. Prosser White has reported cases of dermatitis amongst workers who prepare sulphur colours, organic sulphuric acids, sulphonates, etc.

**LEGISLATION**

In **Spain** boys under sixteen and women under twenty-one years of age are excluded from grinding, boiling, and packing of sulphur; in **France**, young persons under eighteen are excluded from the two former processes, where there is liberation of dust; in **Italy**, boys under fifteen and women under twenty-one are excluded from grinding and refining of sulphur.

In **Greece**, boys under sixteen and young women under eighteen years of age are excluded from operations involving contact with sulphur compounds.

In **France**, women and young persons under eighteen years are excluded from workrooms for the roasting of sulphurous ores, but are on the contrary admitted in sulphur works when the gases are condensed and the ore does not contain arsenic.

In **Belgium**, young persons under sixteen years are excluded from the manufacture of sulphates of sulphur and from roasting the manufacture of sulphate of copper by means of the oxide and the carbonate of this metal and of sulphuric acid, from the manufacture of sulphate of zinc by the action of sulphuric acid on this metal, from that of sulphate of iron by the action of sulphuric acid on iron or cast iron, and from the manufacture of sulphones (women under twenty-one). In **Spain**, boys under sixteen and women under twenty-one years are excluded from the manufacture of sulphate of peroxide of iron by means of the oxide of iron and nitric acid (workrooms in which there is liberation of fumes or in which acids are used).

In **France** absolute exclusion of women as well as of young persons under eighteen years is required in the manufacture of sulphate of peroxide of iron by means of the oxide of peroxide of iron and nitric acid (workrooms where fumes are liberated), and from the manufacture of sul-
phate of protoxide of iron by the action of sulphuric acid on iron filings. Women are also excluded from the manufacture of sulphide of sodium.

In Italy, boys under fifteen and women under twenty-one years are excluded from the manufacture of sulphites.

Injuries caused by sulphur are subject to compulsory compensation in New Brunswick (sulphur and its compounds) and in British Columbia (coal mines), and injuries due to chloride of sulphur in Switzerland.

As regards the other compounds, see articles "Sulphur Dioxide", "Sulphuretted Hydrogen", "Toluene" (sulphochloride), "Dimethylsulphate", "Sodium", "Sulphuric Acid", and "Carbon Disulphide".

Sulphur Dioxide

CHEMISTRY

Sulphur dioxide is a colourless gas of which the formula is SO₂. It has a peculiar irritating and suffocating smell and an acid taste. Its density is 2.86; it is very soluble in water: at 15° C. 43.5 volumes dissolve in 1 volume of water, giving a colourless solution of a density of 1.042 and containing 11.92 per cent. of sulphur dioxide. This solution acts as sulphurous acid (SO₂H), which cannot be isolated. In its gaseous and anhydrous state it does not corrode iron, but a solution of 1 per cent. in water is sufficient to do so.

Sulphur dioxide can under certain conditions be reduced by some bodies (for example, hydrogen); it is still more easily oxidised (see article "Sulphuric Acid"); it acts as a reducing agent; it has decalcifying properties (hence its use in the manufacture of gelatine); and, finally, it has disinfecting properties.

It is used in industry in its gaseous state, or in solution, or as liquefied gas. It is easily obtained in this latter state by compressing purified and dry gas, or freezing at —15° C. It is a colourless liquid, with a pungent smell of a density of 1.44. Each litre gives 500 litres of gas at 0° C. and 760 mm. It boils at —8° C. and produces considerable cold on evaporation. It is stored and transported in iron or steel cylinders which have a resistance of 30 atmospheres, filled in the proportion of one kilogram of liquid sulphurous acid to 0.8 litre of capacity. Glass tubes sealed by flame are also used containing a maximum of 100 grams of sulphur dioxide, three quarter parts filled and transported in wire receptacles protected with "kieselguhr".

MANUFACTURE

The preparation of sulphur dioxide is carried out by (a) the combustion of sulphur, (b) the roasting of sulphides, (c) the combustion of sulphuretted hydrogen, (d) the reduction of sulphates, and (e) recovery from mixed gases.

(a) Combustion of sulphur. — Sulphur is burnt in a current of air upon the floor of special kilns. The operation is carried out slowly and at a relatively low temperature to avoid sublimation of the sulphur, which always occurs with a raised temperature even if cooling apparatus be installed. The necessary air is supplied by fans, by exhaust ventilation, or by pressure.

Numerous types of kiln have been made, some even mechanical, but they are only capable of producing small quantities of sulphur dioxide; large quantities are obtained by roasting pyrites.

The gas on leaving the kilns is cooled and purified. Purification is necessary with a sulphur which is very impure and full of ash dust; it is effected in an apparatus, called a sublimator, consisting of tubes in which the dust is deposited. The cooling takes place in worms of various forms, or in flues. When sulphur dioxide is required to be used in solution the gas is condensed in vessels made of pitch pine, arranged in series, in which the absorbing liquid is placed.

(b) Roasting of sulphides containing 20 to 25 per cent. of sulphur (pyrites): sulphides of iron : blends : sulphides
of zinc). Pyrites arrives usually at the chemical works already pulverised, or else is reduced to the size of bullets which issue in a continuous stream from crushing mills. Some kilns only require a preliminary breaking up of the ore.

The pyrites kilns are constructed on the principle of chambers with five or six partitions arranged in layers varying in shape and disposition. The ore passes from the top to the bottom whilst the gases arising from the hearth circulate from the bottom to the top, or in making sulphate of calcium, which contains from 1 to 2.25 per cent. of dross in a high temperature furnace, further obtained by breaking up the ore. Various processes use these separations, by the combustion of sulphuretted hydrogen.

(c) Combustion of sulphuretted hydrogen. — This gas is a residue from making of soda by the Leblanc process, or is obtained by the reduction of sulphate of calcium, and in making sulphate of ammonia. The combustion is carried out in special kilns with a burner constructed on the Bunsen principle.

(d) Reduction of sulphates. — It is possible to obtain sulphur dioxide which may be used straightway for making sulphuric acid. The sulphates most often used are gypsum and the sulphate of magnesium. The latter is reduced with charcoal at a temperature of 850-950° C. (Griesheim has used this process of making sulphuric acid since 1913.) The liberation of sulphur in the form of a sulphurous gas. The gas so obtained contains from 5 to 6 per cent. of sulphur dioxide. The addition of sulphate of calcium increases the strength of the sulphur dioxide.

(e) Recovery of sulphur dioxide from mixed gases. — It is possible to obtain sulphurous gas by the combustion of products used to purify gases rich in sulphur (purifying materials) or to recover it directly from the mixture of gases. Absorption of the gas by water in washing towers is not good since 1 to 2 per cent. of the sulphur dioxide is not caught. Animal or wood charcoal has a greater absorbing power. Special substances (carboraffin, etc.) are also used.

It is important to remember that the heating of a solution of sulphur with sulphide of carbon gives a gas very strong in sulphur dioxide (75 per cent.).

Liquefied sulphur dioxide is prepared for industrial purposes by the process of Haenisch and Schroeder. The gas obtained from the roasting of pyrites is absorbed in water; the weak solution is strengthened by evaporation. The steam and gas which come off are passed into a drying tower and after complete drying the sulphur dioxide is passed into a compressor, then into a worm where it is retained and liquefied. It then passes into the collecting vessel.

SOURCES OF INTOXICATION

1. During manufacture. — During roasting the workers are continually exposed to the inhalation of small quantities of gas; but the risk is greatest when great quantities of sulphur dioxide are liberated, especially following bad management of the process.

Workers are also possibly exposed to the absorption of arsenical products (arsenious acid) if the pyrites is arsenical (which is often the case). Kobert has shown that the danger lies not only in the inhalation of vapours but also from the clothes becoming impregnated with sulphur dioxide.

During the manufacture of liquefied sulphur dioxide workers are exposed to inhaling the gas which escapes from the apparatus owing to the erosion of the compressor pumps and the receptacles used for transport, which become corroded if the gas is not perfectly anhydrous. A change of temperature may cause the metal receptacles to explode.

2. During its use. — Sulphur dioxide is in frequent use, particularly for the
SULPHUR DIOXIDE

Following processes: its own manufacture and that of sulphuric acid; the manufacture of cellulose, of glue and gelatine from bones (making use of the decalcifying properties of sulphur dioxide); in the conversion of starch into sugar; in extinguishing fires; in dying (using the reducing properties); in bleaching wool, silk, paper pulp, feathers, straw (the hat industry), sponges, gelatine, wax, hair (decoloration and disinfection of white brushes); making use of its decolorising properties. In all these processes sulphur dioxide plays an antichlorine part, that is to say, it neutralises the chlorine used in the preliminary bleaching.

It is also employed for whitening articles of food (maize flour, sugar, etc.) for keeping in good condition fruit, preserves, beer, malt, etc., instead of bisulphite of soda or lime. Its disinfecting properties are used both for the disinfection of boxes used for preserves, or barrels (sulphuring wine casks by matches of sulphur) or buildings and ships (destroying rats): the sterilisation of unfermented wine to insure it keeping, etc.

Sulphur dioxide is used in refrigerating machines by the method of R. Pictet (there is danger when repairs have to be carried out). The use of sulphurous gas in steam engines to increase their power has been recommended.

3. During certain processes. — We are concerned here with those processes in which a liberation of sulphur dioxide occurs: in metallurgy when the ores, as is very usual, contain sulphur at least in the form of impurities (ores of lead, copper, zinc, antimony, arsenic, etc.); this sulphur becomes changed into sulphur dioxide and partially into sulphuric acid as soon as the ore is roasted. It is in addition set free in the manufacture of ultra-marine blue, in some of the pottery processes, in glass making, in making colours obtained from tar, in vulcanising rubber, in refining raw petrol (opening stills), in tanning with chrome, in burning coal containing 0.5 to 2 per cent. of sulphur, etc.

TOXIC ACTION

Sulphur dioxide is an irritant and caustic gas of which the path of entry into the system is by the respiratory passages. Its well-known local action upon the mucous membranes is due, according to Robert and Lehmann, to its transformation into sulphurous acid (H₂SO₃), which becomes oxidised into sulphuric acid (H₂SO₄). On the other hand it might be due to a delayed effect, possibly reflex, or possibly due to some disturbance or modification of the blood. To produce this result the sulphur dioxide must be inhaled in large quantities. Other authors deny this action upon the blood.

Sulphur dioxide, even in weak concentrations, acts very quickly upon the mucous membranes, particularly those of the respiratory system. The strength which can be tolerated has been fixed by Villaret at 0.07 per thousand, but on the other hand it varies with individuals and with the degree to which they have become inured to it. Ogata and Lehmann have shown that for individuals unaccustomed to it a strength of 0.02-0.03 mgr. per thousand is hardly borne, that a strength of 0.04 mgr. causes embarrassment, and that 0.06 mgr. is the greatest strength which can be borne for half an hour without causing injury. Some individuals who are accustomed to it can, on the contrary, stand a strength of 0.1 to 0.12 mgr. per thousand and Lehmann has reported some cases which have tolerated a strength as high as 0.20 mgr. per thousand.

Recently (1924), Kiichiro Muto has demonstrated experimentally arrest of respiration while the heart continued to beat. The smallest fatal dose has been 1.5 per cent. in volume. Electric stimulation shows that the diaphragm reacts. The gas therefore acts directly upon the respiratory centre and paralyses it. On the other hand, according to some experts (Weyl, for example) sulphur dioxide should have beneficial effects owing to its bactericidal power when inhaled for a long period in concentrations which are not too strong. In the opinion of some works managers the men employed in roasting ores rich in sulphur suffer less sickness, and Floret has noticed a great diminution of phthisis among them.

SYMPTOMS

With those who are not accustomed to sulphur dioxide a quite weak concentration of it produces an acid taste in the mouth, an increased flow of saliva and irritation of the nasal, ocular and respiratory mucous membrane, in which area sneezing and attacks of coughing occur which are often spasmodic. If the action is too severe or too prolonged then catarrhal inflammation, either bronchial or pulmonary, occurs and often blood-stained, expectoration. In some cases congestion and pulmonary asthma have
been noticed. Dental lesions do not occur as in the case with industries employing sulphuric or nitric acid. Serious cases caused by this gas are rarely fatal. Further, when the absorption is from high concentrations, digestive troubles (loss of appetite, acid eruptions, and irregular motions) and a livid discoloration of the mucous membranes are noticed.

**DETECTION OF SULPHUR DIOXIDE**

This is done chiefly by the smell or preferably by chemical titration (process of Lehmann with iodine and hyposulphite of soda). In the process of Lambris the gas is absorbed by tampons moistened with water and impregnated with methyl-orange as an indicator, the tampons being of a light yellow colour. The gas then passes over a tampon impregnated with oxygenated water, on which it is retained in the form of sulphuric acid. The pads of cotton wool are placed in an absorbing apparatus of glass through which the air to be analysed is passed. This method enables the gas to be detected in dilutions of 1 in 500,000. Lambris claims that after an exposure for ten minutes the gas can be detected at a dilution of 1 in 2,500,000.

It is necessary sometimes to examine fumes from a chimney to detect the presence of sulphur dioxide, carbon dioxide, etc. The fumes are passed successively into a chamber, cooled on the exterior, where a portion of the steam condenses in tubes of chloride of calcium. The fumes then pass through a dust filter made of a round piece of felt (an examination of the dust is sometimes interesting), into a 25 per cent. aqueous solution of caustic soda, and finally into a water suction pump by which the volume of the gas is measured. The gas in the condensed steam, which always contains sulphuric acid, can be estimated by the iodometric method (Balthazard, 1929).

**HYGIENE**

All necessary precautions must be taken in the manufacture of sulphur dioxide to prevent leakage from kilns and apparatus, to assure intensive condensation of the gas, and to provide an effective ventilating and extracting system in workshops. As regards the protection of the individual, overalls should be worn and breathing apparatus provided with compressed oxygen for the use of workers.

**LEGISLATION**

Women and children are not allowed to work in any sulphur dioxide works in the following countries: Belgium: boys of less than 16 years and girls younger than 21; Greece: boys of less than 16 years and girls younger than 18; Italy: boys under 15 years and girls under 21; The Netherlands: both sexes under 18. In Germany an order of the Chancellor of the Empire dated 22 October 1902, regulates the disinfection and bleaching of brushes by sulphur dioxide; in Great Britain "The Alkali Works Regulation Act" of 1901, as well as the regulations for the chemical industry of 11 July 1922, define the measures to be taken to prevent the escape of poisonous gases (in which sulphur dioxide is included). (See on this subject the article on "Poisonous Gases").

In France, the Netherlands and Russia it is compulsory to notify any damage to health caused by sulphur dioxide.

Legal compensation only exists in British Columbia (eczema caused by the vapour of sulphur); in Finland; in Japan (conjunctivitis caused by irritant gases); in Missouri (United States) (poisonous gases in general), and in Switzerland.

In Great Britain gassing by sulphur dioxide, like other forms of gassing, is classed as an accident and compensated accordingly.

***

**Sulphuretted Hydrogen**

(Sulphide of Hydrogen; Hydrosulphuric Acid)

French: Hydrogène sulfurée; Acide sulfhydrique; Acide hydrosulfuratique. — German: Schwefelwasserstoff. — Italian: Idrogeno solforato; Acido solforidrico. — Spanish: Acido hidrotonico.

**PROPERTIES**

Sulphuretted hydrogen (formula H,S) is found in the natural state in certain sulphurous mineral waters, either in a free state or in the state of sulphides or as alkaline sulph-hydrates; and also in emanations from volcanic areas (fumaroles). It is produced each time waters charged with sulphates come into contact with organic materials, and is also liberated during the decomposition of all organic matter which contains sulphur, such as eggs and faecal material.

Sulphuretted hydrogen is a colourless gas, with a very foetid odour of rotten eggs, more offensive in weak than in strong concentrations. Beyond a certain concentration its characteristic odour does not increase in proportion; and at high concentrations, which may very quickly have fatal effects, sulphuretted hydrogen has an odour analogous to that of hydrochloric acid. The odour of this gas is perceptible even at a concentration of 0.001-0.002 per thousand. It is heavier than air, one litre weighing 1.532 grm. at 60° C. and 760 mm. It is also liberated during the decomposition of large quantities of gas in deep cavities such as vats or cellars; and explains why a worker who falls
SULPHURETTED HYDROGEN

into such is immediately plunged into a dangerous atmosphere (Zangger).

At 17 atmospheres sulphuretted hydrogen condenses into a colourless liquid (density 0.91), which boils at -61.8° C. and can be solidified at -83° C.

Inflammable in the air, it burns with a blue flame; when mixed with oxygen it explodes when lighted. Research has shown that the lower limit of inflammability is reached with a strength of between 25.2 and 59 per cent. Other authorities estimate that explosion is produced in the air with a concentration of 0.1 per cent. If the sulphuretted hydrogen comes near a jet of flame.

Sulphuretted hydrogen is slightly soluble in water and very soluble in alcohol, which dissolves 18 times its volume at 0° C. and 72 times at 10° C. The clear aqueous solution, which has a sweetish oily taste, readily becomes cloudy on account of absorption of oxygen from the air. This solidification, set in action by light, makes it necessary to keep the solution in bottles which must be filled full and tightly corked. On boiling all the sulphuretted hydrogen contained in its solutions is set free.

Sulphuretted hydrogen acts as a weak acid; it turns litmus paper a wine red.

Preparation

Sulphuretted hydrogen is obtained in laboratories by the action of dilute hydrochloric or sulphuric acid on sulphide of iron. Chemically it is obtained pure by making sulphide of antimony react on concentrated hydrochloric acid. Industrially it is produced by numerous processes of which the most important are the following: decomposition of sulphide of iron by sulphuric acid in apparatus with or without pressure, of which the latter are preferable, for in case of a leak they do not allow great quantities of sulphuretted hydrogen to escape; treatment of soda lyes (vat waste) by hydrochloric acid; decomposition of sulphide of calcium obtained by the reaction of gypsum and charcoal by means of steam and carbon dioxide; decomposition of sulphur, charcoal and steam at red heat. Sulphuretted hydrogen is liquefied industrially by means of a double-action compressor, the piston of which is always covered with mineral oil, and of a condenser with a worm surrounded by cold water.

Toxic Action

According to Mitchell and Davenport (1924) sulphuretted hydrogen is one of the most poisonous gases. These writers compare it to prussic acid on account of the rapidity with which it acts. Even in a concentration of 0.005 per thousand, such as is found in industry, this gas presents characteristics so toxic as to classify it among the industrial poisons.

This gas is quite poisonous and may even be fatal in concentrations which cannot be detected by smell (Lehmann). Experiments on animals show that a strength of 1.8 mg. to 3.6 mg. per litre of air causes speedy death among cats; that 0.7 to 1.2 mg. is dangerous and even fatal in from half to one hour; that a strength of 0.4 to 0.6 mg. does not cause immediate manifestations, even at the end of 30 to 60 minutes, nor serious ulcer manifestations; and that a dose of 0.1 mg. per litre does not cause important manifestations after an exposure of six hours. No immunity has been observed to be acquired from exposure (Lehmann); on the contrary, an exaggerated sensibility appears, especially after a first attack.

This fact, which has been reported by chemists working with sulphuretted hydrogen, explains the great labour turnover in artificial silk factories of recent erection (Rodenacker).

The irritant action of products steamed in this gas, as dust of paper, films, etc., has also been pointed out.

Sulphuretted hydrogen acts in very weak doses; according to Haggard a strength of 0.01 and 0.15 per cent. causes symptoms of local irritation after some hours of exposure. A condition of this kind is rare outside laboratories. Nevertheless prolonged inhalation can in practice cause chronic poisoning. A strength of 0.02 to 0.03 per cent. causes local irritation at the end of an hour and slight general symptoms at the end of a longer time; a strength of 0.05 to 0.07 per cent. causes local irritation and slight general symptoms at the end of an hour. After several hours (three hours) death occurs from pulmonary oedema.

Hamilton finds that the danger commences with doses of 0.075 per cent. and Lehmann that a dose of 0.05 per cent. of sulphuretted hydrogen causes at the end of thirty minutes coughing, air hunger, palpitation, lassitude, palor, cold sweats, headache, and giddi-
ness. He considers that: a dose of 0.07-0.08 per cent. is dangerous to life in a few minutes; a dose of 0.09 per cent. causes a general poisoning in thirty minutes and death in less than an hour; a dose of 0.15 per cent. is fatal in 15 to 30 minutes, as has already been reported by Oliver; a dose of 0.18 per cent. causes immediate death by paralysis of the respiration.

According to Kranenburg and Kesse, 20 mg. per cubic metre (in artificial silk factories and sugar refineries) has been known to cause conjunctivitis and slight keratitis.

The alkaline sulphides of potassium, sodium, and calcium, in addition to their irritant action, can give off sulphuretted hydrogen, and on this account are dangerous.

Susceptibility to the poison varies very much according to the individual, but it has been constantly remarked that it is increased by previous attacks. In the same way as with a simple, acquired immunity in man has never been observed. This poison has not a cumulative action; further it is not completely absorbed, for, according to Lehmann, the higher the percentage of sulphuretted hydrogen in the air, and the greater the duration of its action, the less completely is it absorbed.

Absorption takes place only by the respiratory passages. Sulphuretted hydrogen in the system exercises a double action: (1) a local irritation of the tissues and exposed mucous membranes of the throat, mouth and eyes, and more particularly of the respiratory mucous membrane; but this local action is often lost sight of when general poisoning supervenes; (2) a general toxic action with a characteristic picture caused by paralysis of the central nervous system (Bohl). If sulphuretted hydrogen is in low concentration, it may exercise a stimulating action; in higher concentrations, it causes a depressing effect both physically and mentally.

Its action on the respiratory apparatus, however, is immediate and proportionate to its concentration. According to Haggard, a dose of 0.1 per cent. has a negligible influence on the respiration. Above this limit, hyperpnoea occurs in a very few minutes; it causes death by cardiac failure, through action on the ends of the vagus nerve. Above 0.3 per cent. death occurs from respiratory failure.

According to Rodenacker, this gas exerts not only a local irritant action, but also a general action on the system. Sulphuretted hydrogen is not a poison of the nervous system even if it causes cramp, which is only the result of an internal asphyxia of the tissues. The poisoned animal has air-hunger even in an atmosphere of oxygen; the fact is this gas is a poison of catalysts, for it transforms iron (which acts as a catalyst) into a ferrous-sulphide compound which is inefficient as a catalyst. Consequently it arrests cell respiration and is the cause of apoplectic deaths. It has then a toxic action analogous to that of prussic acid, which is a poison to catalysts and in a weak concentration irritates the conjunctiva. That is why ocular lesions are not symptoms of a simple local irritation, but of a local arrest of oxidation. This also explains why the intravenous injection of colloidal iron is in this case followed by good results.

Blood. — It is a blood poison which modifies the haematic pigment without causing toxic disturbances (Loewy). The acute cases belong without doubt to the series of anoxaemias studied particularly by Haldane.

All authorities are not agreed as to whether it reduces haemoglobin and transforms the iron contained in the molecule into sulphide of iron (Liebig, Heim), for if that took place, it could only be in very slow forms, ending fatally in a state of coma; whereas death generally occurs too quickly for these reactions to take place.

There is also disagreement as to the possibility of the poison combining with the alkalies of the blood to form alkaline sulphides, notably of sodium. According to Haggard, sulphuretted hydrogen is carried in the blood in the form of a combination which is easily dissociated, for it has been proved experimentally in vivo that sulphide of sodium injected intravenously or intra-muscularly on coming in contact with the blood is hydrolysed and causes a liberation of sulphuretted hydrogen which is eliminated in its turn by the respiratory passages.

According to Hoppe Seyler, sulphuretted hydrogen will combine with oxyhaemoglobin, but not with reduced haemoglobin and will give sulphometahaemoglobin. On the other hand, Harnack considers that it acts only with sulphohaemoglobin, for sulphuretted hydrogen combines with reduced haemoglobin, but not with oxyhaemoglobin. Some authors do not admit these combinations with the formation of abnormal products. According to Haggard, sulphohaemoglobin or sulphometahaemoglobin are never formed in vivo, but can be formed in vitro when...
the blood is totally reduced, and in the presence of toxic doses of a concentrated mixture of sulphuric acid or of the inhaled gas, of which will cause immediate death. On the other hand, German experts admit that the sulphohaemoglobin can be detected, although rarely, during life, and even with a dose of 0.00578 per cent, of sulphuretted hydrogen in the blood (Mayer), when certain particular conditions are realised.

According to Haggard, sulphuretted hydrogen on contact with the blood is oxidised into sulphuric acid or into associated acids which are neutralised by salts of sodium. These products of oxidation are not poisonous. This series of oxidations terminates the physiological action of the gas absorbed, and it is free and unoxidised gas which causes the characteristic toxic symptoms. The blood undergoes a proportional reduction which is, however, insignificant, even when an immediately fatal quantity is absorbed; this reduction does not contribute to increase the poisonous action of the gas.

** Sources of Poisoning **

1. During its preparation. — Escapes of this poisonous gas may occur from the producing apparatus, from derangement of the apparatus, from joints, tubing, taps accidentally turned on, or interference with the ventilation in places where sulphuretted hydrogen is produced. In addition, the sulphate of iron and commercial acids used for the production of sulphuretted hydrogen almost always contain impurities such as arsenic and phosphorus, so that the gas is mixed with traces, more or less important, of arseniuretted and phosphoretted hydrogen.

2. During its use. — The gas may be liberated in laboratories during qualitative and quantitative analyses, in which it is used on account of its well-known acid qualities; it precipitates a great number of metals as sulphides. Too often this gas is made use of without the necessary precautions being taken. Cases of chronic poisoning have been caused even among persons living above laboratories (Zangger).

In Industry there is danger during certain operations: purification of arsenic and metallic acids, especially sulphuric and hydrochloric acid; purification of arsenic; manufacture of cinnabar, antimony, and metallic gold; separation of copper in the nickel and cobalt industry. Sulphuretted hydrogen extracted from soda residues and burnt in the presence of an excess of air gives sulphur anhydride, which is used for the manufacture of pure sulphuric acid. If it is passed with a suitably limited quantity of air over a layer of heated anhydrous oxide of iron, it gives off water and sulphur is generated.

Danger also arises in agriculture where the gas is used for disinfection against the cochylis of vines and against locusts.

3. It is liberated as a by-product in the course of certain operations, either alone or with other gases. In practice this condition is the most frequent, and in these mixed poisonings sulphuretted hydrogen constitutes the most toxic agent: gases from putrefaction; from the manufacture of cyanogen; waste waters from tanneries with carbonic anhydride; gas from blast furnaces with carbon monoxide (Zangger).

(a) In the chemical industry, the gas is generated in the following processes: when acids react with metallic sulphides, more particularly when weak acids are concerned, during the treatment of combinations of potassium and sulphur and of such sulphurous metals as pyrites; during the manufacture of chloride of antimony and barium, by the transformation of barium sulphide into carbonate of baryta, and by the manufacture of chloride of barium from sulphide of barium; during reaction of acids with sulphide of barium, and during manufacture of cyanogen.

It is further generated during the release of sulphurous acid from metals (arsenic), distillation of sulphurous waters, elimination of arsenic from acids (see articles "Hydrochloric Acid" and "Sulphuric Acid"), and during operations producing the reduction of sulphates of organic materials.

It accompanies the manufacture of compounds of sulphur and phosphorus, the manufacture of certain special matches, the manufacture of artificial manures from materials rich in phosphate of lime, when, after crushing, the dissolving of insoluble phosphates by sulphuric acid may cause the liberation of sulphuretted hydrogen and other gases and the manufacture of calcium sulphide.

It may be given off during the use of mastics formed of a mixture of sulphur, sal ammoniac, powdered iron and hot water, during distillation of ammonia, from waste water from wolframic acid, during manufacture of thorium, of incandescent mantles,
during extraction of cellulose, manufacture of nitrocellulose, reaction of cellulose sulphite with acids, during manufacture of artificial silk in the spinning department, and in the manufacture of bisulphite of carbon; also in the use of powdered liver of sulphur, thiosulphate of potash, for making sulphurous baths.

It also is present in the manufacture of ultramarine blue, of methylene blue, of methylene violet, and of Prussian blue, by decomposition of ferro-cyanide of potassium and sulphate of iron, of aniline and its colours.

In the dyeing industry the gas is liberated when sulphur or sulphide of sodium are used as reducing agents in the manufacture of sulphides for dyeing, especially during the reduction of sulphide of antimony by acids; in the manufacture of Leblanc soda, during the efflorescence of the soda residue, sulphuretted hydrogen is produced in great quantities, and is burnt into sulphur anhydride. It also occurs during precipitation of soda residues containing sulphide of calcium.

It occurs in soap works, due to the use of raw soda charged with calcium; in gas works from distillation of sulphurous coal, and the treatment of ammoniacal liquor; in distillation of tar and thick lubricating oils from coke ovens; according to Weyl, they contain 10.7 litres of sulphuretted hydrogen per kg. of materials; in preparing water gas. It is also given off from motors using poor gas.

From acetylene in the raw, unwashed and unburnt state, sulphur from coke becomes oxidised into sulphuretted hydrogen in the process of carburation and immediately decomposed into sulphur anhydride. It is not given off during the use of the oxyacetylene blowpipe.

It is given off in refining raw petroleum. Mexican petroleum contains it up to 0.63-0.83 per cent. It comes off from the tanks and pipes on oil tank ships, etc. The risk diminishes as the end of the distillation is reached.

- It is present in the rubber and vulcanite industry; in the manufacture of substitutes (boiling vegetable oils, sulphur and resins with chloride of sulphur); in tanneries in the preservation of undressed skins, and in soaking dry foreign skins in water. The waste waters of tanneries contain a good deal of sulphuretted hydrogen, according to Oliver, up to 12 per cent. in volume. It is given off during the reduction of chronic acid during the manufacture of leather and during the use for tanning of residues of lime containing sulphide of calcium from gas works, and in emptying cess pits.

It also occurs in factories of artificial silk and accumulators during the cleaning of the plant.

(b) In the metal industry: The gas occurs in the manufacture and use of metallic sulphides; in making sulphide of zinc, for example; during cleaning of blast furnaces and certain boilers containing organic materials; during pulverisation, by the wet process, of waste dross utilised for artificial manures, and for the manufacture of cement and artificial stone, during bronzing of metals by sulphide of arsenic.

(c) In mines: The gas may occur in old mines in consequence of the transformation of pyrites under the action of water and heat. Mine gas and subterranean infiltrations always contain a little sulphuretted hydrogen. In blasting in mines the combustion of powder causes the formation of sulphuretted hydrogen with other gases.

This gas is also very common in the air of the Italian lignite mines (Biondi).

(4) Treatment of organic materials: decomposing organic material.—It is found in waste waters from breweries; and in sugar factories, in water from washing sugar beet; from refineries; and from regeneration of animal charcoal; in glue and mastic works; extraction of fats; in obtaining fats from bones by stewing; in the preparation of guts; knocking, etc.; in the manufacture of soap; during decomposition of large quantities of fats; melting of tallow; in organic fats; during steeping of flax and hemp; cleaning spa baths and pipes conveying hot sulphurous water, cess pits, sewers, and accompanying every kind of putrefaction of albuminoid organic matter.

When these waters are used in such a way as to dispel the sulphuretted hydrogen which is dissolved, this gas may cause trouble (the Netherlands medical inspection department has reported this fact several times).

Statistics

In Austria during the period 1914-1918, 6 cases were reported of which 5 were fatal, and in 1922 there were 2 fatal cases in a tannery.

In Germany, the Industrial Association of Chemical Industries gives the following figures for the years 1906-1912:

<table>
<thead>
<tr>
<th>Year</th>

SULPHURETTED HYDROGEN

In the period 1914-1918, 5 cases occurred (all fatal). In 1919 in Prussia there were 15 cases, in Saxony 1 fatal case, in the Duchy of Baden 3 cases, of which one was fatal, in Hesse 1 case.

In 1920, 2 fatal cases occurred and in 1921 several cases according to a report by Teleky and Brezina, in which no figures are given. In one chemical works out of 256 workers, 163 were affected with ocular troubles due to sulphuretted hydrogen. In one factory the sickness rate fell from 121 per cent. during the first quarter to 19.8 per cent. during the last quarter after the adoption of prophylactic measures.

In 1922, 2 cases occurred in the process of "bronzing" metals black.

In Great Britain the cases reported to the Chief Inspector of Factories are set out as follows:

<table>

In the Netherlands in 1920 there was 1 fatal case in the artificial silk industry; in 1921, 1 fatal case in a gas works and several non-fatal. In the sugar refineries there were notified, in 1922, 96 cases of conjunctivitis and 25 cases in an artificial silk factory.

In Switzerland from 1914 to 1918, 3 cases occurred; in 1920, 4 cases; and in 1921 and 1922, 8 cases; in 1923-1924, 2 cases; in 1925, 3 cases; and in 1926, 1 case. Tauss mentions 3 cases of poisoning, of which 2 were fatal, in obtaining fats from bones. Cases occurred among cess-pit scavengers, i.e. the sudden collapse of these workers. These cases are frequent, but are quoted without any mention of numbers.

In the United States in the petrol refineries the gas caused over a period of years, of which no dates are given, 58 cases of asphyxia, 99 cases of conjunctivitis and bronchitis, 158 cases occurred at the receiving of raw petrol. Hamilton described 8 cases, of which 1 was fatal, in the paint industry.

**Symptoms**

Poisoning by sulphuretted hydrogen can appear in an acute, sub-acute, or chronic form. It generally arises directly from the inhalation of the poison; but it is certain that after a clear interval, serious symptoms may yet occur.

In the fulminating form, which resembles apoplectic seizure, after a few seconds of exposure to an atmosphere containing a sufficient quantity of the poisonous gas, there occur: panting respiration, pallor, cramps, paralysis of the pupil, and, immediately after, loss of consciousness, with loss of speech, or with no other warning than a cry. Death occurs with extreme rigidity from respiratory and cardiac paralysis. There is rarely a preliminary state of anxiety (that is, in the kind of seizure which generally occurs in the sudden collapse of cess-pit scavengers). Sniffing, if sufficiently deep, of liquids containing or giving off sulphuretted hydrogen may be sufficient to cause these phenomena.

Artificial respiration carried out early and kept up till oxidation of the sulphuretted hydrogen in the blood has been effected re-establishes normal respiration without serious after-effects (Haggard), but respiration does not re-establish itself spontaneously on account of respiratory paralysis. Further, deficiency of oxygen slows the process of oxidation of the poison and reduces the respiratory mechanism to a sub-normal state.

With a concentration of sufficient strength, from 0.1 to 0.2 per cent., early hyperpnoea due to the poison is followed by a period of apnoea. In this phase sulphuretted hydrogen is no longer inhaled and what is in the blood, is oxidised. If respiration should start up again, the patient, finding himself in an atmosphere contaminated by the gas, is exposed to fresh poisoning and has less chance of recovery. If respiration is not re-established, death from asphyxia follows.

Sub-acute poisoning is characterised by symptoms due to the irritant action of sulphuretted hydrogen which attacks all exposed tissues and mucous membranes. In the respiratory passages is experienced a sensation of burning and of weight on the chest, irritation, congestion and cough. The alveolar cells are affected by degeneration and destruction and contain transudation and cellular elements. Pulmonary oedema may develop from extremely small doses, and may sometimes also come on gradually, from 3 to 8 days, after the absorption of fairly large quantities of sulphuretted hydrogen, and cause death. Moreover, it is recognised that individuals who appear to have left an atmosphere containing this gas in good health may later show toxic symptoms (Haggard).

Symptoms of pulmonary oedema do not usually appear in the ordinary clinical picture of poisoning, either because they are hidden by the general picture, or on account of the short duration of exposure to the poison.

As regards the eyes, the following symptoms are noted: flashes of light, contraction of the pupil, watering, sharp pains, photophobia, difficulty in keeping the eyelids open, inflammation and ulceration of the cornea, hypersen-
sibility of the conjunctiva to light after an exposure to an atmosphere containing 0.14 to 0.2 mg. for six hours (Lehmann).

The following symptoms have also been reported: Activity of the salivary and sudoriparous glands with abundant salivation and profuse cold sweats, which arise from concentrations of sulphuretted hydrogen, which are, nevertheless, insufficient to cause acute poisoning. Rhinitis and pharyngitis also occur.

As regards the alimentary canal, various troubles arise including nausea, vomiting foetid eructations, larial herpes, foetid breath with the odour of sulphur, intestinal catarrh, diarrhoea, pains in the form of colic.

Sometimes kidney lesions with albuminuria are observed and rarely, glycosuria and urethral infection.

Cardiac troubles, characterised by a marked bradycardia, irritability and especially palpitation on exertion are caused by the inhalation of concentrations insufficient to affect the respiratory system.

Those poisoned complain of giddiness, fainting, lassitude, somnolence, a sensation of falling, heaviness in the head, pains in the neck, persistent headache, anxiety and a feeling of constant malaise.

Among the nervous troubles have been noted: loss of memory in some cases, general agitation, running away with failure to recognise surroundings, attacks of frenzy, stupor, muscular jerks, especially of the lower limbs, tetanic cramps, psychic troubles sometimes going as far as delirium, etc. Natanson and Everovska have reported neuroretinitis due to occupational poisoning by sulphuretted hydrogen.

Prolonged absorption of sulphuretted hydrogen in small but continuous doses, which may sometimes be scarcely perceived by the sense of smell, causes chronic troubles, more particularly with sensitive persons. Furbringer draws attention to the susceptibility of heart and lung cases. Further, susceptibility to the poison increases. In this form, as in the immediate sequelae of acute poisoning, there may be noted, even after ceasing work, irritation of the eyes and respiratory passages, cardiac troubles, digestive troubles, diarrhoea without cause, etc.; anaemia and unhealthy appearance, feverishness, shiverings, cold sweats, skin eruptions and furunculosis, and also depression of the nervous system.

Erben has described marked psychic degenerative troubles, and Kowjenikow a systematic degeneration of the spinal cord, with encephalitis and myelitis. Nathanson and Roserowa have reported neuroretinitis and chronic meningitis. They consider that in chronic poisoning sulphuretted hydrogen particularly attacks the nervous system having a selective action on a given part of that system.

Analysis of symptoms, as well as the facts supplied by literature, suggest the possibility of a lesion of the meninges in chronic cases, all the more so that even weak doses can be poisonous if the action is prolonged.

In acute cases recovery or death often occur before there is time to intervene. If recovery takes place, then the after-effects do not last more than a few hours.

In the sub-acute cases, signs of irritation of the mucous membrane may last for some time. It must not be lost sight of that death may occur 12 to 48 hours after from pneumonia, oedema, etc.

In chronic poisoning serious sequelae may arise in the nervous system, but some writers only admit this with reservations (Biondi, for example). In the other forms sequelae are relatively rare. Nevertheless, diabetes (Cahn), blindness (Hamilton), and some cases of insanity and mental depression have been reported.

Among scavengers, sequelae are very common in the nervous system, but they arise especially from the absorption of putrid materials, when those poisoned have fallen into materials in a state of liquefaction.

**Prognosis**

The prognosis in acute, as in chronic, cases is comparatively bad. Sometimes troubles of long duration are found in the nervous system and in the heart. When such poisoning is under consideration, the possibility of a neuritis must especially be left out of account.

---

1 Rodenacker, of Wolfen, has studied (1925) the question of ocular troubles among women working in viscose factories (see article "Artificial Silk"). It is recognised that cases of conjunctivitis among these workwomen are especially frequent when a recently started factory is concerned. Acute and painful irritation of the conjunctiva has been attributed by later to sulphuretted hydrogen and organic compounds of sulphur; by Stiebel to sulphurous anhydride; by Bakker to sulphuretted hydrogen and to organic compounds of arsenic and chlorine; by Knapp, Kranenburg and Lehmann to sulphuretted hydrogen alone. The odour of viscose should be due to sulphuretted hydrogen which is formed during decomposition of triothiocarbonate of sodium in the reaction: \( \text{Na}_2 \text{CS}_2 \rightarrow 2 \text{CS}_2 \text{H}_2 \text{O} \). The formation of sulphuretted hydrogen again occurs in the tanks where spinning materials are steeped, following on the decomposition of triothiocarbonate acid.
SULPHURETTED HYDROGEN

and effort must be made to seek out the etiology (Zangger).

DIAGNOSIS

This presents some difficulties. In a case of probable poisoning by sulphuretted hydrogen, it is absolutely necessary to know the previous history and to study the environment of work. As a matter of fact, autopsy, almost without exception, gives no indication, even in confirmed cases of poisoning; hence, as fatal poisonings come under this definition used to-day for occupational accidents, use must be made of all sources of information.

Death generally supervenes too quickly for changes in the blood to occur.

Detection of sulphohaemoglobin or of sulphonmethaemoglobin in the blood would obviously be characteristic evidence; but their existence after an attack is disputed by some writers. It seems that, if the sulphocompounds may be formed, they are not formed during life, but rather after death, and arise from post-mortem changes. Lehmann moreover suggests that pulmonary oedema is the usual thing (see article "Blood").

Clearly other symptoms caused by the poison gas ought to be diagnosed; but often their etiology is not recognised, or an erroneous etiology is introduced.

DETECTION

Sulphuretted hydrogen is recognised by its smell of rotten eggs, but that is not a sufficient indication of its strength in the air.

Qualitative Detection

(a) Paper that has been treated with acetate of lead is used. Blackening occurs in consequence of the formation of sulphide of lead. But long contact with sulphuretted hydrogen makes the paper become white again due to the transformation of sulphide of lead into the white sulphate, especially when there are only traces of gas to detect.

(b) Sheet copper may be used. Blackening occurs if there is a large quantity of sulphuretted hydrogen; a velvety surface appears on the sheet when it is put in an atmosphere containing sulphuretted hydrogen.

(c) A thin sheet of silver that has been moistened may be used. Blackening takes place due to the formation of sulphide of silver.

(d) The suspected air may be shaken up in water to which has been added 2 per cent. of hydrochloric acid, a piece of sulphate of paramidodimethylaniline, and then a drop of perchloride of iron. If sulphuretted hydrogen is present, the aqueous solution turns a beautiful blue colour due to methylene (Caro and Fischer).

(e) An alkaline solution of nitroprussiate of soda in the presence of sulphuretted hydrogen takes on a violet colour (Reichard) which is perceptible when only 0.018 mg. of this substance is dissolved in an acid or alkaline sulphide. The sensitiveness of the reaction depends on the concentration of the solutions rather than on their absolute quantity.

It is best only to resort to colorimetric procedure when a test cannot be otherwise made, for it necessitates certain tentative processes, and is liable to certain causes of error (Heim).

For example, the methylene blue process is somewhat delicate to manage. The nitroprussiate process is, at its best, less sensitive than the metal salt processes. The reaction of colour turning in the presence of sulphuretted hydrogen is less sensitive, for example, than that of the black colouration of acetate of lead. This process then does not allow the colorimetric estimation of the gas on account of the difficulty of gauging the colour.

Quantitative Detection

The quantity of sulphuretted hydrogen in factory atmospheres, although rarely very great, necessitates the employment of quantitative methods. The estimation can be made with Tutweiler's iodide apparatus, or, according to the process of Lehmann, by making the air pass into a decinormal solution of iodine and determining the diminution of iodine with a decinormal solution of thiosulphate. One cubic centimetre of diminution of the standard corresponds to 1.7 mg. sulphuretted hydrogen.

If the percentage present is sufficiently strong, it can be dealt with on a mercury bath. The gas is absorbed by the help of a ball formed of two parts of weight of ordinary precipitated sulphate of lead and three parts of calcined gypsum mixed and compressed at the end of a platinum wire. This ball, having been dried at 110 °C, and then soaked in phosphoric acid, is ready for use (Ludwig).

Heim uses a method of estimation based on the action exercised by sulphuretted hydrogen on a solution of iodine of a definite concentration and determines the excess of iodine by hypoiodite of soda. This seems to be the best method.

A fixed volume (ten litres for example) of the suspected air is made to pass through a Liebig's absorbing tube containing ten cubic centimetres of centinormal iodine (12.7 grm. of iodine dissolved in a solution of distilled water containing 4 to 5 grm. of potassium iodide diluted to a litre after the dissolving). The iodine is taken up and forms hydriodic acid and sulphur. Absorption of the slightest traces of sulphuretted hydrogen is complete, provided that the passage of the air
through the absorbing tube is sufficiently slow for the reaction to have plenty of
time to take place (Fresenius). The speed
should not exceed two bubbles a minute.
The content of the absorbing tube is
emptied into a beaker; then the tube is
rinsed with distilled water which is added
to the original liquid. This liquor is
brown in consequence of the presence of
an excess of iodine. Some drops of a 1
per cent. solution of starch paste are added, when a deep blue appears, due to iodide of starch.
The existing iodine is estimated with a
solution of standardised hyposulphite of soda which is added until the starch-
iodine colour is affected up to the final
turning of the liquor; ten cubic centi-
methres of the solution should decolorise
exactly ten cubic centimetres of centi-
nae of iodine or in the vicinity. The sili-
ness of the estimation, corresponding to
0.017 mg. by weight of sulphuretted hydro-
gen is quite sufficient. The method of
carrying out the process is facilitated by
the use of a "sulph-hydrometer", which
contains the apparatus and the necessary
reagents for taking the sample and the
estimations.

PROPHYLAXIS

First aid. — In the case of subacute
poisoning, move the patient into the
open air, start artificial respiration by
the Schäfer method, which must be
stopped as soon as normal respiration recom-
menes. Administer a mixture of
oxygen and 5 per cent. carbonic acid,
heart tonic stimulants, ether, campho-
rated oil, etc.

Avoid fouling the air with sulphur-
etted hydrogen. Do not rely on the
smell to detect its presence, and esta-
blish a careful control. Install a
system of artificial ventilation in work-
places. Instruct the workers in the
danger. Organise first-aid equipment.
Mechanical arrangements should en-
sure work being done in closed appara-
tus in safety. It is not sufficient to
remove sulphuretted hydrogen by carry-
ing it off at the actual place of pollu-
tion; the gas must be followed in all
its ramifications so as to ensure that it
does no harm to persons employed in
the factory or in the vicinity. Spec-
tacles, respirators and breathing appa-
rateus may also be used when the
ventilation is not sufficient to eliminate
sulphuretted hydrogen.

In certain cases special precautions
must be taken: thus, for the emptying
of cess-pits it is necessary as a prelimi-
nary measure to put in ferrous sul-
phate, at the rate of five kilos per cubic
metre of materials, or, better, to use
sulphate or chloride of zinc. Workers
should wear safety ropes so that those
poisoned can be rapidly dragged out;

soiled clothing must be immediately
removed. It is still better to carry
out the emptying by mechanical means.

LEGISLATION

The regulations provided for poisonous
gases (see article "Gases and Fumes"
should be applied to sulphuretted hydro-
gen; as regards first aid, it must be re-
membered that rules have been laid down
by the Trade Association of the Chemical
Industries of Germany (1 January 1912).
The notification of injuries caused by
sulphuretted hydrogen is compulsory in the
State of Missouri (poisonous gases),
in France and in the Netherlands; compen-
sation is provided in Switzerland, as
well as in countries which compensate
poisonings due to poisonous gases (Great
Britain, Finland and Germany). Acute
cases are generally considered as acci-
dents.

Sulphuric Acid

Properties

Ordinary sulphuric acid is an oily liquid — colourless, inodorous and heavy — of which the specific gravity varies from 1.07 to 1.8 (pure acid), according to the degree of concentration. This also causes the boiling point to vary; the acid at 62 per cent. of sulphuric acid (50° Be) boils at 147° C.; at 78 per cent. (66° Be) at 200° C.; at 95 per cent. (66° Be) commences to boil at about —34° C. in consequence of the dissociation by heat, the acid should always be handled at the ordinary temperature whatever the concentration, but must be freed from dust, especially to get rid of some of the arsenious oxide that may be present in air and water.

Sulphuric acid does not fume in the air, but gives off vapour even at 30° C.; on boiling, these vapours are heavy, white, and have a sharp smell. At about 400° C. it decomposes into sulphuric anhydride and water. It is often yellow in colour or brown from impurities (traces of organic matters, dusts which are carbonised, etc.). Other impurities present may be lead sulphate, arsenic, copper, antimony and nitrous fumes.

Fuming sulphuric acid or oleum (Nordhausen acid, vitriol oil) is a thick liquid, with a specific gravity varying from 1.86 to 1.89, coloured more or less brown (from traces of organic substances), or without colour (the pure acid used in the manufacture of explosives), formed of a mixture of ordinary sulphuric acid and sulphuric anhydride of varying proportions (as much as 80 per cent. of the anhydride: SO₃). At certain concentrations it crystallises in part into a mass melting at 35°. It gives off white dense fumes spontaneously, and on heating forms sulphuric anhydride.

With water, which they attack greedily, sulphuric acids form combinations (hydrates) with development of much heat. To avoid accidents arising from the liberation of heat, the acid should always be poured into the water — never the contrary.

Sulphuric acid, under certain conditions, attacks metals, giving rise to acid or neutral sulphates. The concentrated acid (66° Be) does not attack iron or steel, this enabling it to be kept and moved in iron tanks, which, on the contrary, are attacked by dilute acid. Lead is not attacked at the ordinary temperature whatever the concentration, but is attacked by evolution of sulphur anhydride by hot acid at a strength of 60° Be. Copper, mercury, silver, antimony, arsenic, sodium, etc., when heated with sulphuric acid also give off sulphurous anhydride. Zinc, iron, aluminium and magnesium yield sulphates and hydrogen. Platinum and gold are not attacked.

Manufacture

Sulphuric acid is made principally from sulphurous anhydride, as the starting point, by the lead chamber process or by the contact process.

For the preparation of sulphur dioxide, see that article. It should be remembered that in its preparation from the roasting of pyrites, the air serving for the purpose should be admitted into the furnace in such proportion as to produce sulphurous acid and should contain the necessary excess of oxygen for the oxidation processes. The transformation of the sulphurous anhydride into sulphuric acid is the only way in which this gas can be utilised in the roasting of blende, and the manufacture of sulphuric acid is always, therefore, an annex to a zinc works (see that article). The gases, on leaving the chamber where they are produced, must be freed from dust, especially to get rid of some of the arsenious oxide formed if the roasted iron pyrites is arsenical. This is carried out in dust chambers or by cooling, or by special apparatus of various kinds (filters, centrifuges, electrical, etc.). The gases from roasting, further, contain a considerable quantity of sulphuric anhydride from the direct union of sulphur dioxide and oxygen through the intervention of the residual oxide of iron from the furnaces which acts as a catalyst (see below, the Contact Process).

Lead Chamber Process

This consists in converting the sulphur dioxide into sulphuric acid in large lead chambers by the action of the oxygen of the air and water in the presence of nitrous fumes. The exact chemical reaction is not yet accurately known. Many theories have been put forward, of which the most generally accepted is that of Lunge, which may be summarised as follows:

Sulphur dioxide, when nitric acid is added, yields: (1) sulphate of nitrosyl, which on contact with steam is decomposed into (2) sulphuric acid and oxides of nitrogen. The latter reforms (3) nitrosyl sulphuric acid under the action of the oxygen of the air and sulphur dioxide gas. These reactions are continuous and follow a closed cycle (2) to (3) and vice versa. The only additions necessary are water, air, and sulphur dioxide.
There are secondary reactions in which different oxides of nitrogen are also formed. The nitrous fumes introduced into the Glover tower (see below) before passage through the lead chambers must not be lost and are recovered in a special apparatus down which sulphuric acid trickles (Gay Lussac tower). The nitrosulphuric acid thus obtained is carried again to the Glover tower, where the oxides of nitrogen are again evolved. Nitric acid is only added to compensate for loss due to leakages in the plant.

**Glover tower.** — On leaving the dust depositing installation, the gases are led at a temperature of 390°C into the Glover tower at a point low down, while in the upper part the nitrosulphuric acid coming from the Gay Lussac tower is distributed. The Glover tower is made of thick lead sheets, lined with acid-proof bricks. It is filled with coarse flint or fire-clay cylinders. The acid carried to the top of the tower is denitriified; the nitrous fumes escaping from the lead chambers and arrested in the Gay Lussac tower are recovered whilst at the same time concentration is effected by heat and absorption of the sulphur dioxide. The acid collected at the bottom of the tower is at 60° to 62° Bé.

**Lead chambers.** — On leaving the Glover tower the gases are driven by fans into the lead chambers, which vary in number (from one to twelve). Generally they form a system of three, having a total capacity of 4,000 to 8,000 cubic metres. Each chamber consists of a huge leaden bell, supported by a wooden framework and suspended over a tank similarly constructed of lead. The acid thus lustes the chamber from the outer air. Thermometers are hung on the walls to record the temperature; lanterns allow the colour of the gas and the progress of the process to be watched. The largest portion of the sulphur dioxide is changed in this chamber into sulphuric acid under the action of air and atomised water in the presence of nitrous fumes. The nitrated products are introduced in the form of nitric acid, which is made to flow slowly over glass or earthenware plates, or pulverised into a fine rain. The water is introduced into the first chamber in an atomised state.

In recent installations, between each chamber towers of the Glover type have been introduced, which has enabled the size of the chambers to be lessened.

The acid collected from the lead chambers is diluted to 50°-53° Bé (about 60 per cent. of pure acid) and used directly for certain kinds of manufacture (e.g. 1)

1. The oxides of nitrogen are introduced into the chamber system either by the decomposition of saltpetre or by injecting nitric acid into the first chamber, or by catalytic oxidation of ammonia, or by injecting nitric acid into the Glover tower.

2. Gay Lussac and Glover towers are nowadays built entirely of masonry.

---

1. To introduce the nitrous fumes other methods may be chosen: addition of saltpetre to the minerals; addition to the gas of oxides of nitrogen prepared in special furnaces; addition of nitrate of lime or nitric acid in the Glover towers, etc.

2. The chambers can be replaced by leaden towers resembling a reversed cone (Gaillard) or by cone-shaped chambers (Mills-Packard system, U.S.A.), etc. The methods of nitration proposed quite recently dispense altogether with lead chambers. Several processes have been patented recently for types of intermediary towers for cooling and mixing the gas. Placed between the chambers, they multiply the surfaces of contact.
superphosphates) or sent for further concentration.

Gay Lussac tower. — This is constructed in a manner similar to that of the Glover tower, but it is taller. The nitric acid in the lead chambers on reaching it comes into contact with the acid at 62° Bé from the Glover tower with its flow directed from above downwards. Nitroso-sulphuric acid is formed, and the oxides of nitrogen are thus recovered. After denitrification the gases escape by a chimney. The nitric-sulphuric acid collected at the bottom of the Gay Lussac tower is sent to the top of the Glover, where, as has been seen, the oxides of nitrogen enter into the manufacture.

Several Gay Lussac towers are often necessary to make sure of good recovery and to prevent the escape of nitrous fumes into the atmosphere. All the apparatus is linked up by lead pipes. Circulation of the gas is maintained by a chimney placed at the end of the system and by a leaden fan (or one of acid resisting fire-clay) placed before the first chamber or between the Gay Lussac towers.

Transference of the acid into the towers is effected by means of compressed air. Different systems allow the acid to be distributed uniformly at the top of the towers (hydraulic tourniquets, Delplace syphon, etc.)

Concentration and purification. — The first is effected in apparatus of various kinds (often simple tanks) made of lead, platinum containing iridium or gilded, glass, porcelain, silicious material, ferro silicon (apparatus of Benker, Kessler, Girard, Gaillaret, etc.). The acid is finally subjected to purification. The arsenic is eliminated by spreading out in narrow vertical iron tubes and on perforated plates. The reaction has to take place at 550° C. — a temperature which is maintained by suitable arrangements for heating and cooling. As they leave the contact chamber, the gases are cooled in a coil and then made to bubble through nitric acid in sheet steel absorbing cylinders, lined on the inside sometimes with acid resisting material. A solution of 20 per cent. or of about 69-70 per cent. of anhydride in sulphuric acid is obtained.

Oleum is obtained most economically by dissolving the sulphuric anhydride from the contact process in the sulphuric acid obtained from the lead chamber process.

Sulphuric acid can again be got from gypsum. A mixture of strictly defined proportions of gypsum, clay and coal finely pulverised and heated catalysts is transformed into sulphuric acid. The principal product is the cement and the acid is merely a by-product.

Sulphuric acid is marketed in carboys or bottles containing 60 litres, packed in iron crates stuffed with straw. Transport of large quantities is done in tank wagons or in wagons made up of eight large vitrified earthenware cisterns. Acid with a concentration above 60° Bé can be carried in cylinders of iron.

Toxic action

Sulphuric acid fumes exert a slightly irritating action like those of other mineral acids (see articles "Nitric Acid" and "Sulphur Dioxide"). The presence of 0.5 to 2 mg. of the vapour per cubic metre of air is hardly detectable by man; from 3-4 mg. per cubic metre becomes noticeable, and from 6 to 8 mg. strongly so.

The action of the acid is essentially due to its avidity for water and to the changes so induced in albuminoid substances. When the acid is diluted the impurities it may contain play their part (see following paragraphs).
Dangers of Poisoning

In the Course of Manufacture

The dangers in the lead chamber process are as follows:

1. Acid fumes. — The acid fumes (from sulphur dioxide, sulphuric acid, and nitrous fumes (see these articles)) act on the mucous membranes and respiratory tract. The fumes may escape in quantity, in which case the danger arises not only from continuous and constant inhalation of small quantities, or from staying in the chambers containing slight concentration, but also from extensive absorption of large quantities, especially when the process is not working properly. The trouble in question used frequently to occur with the old roasting furnaces. The danger from acid fumes is present on entering the lead chambers, when they have to be cleaned, or when taking samples (but here nitrous fumes are the main source of risk); in the course of concentrating the acid (when large quantities of the fumes are evolved); in the course of carrying the acid (fatal cases have been reported as a result of fumes as well as burns from breakage of the receptacles); in cleaning the tank wagons, etc.

2. Arsenic compounds. — Danger arises from the gases given off in roasting which may contain arsenic acid if the pyrites is arsenical. The lead burners and fitters of the lead chambers run a risk of arsenic poisoning if they use a hydrogen blowpipe made from zinc and sulphuric acid. When these two products contain arsenic, arsineuretted hydrogen gas is formed, which may poison the workman directly by escape from the pipes, or from combustion in the flame when it is converted into the very poisonous arsenic acid. Arsineuretted hydrogen gas may also be given off in removing by means of dilute sulphuric acid the mud containing traces of arsenic at the bottom of the iron tank wagons.

3. Lead poisoning. — Chronic poisoning has been observed among the lead burners and fitters of the lead chambers, as well as among those engaged in cleaning them. The risk of poisoning among them is all the more serious as they are skilled workmen, which makes a change of employment difficult.

4. Poisoning by sulphotretted hydrogen. — Poisoning by sulphotretted hydrogen arising in the purification of sulphuric acid has also been noted.

In the Course of its Use

The danger arises from the liquid used and the fumes given off. Among the many applications of sulphuric acid (almost universally used in the chemical industry) the most important are: dilute chamber acid (50-52° Bé) for making hydrogen gas, carbonic acid gas, hydro sulphuric, hydrocyanic acid gas, different sulphates (aluminium, zinc, copper, barium, iron, etc.), alum, etc.; to obtain weak acids: citric, tartaric; to make peroxide of hydrogen, colours (aniline black); in tanning hides; in carbonising wool; in scouring, etching and engraving metals; in accumulator manufacture (formation); for various galvanic technical purposes; in the making of yeasts, the treatment of molasses, etc. Very dilute acid has been employed in agriculture for the destruction of weeds; acid from the Glover tower (60-62° Bé) is used for making superphosphates, ammonium sulphate, artificial manure, soaps, stearine, oleine, wax, sulphate of soda and Leblanc soda, various metallic sulphates, mineral acids (hydrochloric, nitric, hydrobromic, chromic phosphorus, bromine, iodine, potassium bichromate; for the oxidation of organic compounds by a mixture of sulphuric acid and potassium bichromate; for the purification of fats and oils; in the metallurgy of cobalt, nickel, silver and gold.

The concentrated acid (66° Bé) is used in the preparation of concentrated mineral acids (nitric, boric) and numerous organic products: acetic, tartaric, phenois, sulphuric ether and different ether compounds; sulphonated, organic acids, artificial colours; for the sulphonation of a certain number of organic compounds, for drying gas, for the purification of vegetable, animal and mineral oils as well as paraffins; for nitrating organic matters (mixed with nitric acid) to give important products, generally explosives: nitro-cellulose, nitro-glycerine, gun cotton, nitro-benzene, etc.

The uses of oleum similarly are numerous and important: sulphonation of organic substances, the manufacture of sulphonated organic acids, intermediate substances, colouring matters, alizarine, phosgene, saccharine, purification and refining of mineral oils, etc.

Statistics

These are not numerous, and, further, often include cases set up by hydrochloric acid or other acids. In Switzerland cases of intoxication or ulceration giving
rise to compensation as accidents numbered 2 in 1918; 2 in 1919; 13 in 1920; and 11 in 1921.

Several severe — even fatal — cases have occurred to workmen engaged in cleaning Gay Lussac towers and during the rectification of the distillates from naphtha by sulphuric acid. This is not the place for dealing with the caustic effects, burns, etc., occurring to the workmen manipulating sulphuric acid, which naturally do not appear in international statistics.

According to Leymann (1906), 1,389 workers engaged in German sulphuric acid factories showed for the period 1881-1904 the following sickness rates: for 100 workers 1.0 nervous diseases, 15.1 respiratory diseases, 14.4 digestive diseases, 8.9 infectious diseases, 5.5 burns, 9.5 external lesions, 9.2 diseases of the locomotor system, 3.4 dermitis.

**SYMPTOMS**

The lesions affect mainly the mucous membranes, the teeth, the skin, and the respiratory tract.

The burns by sulphuric acid, according to Gaucher and Gougerot, may be simple, indolent, or exuberant. Some burn more rapidly like a small wound, leaving a slightly pigmented cicatrice. If it is not very extensive the burn has sharply defined edges and is characterised by inflamed areas starting from a bluish centre and spreading into the healthy surrounding skin. Some burns cicatrise slowly with an ulcerated and infiltrated base; the cicatrice is violet brown, pale at the centre and deep in colour at the periphery where the retracted skin is thrown into folds. The scar tissue is supple and infiltrated, the pigmentation often extends to the healthy peripheral parts. If the ulceration is open cicatrisation is slower with violet granulations which are troublesome to treat.

At the time of burning by the liquid there is pain, blanching and later browning of the skin, desquamation, and after some minutes' redness, swelling of the tissues near the part burnt, and production of the condition described above. If the skin lesion is extensive, massive bloodstained coagulation occurs, with duodenal ulceration and rapid death in a state of coma. The urine need not be altered, but it often contains albumen, hyaline epithelial casts, and blood. As a result of the products of disintegration of the albumen circulating in the blood there may be rise of temperature. When a severe lesion heals it does so often with formation of adherent scar tissue necessitating not infrequently plastic operations.

According to Leymann, burns reached a rate of 5.5 per cent. amongst workers in the sulphuric acid industry, whilst the figure is only 1 per cent. for all the workers in the other chemical industries.

Lesions of the respiratory system are set up by acid fumes, either by the direct action of the fumes on the mucous membranes or by absorption of atomised acid present in the atmosphere, as for instance in workshops in which storage batteries are charged. Pain does not set in just at once. According to Leymann, the number of patients suffering from affections of the respiratory system exceeds that for the whole industry, and in the acid factories respiratory disease chiefly attacks the workers engaged on the manufacture of the products properly so called. Sometimes the irritant lesions are sufficiently serious to cause death (for further details, see article "Nitric Acid", "Sulphur Dioxide", "Acids", and "Chemical Trades").

On the ocular mucous membranes the acid fumes or droplets of acid set up conjunctivitis, keratitis with formation of leucoma, scarring, etc. Some cases of blindness are described.

The effect on the teeth is characteristic and points to chronic action of the acid fumes (see article "Mouth and Teeth").

**Diagnosis** presents few difficulties.

**DEMONSTRATION**

Lehmann has suggested aspiration of a known quantity of air through moistened cotton wool, and then titrating by a solution of caustic soda with Congo red as an indicator or precipitation by barium sulphate.

**HYGIENE**

Application of all the measures recognised for the construction and maintenance of premises devoted to chemical operations (flooring, walls, cleanliness, etc.). Factories should not be near dwelling houses unless condensation of the fumes is perfect. Injurious fumes should be absorbed or condensed, localised fumes should be effectively retained in completely closed and airtight apparatus, or kept under a negative pressure by artificial ventilation, if necessary.

The pyrites furnaces should not allow gas to escape and the burnt pyrites should not be withdrawn from the cinders until they have been sufficiently cooled to render them inodorous. Gases if not absorbed ought not to be discharged into the atmosphere except through a very tall stack. In a well-managed works the
content in acid of the final gas should not exceed 0.1 per cent, in volume. In Great Britain, the Alkali, etc., Works Regulation Act of 1906 lays it down that a sulphuric acid works must not allow the escaping gas to exceed 4 grains of sulphuric acid in each cubic foot corresponding to 26 per cent. of sulphur. A sulphuric acid works must not allow the residual content in acid of the final gas to exceed 0.1 per cent, in volume. The Regulation Act of 1906 lays it down that the acid of the final gas should not exceed 0.1 per cent, in volume. In Great Britain, the Alkali, etc., Works Regulation Act of 1906 lays it down that a sulphuric acid works must not allow the escaping gas to exceed 4 grains of sulphuric acid in each cubic foot corresponding to 26 per cent. of sulphur. A sulphuric acid works must not allow the residual content in acid of the final gas to exceed 0.1 per cent, in volume. The Regulation Act of 1906 lays it down that the acid of the final gas should not exceed 0.1 per cent, in volume. In Great Britain, the Alkali, etc., Works Regulation Act of 1906 lays it down that a sulphuric acid works must not allow the escaping gas to exceed 4 grains of sulphuric acid in each cubic foot corresponding to 26 per cent. of sulphur. A sulphuric acid works must not allow the residual content in acid of the final gas to exceed 0.1 per cent, in volume.

The construction, maintenance, and cleaning of the towers and chambers should be carried out according to the recognised rules for safety. The emptying and cleansing of the Gay Lussac towers and of the chambers should be done mechanically and from the outside. If this system cannot be adopted, after careful washing with water and steam (to eliminate the nitro-sulphuric acid) to remove the mud remaining on the floor of the chambers and towers, tests of the air should be made as to the presence of acid gases before allowing the workpeople to enter. If gas is present the washing should be repeated. Exhaust ventilation should be maintained from above downwards so as to draw the fumes away from the men engaged in cleaning operations. Circulation of the acid should be maintained automatically. The gases should be completely purified so as to obtain a product free especially of traces of arsenic. Workrooms should be well ventilated. Gas pipes should be tested periodically and maintained in a good state of repair so as to avoid all escape of poisonous gases. Arrangements should allow of examination for, and verification of, the state and nature of the gases.

All apparatus and pipes should be kept as airtight as possible in factories making use of the contact process. Where repairs have to be made, work should be stopped and a fan installed behind the reservoir for absorption of the sulphur dioxide. The residual gases should be passed over a filter of sand to rid them of acid. Conveyance of the acid and mixtures containing it should be carried out in a closed system by compressed air.

Workmen engaged in cleaning and repairing should have sufficient and suitable breathing apparatus or respirators placed at their disposal. It should be remembered that no substance used for impregnating the mask is capable of neutralising the toxic action of the oxides of nitrogen. The workmen should be instructed as to the danger they are exposed to during the cleaning of the reservoirs.

No solid or liquid product should be allowed to run into water courses or pits without having been previously cooled and neutralised. The danger of lead poisoning to men employed in the lead chambers should be recognised and preventive measures taken.

In the course of manipulation, the filling of receptacles which previously have contained soda or oleum with sulphuric acid, or, inversely, the filling of receptacles which have contained sulphuric acid with soda is dangerous without careful cleaning. Great care also should be taken in cleaning apparatus, receptacles, etc., which have contained sulphuric acid. Transport should be made in receptacles of iron or fireclay carboys, or in special wagons allowing transport, and emptying should be done in such a way as to avoid all chance of splashing or upsetting. Generally speaking, acids or alkalies should be pumped or aspirated into receptacles rather than be poured in, because the pressure always causes some to escape into the air. When it becomes necessary to enter tank wagons to clean them special precautions should be taken, such as preliminary energetic ventilation continued even during the operation of cleaning or washing with a hose pipe or with a dilute solution of soda. Removal of the mud by scouring should be done without the necessity for men having to enter the reservoir. If a carboy breaks, sawdust should never be used for lappping the escaped liquid because it gives rise to formation of large quantities of sulphur dioxide which attack the respiratory tract. (See also article "Acids ".)

Personal preventive measures include wearing of gloves, goggles and clogs; use of breathing apparatus where necessary. Oxygen recovery apparatus should be available.

First aid is the province of the medical man, but effort should be made immediately to neutralise the action of the acid by the use of alkali or starch.

Legislation

Women are forbidden to work in sulphuric acid factories in Argentina. Young persons under sixteen years of age are excluded from such factories in Belgium and Quebec (Canada); under eighteen in France (from workrooms where fumes are given off or where acid is manipulated) and in the Netherlands; male young persons under fifteen are excluded in Italy, Greece and Japan, and under sixteen in Spain. Female young persons under eighteen years are excluded from such factories in Greece and under twenty-one years in Spain, Italy and Japan.

Special requirements have been laid down in Germany by the Federation of Chemical Industries (it. Anz. 1893, No. 283)
having special odour when fresh and, an astringent

The leaves and young buds of certain plants belonging to the Rhus and Coriaria families furnish sumac, which is one of the best substances used in the tanning of skins. The most commonly cultivated kinds of sumac are the Rhus Cordaia Linn. (true sumac of Asia Minor and the Mediterranean countries and especially of Sicily, where it grows in the form of a shrub 3 to 4 metres high in various regions, even the most arid, without much attention); Rhus cotinus Linn. (tintorial sumac), in Europe and in Asia; the Cordaia Myrtifolia Linn. in Central Europe and North Africa; the Rhus glabra Linn., the Rhus Typhina Linn. (American sumac), etc. In Italy the leaves harvested generally from July to September are collected in various depots where they are spread out for drying when unduly moist. They are then sorted, freed by ventilation from debris (earth, pieces of wood, etc.), freed from stalks and small branches, then made into compressed 'balls and covered with cloth sewn together at the edges or tied with string, each ball weighing about 250 kg., 100 kg. of crude sumac give about 80 to 83 kg. of sumac in leaf form as placed on the market, 4 to 6 kg. of earth and 12 to 16 kg. of wood.

Leaves of Sicilian sumac in the dry state have a clear greyish green colour and are covered on both surfaces by fine hairs of a very characteristic form. Powdered sumac is soft to the touch and of a yellowish grey-green with an agreeable odour when fresh and an astringent taste. In the damp state it is liable to fermentation. Sicilian sumac contains 21 to 30 per cent. of tannic and 4 to 52 per cent. of extractive substances which are not tannic, and 6 per cent. of ash. The yellowish colouring material is myrecite.

The preparation of powdered sumac takes place in special workshops where the leaves are ground after being well dried. The product obtained is passed through a series of sifting machines which impart to the powder various degrees of fineness and eliminate impurities. The latter (unsifted parts, ligneous material, peduncles of leaves, small rootlets, etc.) are returned for further grinding and sifting. The various powders are then mixed in order to give the commercial product. The powder after preparation is placed in sacks and stored or exported.

Sumac is utilized for tanning goat and sheep skins in the Morocco leather industry, for dyeing cotton Turkey red and for dyeing a grey colour with salts of iron. It is finally employed as a mordant and as a loading or weighting agent in the manufacture of silk.

Sumac extract is obtained by treating powdered sumac with water. The solution is filtered, bleached and concentrated.

The extract is in the form of a liquid more or less dense according to the concentration, of yellowish or light brown colour with a very astringent taste. It is used in the tanning of light skins and for clarifying in all kinds of tanning in order to soften the surface of the skin. It is likewise used in dyeing.

Sources of Risk

The sources of risk are conditioned principally by the dust from the sumac, which is very abundant in course of grinding.

The atmosphere near the grinding mills is so laden with dust that it is impossible for anyone coming from outside to breathe freely even for a short length of time.

Guardione (1913) reports that workers handling sumac are in the habit of tying over their mouths and noses a handkerchief which is knotted at the back of the neck in a loose fashion in order that it may constitute a sort of bag permitting at once of the entry of the air and serving as a kind of filter. During the first hours of work this handkerchief constitutes an effective protective mask, but little by little the respiratory surface diminishes, since it is rendered damp by the breath and therefore more liable to retain the particles of sumac dust. On this account the workers engaged in grinding should be obliged to remove their masks and be sent into the open air every hour. Workers engaged on emp-
tying the machines and working in a less dusty atmosphere might, on the other hand, retain the protective handkerchief for the full length of the working shift.

This dust appears to exercise a purely mechanical action on the mucous membranes, although certain authorities are of the opinion that sumac also exerts a bactericide action.

Fatigue has been mentioned by Guardione as a further source of injury, more especially in the case of workers engaged in unloading sacks the weight of which varies from 60 to 80 kg. Further, in emptying these sacks into the grinding machines the workers in question are obliged to mount a narrow and steep ladder. The weight of the sacks of powder varies between 75 and 82 kg. The transport of these sacks lasts throughout the whole of the working day (in 1913 from eight to twelve or even sixteen hours), and the work is effected during the greater part of the time in a very dusty atmosphere. Despite the fact that the industry is seasonal and that the sumac workers pass freely from one type of work to another, it is nevertheless true that the filling of the sacks is usually effected by workers who, on account of weakness or some affection of the respiratory system, are not suited for the other operations of a more or less tiring character. In the ordinary course of events the workers are in the habit of completing a series of operations passing from the loading department to the grinding department and thenceforth to the bagging rooms.

**Pathology**

Workers engaged in manipulating sumac do not in any wise suffer from the effects of the work even for a prolonged period, provided they have a good constitution. Delicate subjects, on the other hand, especially those with weak respiratory systems, commence to show symptoms from the first days onwards when engaged on grinding. At the end of a certain time the workers suffer from some discomfort which at times obliges them to remove the protective handkerchief and to go into the open air. These attacks of discomfort are more or less frequent in accordance with the constitution of the worker and the kind of life he leads. Those who remain thirty to forty years in the industry constitute exceptions, for even after a period of twenty-five or thirty years many workers are in poor health. Their general health is precarious and they are thin and pale.

Amongst 84 workers examined by Guardione the age-distribution was as follows: 22 workers were aged between twenty and thirty; 27 between thirty and forty; 16 between forty and fifty; 12 between fifty and sixty, and 9 between sixty and seventy.

Guardione has noted *nasal catarrh* generally accompanied by rhinitis which finally evolves into *hypertrophic chronic rhinitis*. The nasal secretion is very abundant, yellowish in colour and laden with sumac dust. Old workers in the industry have often a hoarse nasal voice and suffer from aphonia and chronic diffuse catarrh of the mucus of the larynx which on examination appears swollen and brownish red. The vocal cords are larger than normal. Respiratory lesions more or less serious in character affected 52 out of 84 workers examined, consisting in chronic bronchitis with abundant expectoration of yellowish matter (very numerous and clearly perceptible particles of sumac), pulmonary emphysema (24 cases) affecting chiefly the older workers, 6 of whom only presented the classical clinical picture of emphysema. This disease form is to be accounted for by the action of mechanical causes (dust, obstruction of the respiration by the handkerchief, undue effort of strain) and by trophic disturbance due to the particles of sumac. The alveolar lesions bring about trophic changes of the connective tissue and elastic fibres.

True pneumoconiosis has never been noted even amongst those who had worked in the industry for thirty years and upward, nor has pulmonary tuberculosis, and this fact is ascribed by certain authorities to the action of the tannic acid. No radiographic data are available.

Workers in the sumac industry are predisposed to respiratory disease which in their case follows a serious course and obliges them to cease work.

Pulmonary emphysema is often accompanied by circulatory derangements peculiar to this disease. Guardione has not met with disease affecting the other systems.

Of the family *Anacardiaceae*, the species *Rhus* are those which cause the greatest number of cases of skin trouble. The *Rhus cotinus* is said to contain a toxic alkaloid (phyllentine), the *Rhus venenata* a volatile alkaloid isolated for the first time in 1857 by Kihl; Maish and Pfaff, however, in 1864 are said to have found that this principle already active in 1/1000th mg. consists
of an acid which they have designated toxicodendronic acid.

The tropical varieties of the Rhhus genus, about sixty in number, and particularly the American varieties, are said to be more highly toxic and more highly irritant for the skin. They exert an action not only on the hands and forearms, but also on the face, the back of the neck and often on the whole body. The R. Toxicodendron (toxic or poisonous ivy) has caused, as sequela of the acute form, leucoderma. Serious forms have been caused by R. metopium or Jamaica sumac (Sumac Cardot) and by the R. Diversiloba (toxic or poisonous oak), and even fatal cases have been reported.

After a period ranging from a few hours to a few days of incubation, the part affected becomes covered with numerous vesicles accompanied by itching and a burning sensation. The phenomena disappear in general at the end of several days. In serious cases there is fever and paresthesia. The lesion may even evolve into a chronic form (Broers).

The occupational categories affected are agricultural workers, gardeners, etc.

The skin lesions caused by the different kinds of sumac are well known amongst the coolies working in the tobacco and rubber plantations, for instance, in British North Borneo. The Rhhus which causes this type of dermatitis is known under the name of Run gus or Ringus.

**Hygiene**

Grinding operations should be effected as far as possible in closed apparatus, and the transport of the powder to the various machines (sifters, bagging machines, etc.) should also be effected by mechanical means.

Measures of individual hygiene — working clothes, adequate cleanliness, wearing of respiratory apparatus, etc. — should be adopted.

**Bibliography**

**Superphosphate Industry**

French: Industrie des superphosphates.
German: Superphosphatindustrie.
Italian: Fabbrica di superfosfati.
Spanish: Industria de superfósforo.

**Chemical Properties**

The fact that vegetables can only assimilate rapidly soluble substances led Gustav von Liebig (1840) to suggest rendering soluble (disintegration) of phosphate of lime (from bones) by means of sulphuric acid. The adoption of this method has resulted in an increased return from the soil due to the use of this new artificial manure (soluble phosphate of lime), and on the other hand has benefited manufacturers as well as farmers by giving them a means of utilising sulphuric acid in the manufacture of superphosphate fertilisers.

Superphosphate is prepared from natural phosphate of lime or of phosphate of bones. Deposits of tricalcic phosphate (CA₃PO₄) are fairly numerous in America (Florida, Tennessee, and Carolina), in Africa (Algeria and Tunis), in France, in Britain, in Canada, in Germany, etc. There are two principal varieties: phosphorite (the most abundant) and apatite (found in Canada, Spain, Norway, and Sweden).

**Industrial Manipulation**

Superphosphates are obtained by mixing thoroughly-ground tricalcic phosphate with a sufficient quantity of sulphuric acid to set free the largest possible quantity of phosphoric acid.

According to the quantity of acid employed, different proportions of monocalcic phosphate mixed with sulphate of lime are obtained. The mixture, which has become solid, is left aside for some time, then dried and stored. From the quantities of soluble and insoluble phosphoric acid and carbonates and silicates which the crude phosphate contains (these quantities vary), the chemist can calculate the strength and the quantity of sulphuric acid which should be used.

The manufacture of superphosphates entails the following operations:

(a) *Transport of raw materials and particularly of sulphuric acid.* — The only question of importance here is the use of sulphuric acid obtained from the acid chamber process at 53° B. When the sulphuric acid factory is very close to the superphosphate factory the liquid acid is conveyed thither directly in pipes. In this case an installation faultless from a technical point of view (stoppers, etc.) eliminates practically all risk.
For the transport of large quantities of acid, reservoir wagons are used; here it is necessary to take the greatest precautions against risk of explosion when they are emptied by means of pipes (see article "Sulphuric Acid").

Further, the manipulation of acid in an impurified state coming as waste from explosive factories not only involves a risk of explosion, but also the possibility of serious cases of poisoning (from nitrous gas, hydrogen gas, arsениуретттed gas). Reservoir wagons should, as far as possible, be emptied by means of pipes (see article "Sulphuric Acid").

It must also be remembered that a kind of sludge containing arsenic, and imbued with sulphuric acid, is formed in the reservoirs. In stirring up this sludge with the addition of water (in cleaning for example), a dilute acid solution is formed which gives off hydrogen (danger of explosion) and particularly arsениуреттт hydrogen (the cause of frequent poisoning).

Smaller undertakings often effect the transport of the acid in large glass bulbs which unfortunately are easily broken. This risk can be eliminated by the use of glass recipients covered with straw or basket work (carboys) transported in wagons or cars provided with shock-resistance devices and having a pipe worked by a lever for emptying and also devices assuring absolute safety for the operation of drawing off. Workers engaged on such operations should wear protective goggles.

For preliminary weighing it is necessary to use as far as possible automatic measuring and drawing-off apparatus.

For hygiene of the workshops, see articles "Industrial Hygiene" and "Acids".

(b) Breaking of crude phosphates.
— The crude phosphates, which according to the country of origin are in large or small pieces, have first to be broken up with a view to augmenting the surface which can be attacked by the acid. The breaking up of the raw material in a very dry state, and sometimes even calcined, is a fairly disagreeable operation accompanied by the production of thick clouds of dust.

Grinding by hand was the method first practised and was carried out in the open air, where possible under a roof affording protection from all winds to obviate the disagreeable effects from dust raised. The work was also carried out, however, in closed workshops where the dust was a veritable torment for the workers and干活ly endangered their health.

Grinding machines, provided with devices which completely envelop them and allow of mechanical loading by means of cranes, have now been adopted by the best-equipped firms. Improved conditions are guaranteed by using a ball grinder in which the dust produced in a closed space is conducted by a ventilator to a dust chamber and the ground product in a state of fine subdivision is led directly to the place of disintegration.

Though there is a lack of precise data in regard to serious affections proved beyond doubt as due to the dust of crude phosphate, it is commonly known that affections of the mucous membrane (eyes, nose, rhino-pharynx and respiratory passages) are set up. It is consequently advisable to eliminate dust production as completely as possible. In addition to the dust hazard, there is also a certain amount of fatigue due to the disagreeable noise of the grinding machines.

Hygiene. Grinding of crude phosphates should be done in closed apparatus preventing any escape of dust and provided with an effective exhaust device (having ducts leading to a dust chamber provided with a filter) in order that the workshop may be kept free from dust.

In Italy success has attended the installation of a system in which dust chambers are coupled together (cyclone system) and the rate of the air current is diminished. This system, however, is accompanied by less favourable conditions in the workrooms. It would be preferable to pass the air through cloth filters and refrain from reducing the rate of the air current. The flooring should be hard and compact; the workshops should have high ceilings and should be well ventilated and easily cleaned.

(c) Disintegration (mixing with acid).
— This operation, which consists in mixing thoroughly the crude phosphorus with the sulphuric acid, is inevitably accompanied by liberation of noxious fumes. The method of mixing in open trenches is very disagreeable for the workers and the neighbourhood, and has to-day given place to mixing in mixers connected with the superphosphate stores; this method allows of the heat generated during the operation being stored and utilised, and permits at the same time suppression of the noxious fumes.

The disintegrator consists of a closed kettle within which a wheel with wings or blades mixes thoroughly the raw
materials. The mixed product is then poured through openings with automatic closing into a "den" for storing the superphosphates — usually located directly below the disintegrator. Gases given off during the reaction (especially carbonic anhydride, sulphuric acid, hydrofluoric anhydride, and silicon fluoride) are drawn off by a system of pipes and chemically or physically converted before being liberated.

Amongst the noxious gases in superphosphate factories must be remembered hydrofluoric acid (see this article), the caustic action of which is immediately recognisable by the fact that the windows and electric lamps lose their polish after the lapse of a few days. Instead of discharging the fumes of silicon fluoride, acid gases, etc. into the upper strata of the atmosphere, it is much better to condense them and have them absorbed in refrigerating chambers and washed with water in towers (Korling system).

Condensation of silicon fluoride presents some difficulties, for the silicon produced is converted into a gelatinous mass. A method for long in vogue in Italy is the adaptation of a square tower inside which the gas passes from the top downwards and is withdrawn by water which falls in cascades over inclined "baffles". As the water leaves the fluosilicic acid and the gelatinous silicon it produces at the same time a current of air through the opening for charging the mixer where the disintegration of the phosphorite with the sulphuric acid takes place. This method of ventilation prevents any return of silicon fluoride or nitric acid fumes.

The waste water from the factory strongly impregnated with acid should not be discharged into watercourses without first being neutralised (with carbonate of calcium, for instance) or purified in some other manner. A thorough cleaning of all condensation and absorption apparatus should not be permitted except after effective ventilation, and the workers engaged on this work should be provided with respiratory apparatus since the incrustations formed in the walls and the flooring continue to give off considerable quantities of very caustic gas. Further, the uncovered parts of the body (face, hands) must be protected from contact with the hydrofluoric acid. According to certain authorities, these incrustations, which seem at first dry even to the touch, become activated as soon as they are displaced and give off fluosilicic acid which separates from the silicic acid. Consequently, it is advisable to pour potassium chloride over such incrustations with the object of transforming the fluosilicic acid into an insoluble hydrofluosilicate.

It is well to remember that with a modern installation the workers are not exposed to danger except where the machinery is defective from a technical point of view or where the operations are not effected in the appropriate manner.

(d) *Emptying the disintegration dens*. — The process of disintegration being over, the superphosphate produced is removed from the "dens" and thereafter dried and transported to stores (warehousing). Amongst the risks to which workers are exposed at this stage must be noted lesions of the skin and mucous membrane (eyes, respiratory passages) due to the caustic properties of the heated mass of superphosphates and poisoning from toxic fumes. On the other hand, carelessness in working may dislodge great masses of the product and give rise to very serious accidents.

Superphosphate "dens" should be emptied with all possible haste. As the product becomes more and more damp in course of cooling as a consequence of the condensation of steam, the workers are brought in contact with a product the temperature of which reaches 100° C. and over and are obliged to work in a hot and damp atmosphere. In addition to the risk of burns, the workers are exposed to damage from the hot and humid atmosphere, which hinders respiration, as well as from the presence of the noxious fumes referred to above which the finished product continues to set free in spite of the best adapted systems of ventilation. The wearing of respiratory apparatus of cloths or sponges over the nose and mouth reduces in fact the baneful action of the gas, but it impedes respiration and makes the work more and more burdensome to the workers engaged in narrow, overheated places.

The clearing out by hand of the "dens" is very difficult in practice even where the ceiling is high, because the free space left above the compact mass of the product is so restricted that it is impossible to attack the mass from the top. The workers have therefore recourse to a dangerous method, which consists in undercutting the mass in order to cause the top part to topple over. This method is one evidently liable to cause numerous serious accidents, often even fatal (fractures of limbs, crushing of the workers by
the fall of large blocks, or by the sliding down of the entire mass, and such accidents have not decreased since undercutting has been prohibited.

It has been held that such grave risks could be eliminated by increasing the space in the "dens", improving the ventilation and enforcing strict supervision. It must be recognised, however, that such precautions are not enforced or do not have the desired effect, and that the only adequate prophylactic measure would be the substitution of mechanical and automatic methods for manual labour.

When it is necessary for the workers to work in the "dens", the greater part of the noxious gases can be removed by an exhaust device which creates a depression favouring the withdrawal of dust towards the back of the mass of superphosphates.

With certain mechanical installations the workers have nevertheless to execute by hand the most important part of the work and are, despite such installations, exposed to the above-mentioned risks. The heads of undertakings and the chemists of the Association of German Manure Manufacturers replied in the negative (1921) to the question: "Does there exist an apparatus of proved application for emptying mechanically the disintegration dens?". This declaration had the happy result of stimulating a series of experiments and led to the discovery in the two following years of methods of emptying the disintegration "dens" under much more hygienic conditions.

The devices suggested (dredging devices) exercise on the porous but solid block of disintegrated superphosphates a cutting, hollowing-out, scraping or scratching action. The "dens" consist of recipients fixed or mobile in the form of vertical or horizontal vats. If the "den" is fixed, the emptying apparatus is hooked on above or at the side and made to penetrate to the interior. If on the contrary the "den" is mobile, it is transferred with its contents to the emptying apparatus which is fixed and which under these circumstances can be constructed in the "den" itself. The detached fragments fall on to travelling streets which convey them to other apparatus where they undergo the requisite mechanical transformation. The whole operation is carried out in a closed space; the gases given off by the reaction are withdrawn by the aid of powerful exhaust devices.

Modern apparatus have not only reduced the number of workers required to effect the operation in question, but have also eliminated almost entirely the risks which formerly accompanied this work. Further, in so far as regards the above-mentioned operation, the data furnished by the technical administration branches of superphosphate factories have once again proved that the improvement of health conditions implies improved economy and efficiency.

Hygiene. In the interests of the protection of the workers, the crude phosphate should be disintegrated in perfectly airtight containers. Every opening in such containers should be provided with closing devices which can be hermetically sealed. Before starting up the mixing machine, all openings of the container should be hermetically sealed saving only those serving to connect the latter to the mixing machine or for withdrawal of the gas produced in course of disintegration. These gases should be withdrawn by means of a powerful exhaust which should be set in motion before starting up the mixing machine. Emptying should be effected mechanically or, where this is not possible, all precautions should be taken to assure good ventilation of the working posts and of the "den". The workers engaged in emptying should have protection for the mouth and nose and should wear suitable shoes. Undercutting of the mass of superphosphates should be strictly prohibited. Highly acid gas from disintegration (about 5 grm. of sulphurous anhydride and 1 grm. of hydrofluoric acid per cubic metre of air) should not be allowed to escape directly into the atmosphere, and the waste water from the process of absorption and washing of the disintegration fumes (containing over 3 grm. of free acid calculated as sulphuric acid, and over 0.5 grm. of free alkali or alkaline earth calculated as caustic soda, not more than 0.05 grm. of arsenic and finally not more than 10 grm. of dry residue per litre) should not be allowed to escape into the subsoil or public canals or water courses.

(e) Drying and crushing. — The fresh superphosphate which becomes agglomerated in hard lumps and contains a certain quantity of water cannot be ground fine enough to satisfy the requirements of agriculture without first being dried. This operation, which improves the quality of the product, used to be effected in open hearths heated with coal or steam. Workers engaged near the heaps of superphosphate or occupied in shovelling the mass which continued to give off acid gases (especially fluor compounds)
worked under extremely trying conditions. This method is now replaced by a mechanical process effected with different kinds of drying stoves.

The addition of certain substances such as animal charcoal or bone meal accelerates the mixture and is effected mechanically.

The operation of crushing and sifting can likewise be carried out by the same apparatus as that used for drying.

The greatest danger here is presented by the gas used for heating and by the risk of accident.

**Hygiene.** The measures to be enforced in the interests of the worker and of the neighbourhood are the same as those cited above in section (d).

The workshops should be well ventilated, regularly and thorough cleaned at short intervals. The grinding and sifting should be done in closed and perfectly airtight apparatus provided with suitable and effective dust exhaust mechanism.

The manufacture of double superphosphate comprises the following operations; grinding of the raw material (phosphate), treating of the latter with sulphuric acid at 16-31° B., filtering through jute presses, concentration of the dilute phosphoric acid, mixing of the phosphorite with concentrated phosphoric acid (to obtain the double superphosphate), drying, and grinding of the finished product.

(f) Storing and transport. — Long-continued storing causes not only a chemical change in the product — which no longer has the same soluble phosphoric acid content (reversion to an insoluble state of the superphosphates) — but also agglomeration of the different particles which finally unite in a compact block. The latter must before usage be again ground and sifted. By reason of its hygroscopic properties, the superphosphate gives off relatively little dust; the occupational danger presented by dust therefore gives place to the much graver risk of accident to which workers are exposed in removing the product.

According to a report (1912) of the German Occupational Mutual Society (Berufsgenossenschaft), accidents are unfortunately unavoidable so long as shovelling is done by hand. The regulations for accident prevention prohibit undercutting of the mass when it exceeds two metres in height. According to the Industrial Hygiene Institute of Frankfort, however (1912), workers in factories are often allowed to engage in undercutting of terraces of two metres but constituting in their entirety a height of up to ten metres.

The terraces are cut away from below, cut into from the side, and large masses are suddenly dislodged and spring off with the aid of a hammer and wedge. It often, happens in such cases that considerable fragments detached from the upper part of the heap fall on the workers below or cause those working on the higher terraces to fall.

The masses of superphosphate are now sometimes even blown up with safety explosives, and experience has shown that this method is accompanied by a reduction of accidents so frequent formerly. The facts just recorded in relation to the breaking down of the heaps of superphosphates apply also to the storing and transport of sacks. The regulations prohibit more than four sacks being superimposed.

**Statistics**

There, unfortunately, does not exist important statistical data of incontestable accuracy relating to the health conditions of workers in the superphosphate industry.

**Pathology**

The workers in superphosphate factories are exposed to certain harm and danger of sickness due to the following causes: steam, undue heat during the reaction of the acid on the phosphate (especially while emptying the "dens"), caustic liquids, harmful and toxic gases and fumes such as carbonic anhydride, sulphurous anhydride, nitrous fumes (during treatment of phosphates with sulphuric acid with a nitric acid content), hydrofluoric acid, hydrochloric acid (during treatment with hydrochloric acid or the use of raw materials with a chlorine content), silicon fluoride (from the presence of fluorides of calcium and silica). In one fairly serious case, illness was due to nitric acid fumes given off by a mixture of saltpetre from Chile with superphosphates probably in a very acid state.

Besides cases of dermatitis reported in Germany and in Great Britain by the industrial inspectors and due chiefly to acid dust, there have been noted amongst workers engaged in emptying the "dens" cases of hoarseness lasting several days, and amongst workers engaged in drying operations purulent abscesses localised on the genital organs, due to soiled hands and arising, without doubt, during transport of hydrofluosilicate of soda. Cases of vertigo during the day and of over-excitement during the night were also noted amongst factory
workers who handled during the war sulphuric acid coming from an explosive factory (traces of nitro compounds).

In the Dutch superphosphate factories there was found 0.0035 mg. of hydrofluoric acid per litre of air (Ronzani see also article “Hydrofluoric Acid”).

The use of superphosphates causes amongst agricultural workers an irritation of the eyelids and of the conjunctivae, ulceration of the cornea with opacity and sometimes loss of the visual function.

LEGISLATION

Very detailed measures of protection for protecting the health and lives of workers in superphosphate factories have been given effect in Germany. The Federal Council, having decided to apply general regulations based on paragraph 1 of section 120 c of the Industrial Code, proceeded to undertake an enquiry in 1906, which revealed the fact that the majority of superphosphate factories were not engaged in the manufacture of this product for more than six or eight weeks in spring and in autumn (when orders are received from farmers). Since women and children were found to be restricted merely to inoffensive operations (sewing and marking the sacks), there seemed to be no ground for adopting measures of protection in respect of them. The conditions attendant on the grant of a permit for construction (section 16 of the Industrial Code) and the special provisions based on sections 120 and 120c were already found to afford the workers a large measure of protection. Though this enquiry (1906) did not lead to the issuing of any special order it stimulated, without doubt, a movement resulting in important improvement in the health conditions of the German superphosphate industry.

In general, women and children are excluded from superphosphate (lime and potash) factories where acid dust and fumes are given off; and young persons of 16 years of age in Belgium, and of under 18 years of age in France, and women of less than 21 years in Spain, are excluded from industrial work. For the other countries, exclusion is imposed under a more general formula applying to chemical manure factories.

Protection of the neighbourhood is provided in Germany by sections 16-25 of the Industrial Code. In virtue of section 10, the superphosphate factories are classed as “establishments which by reason of the situation or of the nature of their workshops may constitute a source of danger and serious inconvenience to the proprietors or inhabitants of neighbouring feus or to the public in general”. Their construction is consequently made subject to the grant of a permit from the competent authority, which is responsible for seeing that the regulations as to complete isolation of the factory, its construction, precautions against fire and in favour of hygiene, both as regards the work conditions and the workers in question, are given effect to. On 29 June 1896 the Occupational Mutual Society of the Chemical Industry published special regulations dealing with accident prevention in manure factories, regulations which were, however, superseded later by the “Regulations on Accident Prevention of the Occupational Co-operative of the Chemical Industry” of 1 January 1912, with appendices based on the typical accident prevention provisions of the Association of German Mutual Societies (Berufsgenossen- schafts-Verband). The provincial police orders and general orders of other authorities are in no wise modified by these provisions of the Occupational Mutual Society of the Chemical Industry.

Hygienic measures must further include the general precautions common to all unhealthy trades (cleanliness, effective ventilation, good lighting, etc.) as well as certain precautions peculiar to the industry in question such as: withdrawal of gas and fumes from apparatus and vats; special manipulation of acids and lye; special care in the cleaning out of apparatus, vats, “trenches”, etc.; protection from noxious gas fumes and dust in general; special precautions in cleaning vats provided with stirring apparatus or steam and acid ducts, and very special care when these have to be entered; effective precaution in working with masses of agglomerated material, and in storing sacks; enforcing of rules as to wearing of glasses, respiratory apparatus, special overalls, and footwear. The workers must be instructed in the dangerous properties of the gas and fumes to which they are liable to be exposed in this industry, in the precautions to be taken to prevent the gas and toxic fumes from escaping into the workshops, in the means of individual protection, in the cleaning of apparatus reservoirs and vats (especially from sulphuric acid), as well as in the special precautions to be observed when entering the latter.

Tracts and posters containing a brief account of the toxic properties of gas and fumes (arseniuretted hydrogen, hydrofluoric acid, carbon oxide, coal fumes, carbonic anhydride, nitrous gas, sulphuric anhydride, as well as the formation of explosive gases, etc.) should be prepared, distributed and posted up.

There exist special apparatus for determining the content of the atmosphere in gas and the nature of the gas liberated. The acid residues, waste liquids and other liquids must be completely neutralised before being thrown out and also deodorised where this is necessary; the gases should be condensed after being made to pass through columns of damp or oiled coke.

BIBLIOGRAPHY

Syphilis (Occupational)

Occupational syphilis is scarcely less common than the syphilitic manifestations of sexual origin. In some regions it is of even greater frequency than the syphilitic affections of genital origin. It was so notably in Russia under the former régime; there departments existed where genital syphilis was 9 to 10 per cent. of all cases and occupational syphilis 80 to 91 per cent. of cases (Popov and Beloussov, 1897).

The pathogenic agent of syphilis is the Treponema pallidum (Spirochaeta pallida); it is found in the lesions which may develop, so to speak, in any part of the body.

Outside the genital area, infection may occur by the intermediary of contact or by the intermediary of the most varied articles contaminated with syphilitic material, provided that the time which lapses between the contamination of the article and the time the treponema is not too long, as the treponema is rather a delicate micro-organism when outside the body. Hence infection is, in most cases, immediate, and only through abrasions of the skin and mucous membranes, even though quite minute.

Mention must be made of infection by the blood and urine of syphilitics, which contain treponemas, and so may form dangerous material. On the other hand, doubts exist as to the presence of treponemas in the milk of syphilitic women.

Statistics

The site of the lesion is most varied. According to some data collected by C. Ruhl in 1918, dealing with 11,829 cases of occupational syphilis described in medical literature, the primary manifestations were situated on the lips in 4,002 cases; in the buccal cavity, on the gums and on the tongue in 1,254; on the tonsils in 1,156; on the eye in 678; on the forehead, temples, ears and scalp in 151; on the cheeks, nose and chin in 691; on the neck, trunk, forearms and arms in 328; on the hands and fingers in 925; on the periungual region, the lower limbs, and the umbilicus in 180; on the perigenital region and the anus in 468 cases.

According to some figures, published by Henry Chabrol in 1925, based on cases observed at the St. Louis Hospital, Paris, during ten years, 1914-1924, out of a total of 11,518 syphilitic chancres, there were 690 cases of occupational chancres, or 6 per cent.

Chancres about the head were the most common; they claimed 79.3 per cent., of which 70.1 were about the mouth and 9.2 on the face. The distribution according to different areas was as follows: lips, 327; tonsils, 86; tongue, gums, palate and mucous membranes of the cheeks, 57; chin, cheeks and nose, 71; eye, 4; and scalp, 1.

Next follow chancres of the neck, trunk and limbs, which account for 88 cases out of the 690, or 12.8 per cent.; hand, 27; forearm and arm, 2; pubes, breast and thigh, 43; toes, 2; groin, buttocks and abdomen, 12; and neck, 2. Then come chancres of the anus and the perineal region, amounting to 56 cases out of the 690, of which 17 were in men and 39 in women, giving 8.02 per cent.

As regards localisation on the fingers, it has been found to account for about 4 per cent. of occupational chancres and 0.25 per cent. of syphilitic chancres in general. The method of contamination in these cases was either venereal (18 out of 59), or due to occupation (4 cases), or to traumatism or accident (5 cases), of which 5 were bites (G. Bienfait, 1925).

Occupational Pathology

Extra-genital syphilis of occupational origin is met with chiefly among:

(1) Medical personnel (doctors, midwives and nurses). To this category belong all forms of syphilis, whether occurring among doctors treating syphilitics, surgeons, gynaecologists, dentists and laryngologists, in whom, in most of the cases, the lesion is situated on the fingers or the hand; more rarely, it occurs on the face, particularly when the patient suffers from an open syphilitic lesion and coughs or spits at the time of the examination (Desmarres in 1854 and Le Loir in 1866).

As regards localisation on the face, it is still a matter of dispute as to whether a hand soiled by virulent material can possibly carry infection to the nose or eye (Boucheron in 1866; Buret in 1892; Hutchinson in 1879).

Localisation on the eyes and surrounding parts has been reported by Alexander, following upon irrigation carried out on a syphilitic patient, and by Enslen and Schweinitz, following the projection of amniotic fluid containing syphilitic virus into the eye.

Truβ has collected 300 cases of
syphilitic infection among doctors as the result of their work. According to Hallot, the number of occupational syphilitic chancres among doctors, as shown in all literature up to 1924, reached 530. Djeumitsky and Slanko in 1929 received 314 replies to a questionnaire on the subject of occupational syphilis sent out to doctors, in this way they learned of 43 cases, to which were added 8 cases published after the enquiry. Of these 43 cases, 24 were investigated at Kharkov and the persons affected were doctors in 25 cases, 2 of them being women; dentists in 2 cases, one being a woman; hospital attendants in 10; midwives in 10; and nurses in 4, 2 being women. The predominance of the lesions among men has been explained by the fact that women less frequently specialise in the occupations involving exposure to the contagion. Among the latter, the infection occurred 17 times from attending confinements, 10 from giving syphilitic treatment, 6 after gynaecological operations, and 5 after surgical operations. The situation of the lesion was in 29 cases out of 4 on the fingers, i.e. 67 per cent. Among the 25 doctors infected, the development was serious in 11 cases.

Metschersky and Olesoff in 1929 reported 5 cases of typical occupational syphilis, and Dujardin in 1932 reported 2 cases (a gynaecologist and an ear and throat specialist: infection on the fingers). The occupations of the infected persons were: doctors and pathologists, 14; dissecting-room attendants, 6; and laboratory attendants, 2. The course of the disease thus contracted has often been serious.

(2) Wet nurses who feed congenital syphilitic infants. The lesion is situated on the breasts and chiefly in the areolar regions. But there have also been noticed in wet nurses and nursemaids who have charge of infected children, buccal and lingual lesions, due to either kissing the infant, or to the habit of putting in the mouth the teat, or the spoon with which the infant has been fed. Lesions have also been observed on the eyelids, due to contact with a pillow on which the infant has dribbled (Pellizzari, 1862); and on the forearm, due to carrying infants having syphilitic lesions in the region of the anus.

(3) Glass-blowers. In consequence of passing the blowpipe from one workman to another, the lesion is naturally situated on the buccal mucous membrane. With glass-blowers the mucous membrane is very often found in a chronically inflamed state, with excoriations and rhagades produced by the pressure of the blowpipe on the lips and gums; they thus facilitate the entrance of the virus. Some small epidemics of this kind have been reported: at Milan (6 workers; Bernacchi, 1910); at Florence (Mibelli, 1920); to which should be added epidemics which occurred some time ago at Rive-de-Gier (20 cases, Violleau, 1962) and at Montluçon (30 cases, Dechaux, 1868-1869). There is also mention in literature of 82 cases of syphilitic infection reported in the records of the hospital of Antiquaille at Lyons (1858-1872) and of cases described by Ravogli and Rasori (Italy 1880), Siegmund (4 cases, Austria, 1863) and Heiberg (9 cases, Denmark, 1883).

Medical supervision on the one part and propaganda relating to sexual hygiene on the other part, but chiefly the introduction of mechanical technical methods, have much reduced and almost eliminated this danger.

(4) Goldsmiths may be affected in consequence of the use of the blowpipe. This danger is much less common; the only cases known are 3 situated on the lips, described by Margoniner in 1863.

(5) Workers in various other occupations. These cases are very rare; but mention may be made of the following, drawn, for the most part, from old authors: infection caused by the use of signal whistles by several railway
guards (Gross, 1874; Taylor, 1890); by musical instruments used by several persons — a cornet (Sigmund, 1863), a clarinet (Pospělov, 1889), and a flute (Vigüier, 1888). Lesions on the lips or tonsils have also been observed in chefs who have tasted dishes with a spoon which had been used by an infected fellow chef (Jullien, 1886; Tschistiakoff, 1890).

Furriers (3 cases) have been infected in consequence of the habit of biting threads with the teeth (Poray-Koschitz, 1889); shoemakers and upholsterers from holding between the teeth before use nails which have been infected previously by syphilitic workmen addicted to the same practice.

Occupational infections have been described among cashiers infected by coins and bank-notes (Desnos, 1889; Fitzgibbon, 1889; Robinson, 1884), among laundrymaids and housemaids from contact with infected linen (Boeck, 1875; Dornig, 1885; Guntz, 1883; Neumann, 1888); among rag-pickers (Fourrier, 1885) and also, as quite an exceptional case, a police officer bitten in the exercise of his duties by a syphilitic prisoner (Finger, 1926).

Injuries may activate a latent syphilitic infection and cause syphilitic lesions to appear at the point of injury. Klander reports the occurrence of cutaneous gumma, and of gumma of the testicle due to this cause. According to Diez, the relation between traumatism and syphilis can be summarised as follows: inoculation of the spirochaete can occur through wounds received from causes inherent to work; injuries caused by accidents in syphilis may lead to atypical and serious developments of the disease, setting up sequelae which do not occur in normal subjects; as a consequence of accidental injuries affecting syphilitic subjects tertiary conditions may become manifest in the injured parts.

Barthélemy considers that, while the occurrence of post-traumatic syphilitic conditions is a fact, it rarely happens. Before accepting or rejecting post-traumatic syphilis, the circumstances of the accident must be rigorously established, and the syphilitic nature of the lesion must be placed beyond possible dispute. Pedes and Donnadieu in 1928 described a case of syphilis of this kind in a working painter who was wounded on the thumb while taking out the panel of a door: the authors draw attention to the fact that it is far fetched to attribute the condition to an occupational origin. Michael considers that traumatism only rarely leads to the development of tertiary syphilis or of para-syphilitic lesions.

Prophylaxis

Prophylaxis against occupational syphilis, although essentially simple, presents in practice notable difficulties, especially from the impossibility of always recognising the existence of the disease. Ignorance concerning infection plays the most important part in contagion. On account of this it is necessary to insist ever more and more on the practical rules of personal hygiene which protect the worker from contagion. In addition to that, stringent methods of diagnosis should be used in all cases in which doubts may exist. This is notably the case with wet nurses, where serological examination of a possible carrier of the virus should be almost obligatory. Amongst workmen, and in hospitals, it is necessary to prevent as much as possible the promiscuous use of all objects which may serve to transmit syphilis. On all occasions when instruments or materials are used, which are capable of transmitting the virus, the rule must be adopted of providing separate instruments or materials for each person, and, in this way, of avoiding the passage of an object from one worker to another. As regards medical personnel, all precautions must be taken during the examination of syphilitic patients or when handling infected materials. India-rubber gloves should be worn, and protective arrangements against the projection of such infected materials as expectoration, pus, or blood, should be made compulsory in all cases in which there is danger of infection.

Legislation

Occupational syphilis in midwives, doctors and nurses is compensated in Bulgaria; and in Mexico for glass-blowers where the primary chancre is buccal, and for the sanitary service where the primary condition is on the hands. It may also be so compensated in countries which have adopted the general formula of "infectious diseases" for the sanitary service. See articles "Infectious Diseases" and "Medical and Allied Professions".

Talc

Talc is a silicate of hydrated magnesium \((\text{Si}_4\text{O}_{12}\text{Mg},\text{H}_2)\) which is found in stratified compact masses with varying colour aspects (white, green, brown, rose), varied structure (earthy fracture, translucid and mother-of-pearl-like sheets) and varied hardness. When the structure is slightly fibrous and translucid it constitutes the soapy variety known as "steatite" which gives a white powder oily to the touch.

Talc is almost completely acid-resistant; it absorbs and retains perfumes well. Talc powder is a perfect lubricant for the skin, for which it forms a protective coat against irritation due to friction. It has replaced starch for all hygienic purposes.

Artificial talc is obtained by treating the solution of a salt of magnesium, the precipitate of which is washed and dried with silicate of soda. Talc extracted from quarries in more or less bulky form, is submitted to a first process of sorting, which has for its object the removal of grey or green pieces coloured by iron impurities and thus rendered unsuitable for hygienic purposes. After drying in the sun (or artificial drying) and crushing, the talc powder is passed through a series of sifting machines of increasing fineness, furnishing a series of powders of varying grades.

Talc is used as a loading material in the paper and cardboard industry; as a substitute for kaolin; in the textile industry for dressing material and as a lubricant; in the rubber industry; in the preparation of rice-powder, etc.; in the manufacture of small gas and acetylene jets, etc.; in the glass industry for the manufacture of opaque glass; in the colour industry for the manufacture of pastels; as a lubricant for gloves and shoes; for the manufacture of sealing wax; in the perfume industry (impalpable powder) for the preparation of rice-powder, etc.; and as a loading material in soaps, shampoos, creams, etc.

It was Thoral who was the first to describe in detail in 1896 a case of talc pneumoconiosis which he designated under the name of "steatosis" (Specksteinlunge).

The second case, particulars of which were not published, was studied by R. Sand in 1910. It was the case of a woman worker who had worked during several years in an atmosphere rich in talc and who died from a disease contracted during that time. The microscopic preparations of the lungs showed countless talc particles in the alveoli and in the conjunctival tissue, but without great reaction (communication by the author).

In the report on pulmonary diseases due to dust presented at the National Congress on Occupational Diseases at Turin in 1911, Devoto and Cesabianchi referred in detail to the case of Sand, drawing attention to the fact that it was a question of a dust so far considered as harmless, but which, on the other hand, was capable of setting up a slow inflammatory process of chronic and sub-acute nature, yet extending to almost the whole lung, the lesion having even attacked here and there in the case studied the pulmonary alveoli.

A third unpublished case studied clinically and radiographically by Cunningham, of Toronto, relates to a worker who from the age of nine was employed in grinding talc. Cunningham noted typical lesions of pneumoconiosis. In 1931 Zaneli described a fourth case. It was that of a woman worker aged 27 who during five years had been employed in introducing by means of a jet of compressed air large quantities of talc into the inner tubes of bicycle tyres and who also cleaned the exterior surface of these. This work was done in the absence of all
Tantalum, a rare metal less abundant in the earth's crust than gold. It is found in combination with some rare ores (especially niobium), in tantalite, or niobite, melanocerite, samarskite, etc.

Tantalum is obtained from tantalites by melting the ore with potassium dichromate. The product in aqueous solution is brought to boiling point and the residue, consisting of tantalum acid and niobic acid, is treated with hydrofluoric acid to obtain soluble fluorides of tantalum and niobium. Tantalum, a precipitate of the solution from the fluoride of potassium, in the form of fluoride of tantalum and insoluble potassium (the niobium remains in solution) is treated with sodium. The metallic tantalum obtained is in the form of grey-black powder, which is purified by melting in the voltaic arc or in a vacuum. Tantalum is highly resistant to corrosion by chemical agents, except by hydrofluoric acid, which however acts very slowly, and has the highest melting point of all the metals.

Tantalum may be worked in a cold state, drawn, forged, manufactured, polished, hardened, rolled and stamped. The pure metal is still more easily worked.

At the present time tantalum is used in the manufacture of lamps and tubes for the vacuum process, particularly in the radio-electric industry; in the manufacture of certain alloys, of apparatus utilised in the spinning of artificial silk, of coverings for apparatus intended for the chemical industry, in making pen nibs, in the preparation of supplies for use in dental prosthesis, and in the jewellery trade. It is used as a substitute for platinum in making electrical apparatus (electrolytic valves for electrolysis, etc.). In view of the fact, however, that it absorbs a certain quantity of gas as soon as it is brought to a temperature exceeding 350°C, thereby suffering a diminution of its mechanical properties, tantalum will never be very extensively utilised.

No injuries of an occupational character which can be ascribed to tantalum are known.

**Taxidermist**

Taxidermists — those engaged in stuffing animals for trade purposes or naturalists — prepare the animals with a view to their conservation in their natural-state. Animals recently killed, and as clean as possible, are skinned in such a manner that the tegument should not be destroyed and that the skin, fur, feathers or scales which cover it may be preserved intact. This opera-
The skins are then treated with various products applied with a view to their conservation: boricur soap, Brown's solution of chloride of lime, a solution of corrosive sublimate and mixtures containing tannin and calcined alum, etc.

The cleaning of feathers and fur is also effected by rubbing with a wad impregnated with petrol spirit, and thereafter powdered over with plaster of Paris, which is removed when the fur is dry by means of beating with a feather brush.

The skins, after preparation, are stuffed with straw. in order to give them the form of the body, and the heads are finished by insertion of artificial eyes, etc. At the present time a process of modelling is followed (wood, plaster, cork conglomerate, etc.), which consists in applying the skins to models of the animals prepared in advance.

A Chicago taxidermist has provided a description of the method followed by him in preparing the arsenical solution. He mixes about a pound of white arsenic with 4 parts of water, to which he adds soda, boiling the mixture in the open air until it is dissolved. Into this he plunges the feathers of birds, which he applies while still wet to the straw form or model of the animal. The skins of animals are first treated with salt and water, and after with the above arsenic solution. This expert believed that the arsenic did not act as a skin irritant until the moment at which it became dissolved. He had never suffered from cutaneous symptoms during his long experience as a taxidermist (Hamilton).

Nevertheless, troubles of a specific nature are numerous: cutaneous eruptions, ulceration — mostly situated on the fingers, and recalling the ulceration observed amongst tanners and furriers — lesions of the nails, general symptoms caused by preparations with an arsenic or mercury basis. Barton, quoted by Kobert, has found a typical arsenic neuritis affecting a taxidermist and his wife. The Browne solution prepared where not, fumes which irritate the respiratory and ocular mucous membranes. The possibility of workers engaged in stuffing animals becoming infected as a result of handling skins contaminated with anthrax spores must not be overlooked.

Layet had already in the past drawn attention to the fact that time spent in workrooms containing collections of stuffed animals was likely to endanger the health. The preserving media, having dried and been reduced to dust after the passage of time, became disseminated in the atmosphere, and, after inhalation, were capable of setting up, after some time, symptoms of chronic poisoning.

Arsenic poisoning amongst taxidermists is subject to compulsory notification in the Netherlands; mercury poisoning entitles victims to compensation according to French legislation; compensation is likewise granted in those countries which have a schedule containing the general formula adopted under English legislation (see article "Occupational Diseases: Definition and Compensation").

### Tea and Coffee

**French:** Café, Thé. — **German:** Kaffee, Thee. — **Italian:** Caffé, Te. — **Spanish:** Café, Te.

#### Coffee

An investigation carried out by the Institute of Tropical Medicine of Porto Rico in 1913 ascertained that ascariasis (parasitic disease due to ascarius lumbricoides) was the prevailing disease among coffee workers. Ninety per cent. of 10,140 persons of all ages and both sexes were found to be affected. Nervous symptoms were usually absent, but gastro-intestinal disturbances were common and often very serious. Two serious effects of ascariasis were noted: (1) the upward wandering of worms, causing vomiting, penetration into gall duct and liver or perforation of bowel through a pre-existing ulcer, and (2) intestinal obstruction and abscesses in certain organs. Trichuris trichuria and strongyloides stercoralis are also common in Porto Rico.

Observations based on a three years' study of conditions on Guatemalan coffee plantations have revealed the following facts. The plantations occupy an intermediate temperate zone between 600-800 m. On the Atlantic side the kolono system is in force, that is to say, the labourers get land unsuitable for coffee growing to grow cereals in return for six to twelve days' work per month on the coffee plantations. Under this system conditions were found to be fairly favourable. Many plantations on the Pacific side, however, are not worked on this system, the labour-
ers working full time on the coffee plantations and living in hutments poorly supplied with water. Part of the labour required is imported from the higher land and the movement of population favours the spread of contagious diseases. Diet is poor and alcoholism prevalent. Pneumonia is rare and malaria unusual, but amaebic dysentery is widespread, sometimes sporadic and at others epidemic. A number of cases clinically T.B. were seen, but acid-fast bacilli could not be found and it was suggested that these cases were bronchomyocosis. The course of tuberculosis is one of months rather than years. Widespread alcoholism was found to cause hepatic cirrhosis, death from acute alcohol poisoning, pneumonia, and to give rise to bad dieting, bad housing and much social misery.

Cort, Riley and Payne investigated conditions at Porto Rico to determine the relation between coffee growing and the incidence of ankylostomiasis. Thanks to hygienic improvements and treatment it was found that infection after being extremely widespread amongst workers on coffee plantations has greatly diminished. The soil of these plantations offers an extremely favourable medium for the development of larvae, rain acting as a direct agent for propagation of eggs and larvae. Though living conditions of the coffee workers, unprovided with sanitary conveniences, contribute greatly to the spread of infection. Only by a well-organised scheme of prophylaxis can this disease be prevented from spreading. Trachoma was likewise found to be of frequent occurrence.

**STATISTICS**

Mortality rates on Guatemalan coffee plantations were distributed as follows: 22 per cent. from intestinal parasites, 22.5 per cent. from affections of the intestinal tract, 13 per cent. from affections of the respiratory system, 30 per cent. from acute infectious complaints, chiefly influenza; mortality from amaebic dysentery in an epidemic reached 6 per cent. In 1923 tuberculosis caused 7.7 per cent. of the hospital mortality and in 1924, 6 per cent. (For reference to prevalence of fatal accidents due to serpent and snake bites, see article "Native Labour").

**PATHOLOGY**

Coffee poisoning is widespread in all the coffee-drinking countries. As regards occupation it is most frequently met with amongst students, literary men, orators and the working classes (on the Continent), especially among women: cooks, charwomen, dressmakers and washerwomen, etc.

Nervous symptoms affecting coffee tasters should also be mentioned (see below under "Tea and Coffee Tasting").

**HYGIENE**

Prophylaxis in regard to these diseases which attack the workers in the coffee plantations must be along the lines of the application of certain general and special hygienic precautions (housing, anti-ankylostomiasis campaign, etc.) as already described in preceding articles, for instance "Agricultural Workers, Pathology of", "Ankylostomiasis", etc.

**Tea**

The following results have been revealed in an enquiry to ascertain proofs of health improvement following the adoption of hookworm control measures on Ceylon tea estates. Of 985 coolies examined 99.2 per cent. were found infected with helminthiasis. Carbon tetrachloride was administered to all on the estate and repeated after a year. Reinfection during the first year was to the extent of 20 per cent. of the average original infection and in two years rather less. In another investigation of coolies on Assam estates examination showed an incidence of 93.6 per cent. for hookworm infection. Napier and Foster have studied the incidence of Kala Azar amongst the coolies on the Indian tea plantations (1927).

**TEA AND COFFEE TASTING AND DRINKING**

Tea tasters sit at revolving tables with several samples of infused tea before them. These are sipped to determine the aroma. The taster then rinses his mouth and expectorates. Despite this, owing to continued tests, more or less of the beverage is swallowed and absorbed and may produce chronic intoxication symptoms varying with dosage and individual susceptibility, but mostly characterised by loss of appetite, gastric catarrh, flatulent dyspepsia, constipation, insomnia, irritability, restlessness, muscular trembling, gradual emaciation, and in some cases discoloration of the nails. People who over-indulge in tea or coffee suffer from similar symptoms.
Telluretted Hydrogen

Telluretted hydrogen (formula H₂Te) is a colourless gas with a nauseating smell, recalling somewhat sulphuretted hydrogen and arseniuretted hydrogen. Of high specific gravity it dissolves in water. The solution is relatively stable, but unstable in alcohol.

The gas itself easily becomes dissociated, precipitating tellurium in a black pulverulent form. It is very active chemically, very toxic as are tellurous and telluric acids, their anhydrides and salts.

Once inhaled the gas undergoes dissociation inside the body and tellurium is found in all parts deposited in the cells so that the organs look grey (see the article "Tellurium").

The symptoms of poisoning resemble those of seleniuretted hydrogen. Headache, malaise, weakness, vertigo, respiratory and cardiac symptoms come on after a few minutes after inhalation.

When there is no acute but only chronic poisoning the single symptom — and a very disagreeable one (present also in acute poisoning) — is a strong alliaceous smell of the breath and skin secretions. This symptom may persist for weeks after the poisoning is over (ten weeks in one case). According to Mylius, quoted by Egli-Rüst, absorption of one milligram of telluric acid, or manipulation merely resulting in re-absorption by the skin, suffices to bring on this symptom.

Egli-Rüst reports two cases of intoxication affecting chemists (Oppenheim, Wöhler) and two others in the course of melting spongy platinum derived from minerals containing tellurium.

According to Lewin, symptoms of poisoning have been observed in the course of therapeutic use of basic nitrates of bismuth containing tellurium. It requires only five ten-thousandths of a milligram of bioxide of tellurium to communicate to the breath the smell of garlic.

Tellurium

Chemical Properties

Tellurium (Te), discovered in 1782 and isolated as an element in 1798, was little known until recently, when it was found to be a constituent of the sludge deposited in the electrolytic cells in which copper is refined. This sludge is first treated to
recover the more precious metals, and the residue subsequently to obtain tellurium. It occurs free, in a crystalline state in small quantities in certain minerals, but is more frequently found combined with gold, silver, selenium, or iron. The chief sources of tellurium are tetradymite \((\text{Bi}, \text{Te})\) (bismuth sulpho-telluride); altaite \((\text{Pb}, \text{Te})\); coloradoite \((\text{Hg}, \text{Te})\); calaverite \((\text{Au}, \text{Te})\); sylvanite \((\text{Ag}, \text{Au}, \text{Te})\); petzite \((\text{Ag}, \text{Au}, \text{Te})\); and nagaugite \((\text{Au}, \text{Pb}, \text{Te})\) \((\text{Te} \cdot \text{S} \cdot \text{Sb})\). Native tellurium \((\text{Te}_2\text{O}_3)\) or tellurium ochre is also found. About 17 per cent of tellurium is extracted from the red sulphur of Japan.

Tellurium is a bluish-white, silver-like element with a metallic lustre, with atomic weight of 126.6. It melts at 452°C. When cooled from the molten state it forms hexagonal rhombohedral crystals; when heated in air it burns with a blue flame, forming tellurium oxide \((\text{TeO})\). Tellurium is not attacked by hydrochloric acid, but reacts readily with nitric and sulphuric acids and concentrated caustic potash. Its physical properties resemble those of the metals, but in its chemical properties it is decidedly non-metallic. It forms two oxygen acids: tellurous acid \((\text{H}_2\text{TeO}_3)\) and telluric acid \((\text{H}_2\text{TeO}_4)\), and a number of salts can be prepared from these acids (tellurates of sodium, potassium, cerium, mercury, zinc, copper, silver, etc.). Tellurides or alloys of the metals with tellurium can also be prepared. Halogen compounds (two chlorides, bromides, and iodides of tellurium) are known, as well as several organic compounds.

**Production**

Tellurium may be extracted from minerals or recovered from the sludge in metallurgical processes (electro-refining of copper, lead, and other metals). After recovery of the more valuable metals in electro-refining, the residue is subjected to repeated lixiviation with hydrochloric acid; it is then filtered, and the resultant bright yellow filtrate is treated with sulphur anydride to precipitate the tellurium. On driving off the hydrochloric acid by evaporation, additional precipitation occurs, and further precipitation still on addition of sodium bisulphite. Subsequent heating will cause another precipitation. It is obtained from bismuth telluride by mixing it in a finely powdered state with sodium carbonate; rubbing with oil to a stiff paste; calcining in a closed crucible; lixiviating with cold water, and blowing a current of cold air through the aqueous solution of the resultant sodium telluride, when the tellurium separates out as a grey powder.

**Uses in Industry**

Tellurium is not as yet used to any great extent in industry, but much research, with a view to more extensive application, is in progress. In the glass industry it is used to give a blue, red, or brown colour in glass. Owing to its reducing properties, tellurium has been experimentally utilised in the iron and steel industry in the same way as coke and has also been found useful in revealing the presence of bacterial life.

**Toxic Properties**

The possibility that tellurium might act as an industrial poison was first mooted in 1918 during an enquiry into lead-poisoning in an electrolytic lead refinery, when it was noted that the breath of all workers in a certain department smelt strongly of garlic, though none of them had eaten it. Many of them complained of a dry skin and arrest of perspiration. The symptoms in question could not be attributed to lead poisoning, and further investigation proved them to be confined to the workers who had been in contact with tellurium, in the silver refinery, working at the furnaces at very high temperatures (700 to 760°C.) and where there was exposure to the fumes and dust of tellurium. These fumes were probably in the form of hydrogen telluride, a compound analogous to hydrogen sulphide and arseniuretted hydrogen, and tellurium was also present in the furnace dust probably as oxide and telluride. Sodium telluride is one of the most powerful haemolytic poisons.

In animals small doses markedly reduce the secretion of acid in the gastric juice and stimulate secretion of gastro-intestinal mucus (this being apparently due to paralysis of the secretory nerve endings), while the capillaries of the splanchnic area are dilated. In acute cases there is vomiting, weakening of the reflexes, tremor, somnolence, and death from asphyxia in tonic and clonic convulsions. Before death, intense destruction of the red cells with diminution of the amount of haemoglobin, presence of myelocytes, normoblasts, and sometimes considerable leucocytosis. Large quantities of urobilin, together with haemoglochin, are usually detected in the urine, and in many instances a large quantity of some reducing substance; this is thought by some observers to be sugar and associated with hypoglycaemia and differing from ordinary glycosuria, while others deny that there is glycosuria. Post-mortem examination reveals disintegration of the mucus membrane of the gastro-intestinal tract; intestinal haemor-
rhages; also intense hyperaemia of the organs, and multiple haemorrhagic foci. Large doses produce some albuminuria due to parenchymatous nephritis. Certain authorities, however, are of opinion that there is no evidence of urobilin in the urine, a sign that the liver is functioning well, and this, they say, is borne out by histological findings which reveal but rarely lesions of this organ.

The main channels of entry into the system are the respiratory and alimentary tracts. Marvin Shie and Forrest Deeds believe that salts of tellurium are probably absorbed through the skin. This channel of entry is characteristic of tellurous acid, as, shortly after handling tellurous acid, the garlic-like odour of methyl telluride appears in the breath. A workman, who had collected with his fingers tellurous anhydride that had fallen into a vessel, absorbed sufficient of it to give the garlic-like smell to his breath for a week, and to have a bitter taste in his mouth for 48 hours. A single dose of 0.13 grm. of tellurous oxide, taken experimentally, has sufficed to impart the taste of garlic for two and a half months.

After entry into the system, salts of telluride are reduced to metallic tellurium, forming a methyl telluride which is very volatile, and gives a peculiar garlic-like odour to the secretions and excretions. This formation of methyl telluride is one of the rare cases in which a compound of methyl is formed in the animal body.

The greatest toxic effects are produced during the reduction of the salts. Elimination takes place in the faeces in metallic form; and in the exhaled breath, urine, faeces, and dermal secretions as methyl telluride; and in small quantities, in the bile and urine, in soluble form.

A minority of writers hold the view that tellurium is non-poisonous, but admit that its oxygen compounds, even in small quantities, form dimethyl-telluride in the human body, that they are slightly poisonous, and that hydrogen telluride changes immediately to black telluride when in contact with the moist mucous membrane and has a slight irritating action.

Despite the fairly mild symptoms recorded, the fact that these may have important secondary effects must not be lost sight of. The inhibition of the sweating function renders the persons engaged on furnace work and subjected to very high temperatures, especially in summer, very liable to heat exhaustion, and the inhibition of the secretion of saliva and other digestive juices is liable to bring about lasting digestive disturbances.

Statistics

No severe cases of poisoning have so far been reported. Of thirteen workers examined in a department bringing them into contact with tellurium, seven showed evidence of absorption. Five of these suffered from inhibition of the sweat function (the two who did not had only worked for two weeks). Three workers who had been employed only a short time had dry itching skin, anorexia, nausea, vomiting, depression, and somnolence; eight foreigners were unable to answer questions. Probably if an interpreter had been available symptoms of tellurism would have been discovered among the last mentioned. Mention should also be made of an experimenter who, after having been engaged in melting tellurium in the open air for several hours, slept for no less than 18 hours on end.

Symptoms

Up to the present, the early symptoms noted in man in acute poisoning, even after absorption of small doses, are garlic-like odour of breath and somnolence. Other symptoms are: garlic-like odour of the sweat and the faeces, dryness of mouth, nausea, vomiting, metallic taste, depression, constipation and diarrhoea, and suppression of the sweat functions. The skin becomes harsh and dry, and pruritus often results.

In cases of chronic poisoning the symptoms are retarded digestion, vomiting, loss of appetite, emaciation, and somnolence. Mild tellurism produces the same effects in man and in animals, and it may be expected that the more severe effects will also be similar (see above). Certain authors draw attention to the absence of jaundice as a symptom.

Diagnosis

Such after-effects resemble those produced by absorption of arsenic, antimony, selenium, and lead, and as these metals are almost always present with tellurium industrially, an exact determination of the source of these effects is rather difficult. Three symptoms, however, are distinctive of tellurism: suppression of sweat, dryness of mouth, and garlic-like odour of secretions. Ingestion of arsenic may give a garlic-like odour also, but much fainter than that produced by tellurium and requiring a very much larger dose to produce. Analysis of the urine and faeces may have to be resorted to in doubtful cases.
TESTS FOR PRESENCE OF TELLURIUM

Acid sodium sulphite indicates presence of tellurium in solutions containing as little as 0.00000004 grm. per cent. of tellurium. It is treated with hydrochloric acid with as little chlorine gas as possible, then heated to expel the chlorine. Acid sodium sulphite is added to the solution which is then filtered, leaving tellurium as a black precipitate on the filter paper. Tellurium heated on charcoal gives a white sublimate of tellurium which is volatile, and when in contact with a reducing flame imparts a pale greenish colour to it. If heated with concentrated sulphuric acid it gives a deep crimson colour to the solution, which disappears if the acid is too hot or is diluted with water after cooling.

HYGIENE

Measures of prevention are those generally to be adopted against metallic dusts and fumes: adequate natural and artificial ventilation, removal of fumes at the point at which they are produced, provision of respirators for men engaged in cleaning flues, adequate drinking and washing facilities; personal hygiene. Particular care should be observed in summer when the danger of heat exhaustion is greatest, and strict medical supervision of workers should be provided, with power to the surgeon to suspend from work on the appearance of early symptoms. No special measures have been adopted up to the present.

BIBLIOGRAPHY

Il Lavoro, 11th year, No. 7, 30 Nov. 1920, pp. 204-205. Milan.

Temperature (High and Low)

The temperature of the surroundings in which an individual lives or works exerts a very definite influence on the functions of that individual. These functional changes vary according as the temperature is very high or very low; but to establish the point at which the said influences begin to manifest themselves is not easy, for they are closely associated with other factors, and in particular with sharp variations of temperature, especially as related to the degree of humidity and movement of the air. It can, nevertheless, be asserted that the ideal temperature at which the body does not suffer in any of its functions is at 20° below that of the human body in its physiological state. Admitting that the temperature of the human body under normal conditions varies between 36.5° and 37° C. the optimum surrounding temperature will be between 16.5° and 17° C.

The body tolerates quite well for light occupations temperatures which depart to a certain extent from this point. This is not, however, possible, as has already been said, to fix the limits at which heat and cold begin to exercise a pathological effect, because, in addition to the factors already mentioned, such as sharp variations, the degree of the humidity and of ventilation, the resistance of the individual plays an important part, it being itself modified by pre-existing physical defects. Thus, all conditions being equal, patients suffering from arteriosclerosis, kidney or heart disease, or emphysema are more sensitive when the surrounding temperature departs from an optimum point which, as stated, varies between 16.5° and 17° C.

In order to understand changes in resistance to heat and cold some physiological facts must be recalled.

A man in good health has an internal heat of about 37° C. whatever the temperature of the external surroundings may be; this arises from his body possessing sources of heat production and methods for its elimination, together with a heat-regulating apparatus which ensures that the temperature of the body remains constant.

The production of heat is strictly related to nutrition and muscular activity.

Elimination of heat is carried out: through the skin, by means of irradiation and perspiration; through the lungs, by the process of heating up the inspired air and by the evaporation of water exhaled from the pulmonary surface; and through the digestive system, by means of warming drinks and food which have been consumed. Of these three methods of elimination of heat, the most important is without doubt that of the skin, which by itself eliminates 90 per cent. of the heat produced.
The heat-regulating apparatus is formed by the nervous system and chiefly the vaso-motor nervous system, which causes dilatation or constriction of the capillary vessels, ensuring, in the first case, the loss, and, in the second, the maintenance of heat. This last-mentioned mechanism explains why not only heat and cold but also sudden variations of temperature can cause disease.

Thus, when the surrounding temperature, whether hot or cold, is not uniform, but varies frequently and greatly, the cutaneous vessels, as a result of alternative constrictions and dilatations, undergo changes in their structure, and early arteriosclerosis results. The artery which is the most sensitive is the aorta, which in the process of sclerosing becomes uniformly thickened and elongated, occasioning subjective conditions especially associated with aortic sclerosis.

**INJURIES CAUSED BY HEAT**

Hot air causes two striking phenomena: vaso-motor paralysis and stimulation of the sweat centres, phenomena which are independent one of the other, the first being controlled by the vaso-motor nerves and the second by the excretory nerves of the sudoriparous glands.

In a state of rest, droplets of sweat are not usually formed on the skin under 33° C.; perspiration is carried on imperceptibly. When the external temperature exceeds 33°, perspiration becomes evident and takes the form of sweating which increases with the rise of temperature. As long as the secretion of sweat is moderate, the secreted water evaporates on the surface of the skin, which remains dry (perspiration insensibils); but, when the secretion increases, or, if evaporation is prevented because the surrounding conditions present a high degree of humidity, then the sweat appears on the surface of the skin in the form of little drops, which become united to form larger drops and run down on account of their weight along the skin or are absorbed by the clothing (perspiration sensibils).

Dilatation of the vessels with cutaneous perspiration tends to cool the body, either by increasing the irradiation of the heat, or by increasing the evaporation of the sweat.

If the surroundings are not only warm, but in addition dry, irradiation of heat and evaporation are facilitated and the body is relieved. But when the heat is at the same time moist, phenomena occur to which it is necessary to refer in further detail.

Hot dry air gives rise, by copious sweating, to a considerable loss of materials, especially of water, by the cutaneous path.

Extensive elimination of water through the skin reduces the volume of the blood, by the withdrawal of fluid from the blood and tissues, and, especially, from the subcutaneous cellular tissue, which causes a wrinkled skin. For want of water, intracellular fermentations are attenuated and the anabolic and katabolic functions of intermediary exchanges are altered, with harm to the general condition and loss of vitality.

The blood becomes thickened, and as its viscosity increases it offers an increased resistance to the cardiac systole. The left ventricle dilates and becomes hypertrophied; but, soon after, the myocardium, in consequence of insufficient nutrition, undergoes degeneration which leads to defects in compensation; the condition manifests itself by fatigue, distress, malaise, increased frequency of the pulse and respiration, lowering of the arterial pressure, a feeling of constriction in the epigastric region and oedema at the ankles.

The figured elements of the blood undergo degeneration as a reaction to high temperature. An acceleration in the haemoglobin changes can be observed, and, as the red corpuscles are not regenerated with sufficient quickness, a slight anaemia is set up. The phagocyctic power of the white corpuscles is weakened, which leads to the body being liable to constant infections.

The elimination of fluids through the skin does not sweep away to the necessary degree such products of intermediary exchange as urea, nitrogen and salts, which in consequence accumulate in the body. Thus is produced not only a relative increase of these products, in consequence of diminution in the watery volume, but also an absolute increase which is not compensated by the action of the kidneys. This latter, for its part, is disturbed by reason of the strong concentration of the products in question, which leads to lesions of the renal tubules, the cells of which undergo degenerative processes and prepare the way for nephrosis. All of which leads to auto-intoxication of the body with a diminution of the alkaline reserve, whence arises general malaise, a dulling of the sensory organs, headache, precipitation of the salts in the tissues, with vague and scattered pains, and
oliguria, with thick urine and painful micturition.

The explanation of the dyspnoea which is observed is to be found not only in cardiac insufficiency, but also in excitability of the respiratory centre; thus the body tends, by increased ventilation, to favour the loss of heat. Notwithstanding, a reduction in the volume of blood is produced, an urgent need to take in large quantities of fluid is felt. If this sensation of thirst is satisfied, several evils are reduced, but others remain.

The consumption of large quantities of fluids and their rapid elimination causes sudden disturbances of the arterial pressure which acts on the structure of the vascular tissue and leads to arteriosclerosis. The continual flow of large quantities of water through the system dilutes the juices of the body and the secretions of the glands of organs, leading to a slowing of fermentative actions; the glands of the stomach and the intracellular ferments are seriously affected; hence dyspeptic symptoms follow with poor assimilation of nourishment, and, in consequence, bodily wasting.

If the surroundings are not only warm, but also humid, other pathological phenomena occur of a different kind from those enumerated above. The warm-humid surroundings prevent the evaporation of sweat from the surface of the body and of moisture exhaled from the pulmonary surface; it presents an obstacle to the conduction of heat from the body to the surrounding air, and in consequence it interferes with the two means of loss of heat by way of the skin and the lungs, i.e. irradiation and evaporation.

Under these conditions, overheating of the body may occur and give rise to the morbid phenomena which are characteristic of heat stroke.

Heat stroke, in its mildest forms, is characterised by fatigue, malaise, a sensation of internal heat, burning thirst, a desire for acidulated drinks, dryness of the tongue, anorexia and headache. The skin is dry; sometimes there is fever, a headache. As a rule the whole of the symptoms disappear in between twenty-four and forty-eight hours after a refreshing sleep. But the symptoms may become so aggravated as to produce painful precordial oppression, with dyspnoea, cloudiness of the vision, tinnitus in the ears, vertigo, a tendency to sleep, delirium, and small and frequent pulse. The body may recover from this condition; but death may also occur after a few hours.

A very serious form of heat stroke has been described: the cardiac or syncopal form. The victim falls suddenly to the ground, with a small frequent pulse, and suddenly passes into coma, from which he does not recover. The skin is dry, the face congested and the temperature raised. The coma may be interrupted by convulsions. An asphyxial form is very similar to this cardiac, as a reduction in the volume of blood is produced, an urgent need to take in large quantities of fluid is felt. If this sensation of thirst is satisfied, several evils are reduced, but others remain.

Low temperatures may cause local and general damage.

Local troubles are represented by frost-bites, which will not be referred to here (see article "Skin (Diseases of)", section on Effects of Heat and Cold).

The general damage caused by cold, and, especially, by damp cold, is represented by what are called chills and by diseases due to chills.

In chilling of the body, the same means for controlling the body heat are in action, but with diminution in their function; the ones most often brought into play are the paths of elimination, of which the cutaneous path is the most frequent. The nervous system endeavours to prevent chilling by causing a cutaneous vaso-constriction. In this case the peripheral circulation is reduced to its lowest degree, and the blood flows towards the interior, causing congestion of the viscera. In this way, due to the effect of cold on the skin, cerebral and pulmonary congestions may be produced. But, if the cutaneous vaso-constriction does not occur, or, even if it does, and the loss of heat be great, there may be chilling.

Several forms of chilling are recognised: simple chilling and sudden collapse from cold. The first is characterised by pallor of the skin and constriction of the capillaries. The blood flows towards the deep organs. The body concentrates all its forces to oppose the loss of heat. Shivering and trembling occur, wherein the muscular system reacts with fibrillary contractions intended to light up the body combustion. Reaction may occur at this period, but, if the effects of cold progress, then follows what is a sudden attack by cold.

Sudden attack by cold or cold apoplexy is due to the effect of intense cold. Fatigue, privations, malaise, and immobility favour its occurrence. Cold apoplexy begins when symptoms appear which result from exhaustion.
and paralysis of the different systems. It is characterised by a sensation of fatigue, debility, by painful sensations in the limbs, the head and chest; by lowering of the general temperature, and rigidity and freezing of the extremities. Breathing, at first frequent, becomes slow and deep; the pulse, which was frequent, becomes slow and thready. Stimulation of the central nervous system lessens; the individual feels an urgent desire to sleep, and finally, overcome by the cold, falls into an irresistible sleep, which is the prelude of approaching death.

The anatomical changes consist in hyperaemia of the brain and the internal organs, especially of the heart, and in pleural and pulmonary haemorrhages.

Treatment consists in gentle centripetal massage with vaseline, and in gradual and slow re-warming of the body. This objective can be easily attained by putting the victim into a bath at the temperature of the room, and gradually warming the water up to 30°C., during two to three hours. As soon as the peripheral circulation responds, recourse may be had to injections of cardiac stimulants, and, if necessary, to artificial respiration.

Diseases from chilling include a series of morbid processes of different etiology, such as: inflammations of the air passages, including rhinitis, angina, bronchitis and pneumonia; inflammations of certain serous membranes, including pleurisy and arthritis; inflammation of the muscles, including rheumatism and myositis; of the nerves, comprising the neurites; and of the kidneys, e.g. glomerulo-nephritis.

Bassi in 1931 called attention to the frequency of renal lesions among persons employed in occupations where the temperature is low.

It has been shown that chilling encourages the onset and development of infection by diplococci, by viridans streptococci, and in general the development and evolution of infections, through a reduction of the defensive powers of the body owing to a diminution in the number of leucocytes, with attenuation in their phagocytic activity resulting in smaller production of antitoxins, bacteriolysins, agglutinins and opsonins.

As regards pneumonia a frigore, Galeotti and his pupils hold that there is a correlation between cutaneous vaso-motor phenomena and pulmonary, in that a pulmonary vaso-constriction appears to correspond to a cutaneous vaso-constriction. This fortieth sets up changes in cellular metabolism and in the morphological constitution of the tissues; whence resistance to bacterial invasion is diminished or even phagocytosis is slowed down with retardation in diapedesis.

Pulmonary vaso-constriction is followed by a paralytic dilatation of the vessels, leading to passive hyperaemia. The interstitial transudate which thus arises is a very favourable culture medium for infectious germs.

Some lesions caused by cold have been explained by action at a distance, such as may be instigated by a thorough chilling. Thus Rossbach has shown that the application of ice to the abdomen of a cat is immediately followed by vascular cramp of the trachea; followed after a few minutes by hyperaemia with transudation of fluid which favours the inoculation of germs. In this way is explained the origin of some cases of tracheitis, rhinitis, tophilitis and glomerulo-nephritis, due to cold. In the case of the last mentioned, the cutaneous vaso-constriction is accompanied by constriction of the afferent vessels of the glomeruli, with, in consequence, ischaemia and gangrene of the renal parenchyma, anuria and glomerulo-nephritis.

All that has been stated emphasises the important part played by cold in the genesis of certain morbid conditions.

Whilst heat, either dry or humid, and cold are capable of producing functional changes and true pathological states, it is easily understood that they can render work difficult and even arrest it. In order to weaken the effect of these physical agents, recourse may be had to certain correcting measures.

In the case of heat, suitable ventilation is useful; movement of air without doubt brings a certain relief, which is greater if the movement introduces cooler air into the atmosphere. It is, however, important for the cooling of the air to take place in such a way that the workers are not inconvenienced by draughts. If that should occur, it may cause ill-effects greater than those caused by the heat.

It should, in consequence, be recommended that passing from hot surroundings to cold surroundings should not be done suddenly; in such cases, what are called passage rooms may be recommended, in which the workman can become accustomed gradually to changes of temperature.

In order to prevent the effects of cold, good food is a first necessity: it should include, in a large measure, the foods containing energy or calories,
such as fats and carbohydrates; in this way the production of heat is encouraged. It is also necessary that a man should gradually become accustomed to low temperatures; the body can thus adapt itself, when it feels the ill-effects less. The wearing of clothes which are bad conductors of heat, made of wool, for example, should also be advised. Wherever it is possible, efforts should be made to heat the workrooms; always bearing in mind that the temperature should not descend below 10°C. for work which requires active movements and below 14°C. for sedentary work.

**LEGISLATION**

For the legal measures concerning the temperature of workplaces, see article "Industrial Hygiene (Workshops)". In addition, in France, the Decree of 28 September 1913, dealing with special measures controlling booths outside shops and stores, lays down that in case of cold sufficient means of warming must be arranged for the employees inside the premises. The stables must be provided with pent-roofs or other means for protecting the employees who are working there against inclement weather. A Decree of 21 June 1913 prohibits the employment of young persons and of young girls under sixteen years; boys of from fourteen to eighteen years and girls of from sixteen to eighteen years can only be employed six hours a day with breaks; young persons under eighteen years and women of any age may be employed only up to 8 o'clock in the evening. When the temperature is below 0°C. the employment of young persons and women of any age is forbidden.

As regards compensation for certain ill effects caused by heat and cold, see article "Occupational Diseases: Definition and Compensation".

**Tetanus**

Tetanus is an acute infectious disease caused by the anaerobic bacillus, the *Clostridium tetani*, which has the property of producing toxins having an elective action on the nervous centres and giving rise to muscular contractions which form the symptoms of the disease.

In most cases tetanus is a complication of wounds, whence the expression "traumatic tetanus".

The *Clostridium tetani* bacillus is a rod-shaped, anaerobic bacillus forming the tetanus bacillus. The *Clostridium tetani* bacillus takes the form of a very slender, mobile rod having in the majority of cases at one of its extremities a bright sphere in which spore reactions occur; this is the tetanus spore. This conformation gives to the bacillus the appearance of a drumstick. The unsporulated bacillus is of feeble resistance. It is the spore which constitutes the propagation agent in the tetanus. The anaerobic bacillus is pathogenic for man and the domestic animals, especially the horse. It becomes lodged at the point of contagion, but it acts at a distant point therefrom by the intermediary of a very active toxin which becomes fixed in the nervous centres, giving rise to violent stimulation of the motor cells, whence occur permanent muscular contractions, with redoubled paroxysms which are characteristic of the tetanus attack.

This symptom complex can only develop when a certain amount of the toxin has been produced in the system. It is necessary for this that the bacillus becomes lodged in the body and multiplies. This moreover takes place, in general, to a limited extent.

This is what occurs in the case of wounds infected simultaneously by *anaerobic* germs (for instance, *staphylococci*) which, by consuming oxygen, create around the tetanus germs, which have arrived in the wounds in the form of spores, a sufficiently anaerobic medium. Wounds contused by tearing or crushing, with consequent attrition of the tissues, mortification or deep-seated lacerated wounds, open fractures in the presence of foreign bodies, particularly those of a porous nature which contribute to creating anaerobic conditions, prevent phagocytosis and increase the likelihood of tetanus infection.

The *toxin* possesses the general characteristic of toxins that is to say, when inoculated into animals with requisite proportions and by repeated doses in order to avoid killing the animal, but with the intention, on the other hand, of conferring on it progressive immunity, it causes to appear in the blood an anti-toxin capable of neutralising the toxin even in *vitro* and in *vivo*. It is this anti-toxin, such as it is found in the blood serum of immunised animals, which is largely employed in therapeutic treatment, and with excellent results in the serotherapeutic treatment of tetanus.

The tetanus bacillus in the form of highly resistant spores exists outside,
especially in the cultivated ground of
manured or rather filthy fields and
gardens in the country; likewise in the
dust and mud of roads or routes, and
in the mud of rivers and ponds, etc.
Finally, spores are everywhere through animal excre-
ment, and in particular that of the her-
ivorous animals. The spore introduced
into the intestine of these animals
would appear to find favourable con-
ditions for propagation. Herbivorous
animals therefore constitute agents of
propagation and dissemination of these
germs, whilst the ground only serves
as a depot for their conservation.
This explains the very high tetanus-
infesting capacity of manure heaps
and manured ground, as well as the
quite particular incidence of tetanus
amongst peasants, stable-boys, more
especially when they are in the habit
of walking barefoot, and in general
amongst those workers likely to receive
wounds from tools soiled with dust or
earth from the manure heaps.
In addition to agricultural workers
and peasants, tetanus of occupational
origin has been reported amongst
workers in slaughter houses, knack-
ers' yards, and amongst workers en-
aged in tinning food products, sorters
of bones, horns and hoofs (Koberl), rope-
makers (Oliver), laundresses (Oliver: 2
cases), paper, rag and metal sorters
(in a depot for factory refuse: Hay-
hurst); in jute manufacture (Legge),
and amongst Hungarian pottery work-
ers. On the contrary, no case of
tetanus occurring in mines is known,
despite the fact that horses and mules
are used in these.
Besides cases of occupational tetanus,
mention should be made of tetanus
occurring amongst the wounded during
warfare. The danger from tetanus
is well known in the case of war
wounds, and certain battlefields would
appear to have been particularly
favourable to the outbreak of extensive
epidemics. Tetanus may again occur
subsequent to delivery or miscarriage
through infection of the umbilical
wound (tetanus neo-natorum), or as a
consequence of surgical treatment (cat-
gut, haemostatic gelatine, etc.),
or serum injections. In civilised coun-
tries, however, these forms of tetanus
are of increasingly rare occurrence.
The negro races, Hindus and Malays
appear to be particularly sensitive to
tetanus. There exists in general a
fairly marked predisposition amongst
the inhabitants of hot countries (pri-
mitive habits, ignorance and rudimen-
tary ideas of hygiene), who are
in the habit of walking barefoot and
live in damp huts made of mud. etc.
The incubation period for tetanus in
man varies in accordance with circum-
stances from two to fourteen days. It
may even on occasion be longer for
retarded tetanus; the cases in question
are relatively uncommonly immu-
ised subjects in whom the outbreak
of the disease is provoked by some
special cause (chill, traumatism, etc.)
which diminishes the organic resistance
and enables the germs to get the upper
hand, to multiply and thereafter cause
infection. Cases of this type were
formerly designated "rheumatic tetan-
us" in the absence of satisfactory
explanations of the mechanism of in-
fec tion.
In certain cases, symptoms of in-
vasion of the system and of the disease
itself are preceded by premonitory
local or general phenomena. Tetanus
is characterised by permanent contrac-
tions which affect particularly the
muscles of the jaw (hence trismus), the
muscles of the back of the neck and of
the back (hence opisthotonos). These
contractions finally spread to the
muscles of the face (tetanic mask,
sardonic grin) and at times to those of
the tongue, pharynx, larynx, the trunk
and the vertebral column. In certain
cases the patient only touches his bed
with his head and sacrum, the back
being bent in the form of an arc. The
contractions which
affect the muscles of the hand and the forearm,
include the diaphragm.
The duration of the illness
may vary from some hours to some
weeks. Death may be due to a spasm
of the glottis, to sudden syncope,
paralysis of the heart, or permanent
contraction of the diaphragm.
The patient may however recover, even in
very serious cases. Where the disease
runs a long course, it may often be
followed by respiratory trouble (bron-
chitis, broncho-pneumonia or pneumo-
nia ab ingestis, etc.).
Clinical diagnosis should be con-
firmed by bacteriological research: re-
search for tetanic bacillus in the secre-
tions from the initial wound, and
when the germ has passed the point
of inoculation in the system, research
should be effected with a view to
finding it in the blood or in the spinal fluid
(cultures, inoculation of animals, de-
monstration of the tetanic toxin in the
blood or in the spinal fluid of the
patient).
Prophylactic measures comprise adequate treatment of all wounds, even the slightest, and the preventive injection of anti-tetanus serum as soon as there exists any suspicion of contamination of the wound by tetanus-infected material. Serum injected opportune is most effective and Ottolenghi is of the opinion that the use of this prophylactic agent is not sufficiently recommended in all cases of suspected wounds. Once the tetanus outbreak has occurred, the effect of the serum is much less certain and the probability of recovery much more doubtful.

Tetanus is subject to compulsory notification in the Netherlands when it affects farm workers, butchers, rag sorters, workers engaged in demolition work, those engaged in the manufacture of animal black, paper and cardboard, as well as cobblers, navvies and gardeners. Victims are entitled to compulsory compensation in Brazil (farm workers), in Chile, Illinois, Mexico (grooms, butchers, stable-boys and workers looking after animals), in Queensland (hospital staff) and the U.S.S.R. (workers engaged in cultivation, forestry and digging foundations).

**Prof. D. Ottolenghi**
(Bologna).

### Tetrachloretane
(or Acetylene Tetrachloride)

French: *Ethane tétrachloré*, or *Tétrachloréthane*, or *Tétrachloruré d'éthane*, or *d'acétylène* — German: *Tetrachloräthan*. — Italian and Spanish: *Tetrachloretano*.

#### CHEMISTRY

Tetrachloretane is a halogen derivative of the homologues of methane, of which the formula is $\text{CHCl}_2$, $\text{CHCl}_3$; it has a boiling point (without decomposing) of between 142° and 147° C. and a specific gravity of 1.58. It is a yellowish liquid, with a smell recalling that of chloroform, non-inflammable, soluble with difficulty in water, slightly volatile, and non-explosive. It is a powerful solvent of organic matters in general and of acetate of cellulose in particular. It is acid resistant. It can be mixed with nitric acid even at a high temperature and under strong pressure.

#### Manufacture

Tetrachloretane was manufactured for the first time in large quantities with a view to technical use in 1903 and placed on the market in 1907 (in Austria) as a solvent of fats and resins. It is obtained by passing acetylene over antimony pentachloride. The acetylene is absorbed and a special compound is formed, into which chlorine is introduced. Each molecule of acetylene fixes four atoms of chlorine and the tetrachloride is formed, and then, again, the pentachloride of antimony. Nowadays it is preferable to combine chlorine and acetylene directly, using antimony chloride as a catalyst. Many processes of manufacture are in use which allow the two gases to combine without risk of explosion.

#### Uses

In the chemical industry for the manufacture of other chlorine derivatives of carbon; boiled with lime and water tetrachloretane loses HCl and yields trichloretylene $\text{CCl}_3$, $\text{CHCl}_3$; on treating tetrachloretane in suspension in water with powdered zinc, a rise of temperature occurs and pure dichloretylene $\text{CHCl}_2=\text{CHCl}$ is distilled; it is used for the extraction of fats or of certain alkaloids (quinine, cocaine), as a solvent of sulphur, acetate of cellulose, or rubber, nitrocellulose or viscose (artificial silk), etc.

It is used in the colour industries, in varnishes and lacquers. During the war it was used as a solvent for cellulose acetate to cover aeroplane wings ("doping"). These varnishes were made up of a solution of acetate of cellulose, tetrachloretane, acetone, benzene, methyl alcohol and amyl acetate. The proportion of tetrachloretane in some solutions reached 60 per cent., in others 35-35. Aeroplane wings vary from 6 to 10 m. in length.

---

1 The following is the list of chlorine derivatives of carbon which can be utilised as solvents in industry; stated in order of their relative toxicity as compared with carbon tetrachloride, according to Lehmann, 1911:

---
and from 1.80 to 3 m. in width, so that the evaporating surface was great. Four to six coats of varnish were applied, and each was allowed to dry before applying the next. Usually two workmen were employed simultaneously, opposite one another.

Tetrachlorethane is still used in the manufacture of enamels, for cleaning pictures, inking rollers for lithographic plates, for the manufacture of films, artificial pearls (see that article), gas masks (as a solvent of acetate of cellulose used to join the transparent sheets of so-called mica, but really acetate of cellulose and in the manufacture of certain "cements" (e.g. for shoes). As it is not explosive, tetrachlorethane is often used instead of carbon bi-suiphide, petrol and benzene. See also article "Pearls (Artificial)."

TOXICITY

For some time it was thought that this substance and solutions containing it were not toxic, but produced temporary narcotic effects like those of chloroform. While, however, the latter had only rarely given rise to symptoms of jaundice, tetrachlorethane induced several such cases. Laboratory experiments (on white rats) served to reproduce the same clinical picture as was found in man (jaundice, fatty degeneration of the liver, etc.). Poisoning is brought about by inhalation of the vapour, and the danger is by so much the greater as its action is slow and its smell pleasant. The worker, therefore, is not sufficiently on his guard. The vapour of this substance is four times as toxic as that of chloroform and the most toxic of the series.

According to experience in England, the organs found most affected are the kidneys and liver. The lesions resemble those set up by T.N.T. without the changes in the blood, such as are set up by nitro-derivatives of benzene and its homologues. The toxic jaundice is of hemo-hepatic character, an obstructive jaundice due to inflammation of the intrahepatic biliary canaliculi as a consequence of direct action of the poison on the hepatic cell. It resembles delayed chloroform poisoning in causing jaundice, and fatty degeneration of the liver, the latter being greatly reduced in size. The kidneys and heart are markedly affected. In severe cases, fatty degeneration affects the muscles also.

Individual susceptibility is very variable. Workers who have had slight attacks and return to work are specially susceptible. A second attack often develops rapidly, terminating in death.

Lehmann gives the following figures as the dose of tetrachlorethane necessary for narcotising cats (these are figures per litre of air): 30-60 mgr. during 5-10 minutes narcosis; about 10 mgr. during 30-60 minutes, narcosis with convulsions; 5 mgr. during 30-60 minutes, no effect.

STATISTICS

France.—During the war, at least 12 fatal cases came to light in the aeroplane and gas mask industry. Probably the number that really occurred was much larger. Recently, cases have been reported in the making of artificial pearls (see that article).

Since 1915, the French Government has prohibited the use of varnishes and dopes containing tetrachlorethane either on account of the symptoms produced or of the technical disadvantages of the substance.

Germany.—In 1913, 10 severe cases of jaundice were reported in Prussia from use of Aviatol and one affecting a saddler who used solution of acetate of cellulose in tetrachlorethane as a cement. In 1914, at Tettow, 15 cases occurred of which several were severe and two fatal; the dope contained 40-60 per cent. (Aviatol, Quitiners, Emaillite). In the early part of 1914, in spite of close regulation, 10 cases with one death occurred in Prussia and from that time its use was prohibited. In Bavaria, similarly, 9 cases with one death were reported from the same cause.

Great Britain.—In 1914, 25 cases, of which 4 were fatal, came to light. According to the report of the Medical Inspector of Factories, up to September 1916, 70 cases of toxic jaundice had been reported, of which 12 proved fatal, besides many slighter cases of illness. In 1917, use of tetrachlorethane was replaced by a solution containing ketones, and benzene, after which only a few cases of jaundice were reported.

Netherlands.—Poisoning was not reported; notwithstanding, the use of Emaillite (generally of German and sometimes of
English origin) caused cases of poisoning in 1915. Analysis showed that the former contained 5-10 per cent. of carbohydrate and tetrachlorethane, and the latter 50-60 per cent. and chloroform as well. Use of the material was prohibited.

United States. — Enquiries by Hamilton in 13 aeroplane factories (in 1917-1918) did not bring to light evidence of occurrence of severe cases of poisoning. According to Lister Roos and R. Bell, however, of 52 persons engaged in doping aeroplane wings, 35 suffered from slight trouble of whom 2 had jaundice and 26 nervous and gastro-intestinal symptoms.

Symptoms

In practice, the clinical picture varies a good deal from one individual to another. Early signs are abnormal fatigue, sweating, loss of appetite, general malaise, somnolence, vertigo, nausea, abdominal pains, nasty taste in the mouth, constipation.

After some days or weeks, jaundice appears with headache and vomiting. The jaundice is more or less marked (skin, conjunctivae) with or without toxaemia. In severe cases, insomnia, stupor, delirium, convulsions and coma are prominent. Petechiae are not uncommon as well as haematemesis and anuria.

Among workers in artificial pearl factories (see that article), peripheral nervous symptoms have been reported.

Blood. — According to Minot and Smith of Boston (1922), the blood may show, even in the absence of clinical symptoms, characteristic changes (large mononuclears up to 12 and even 40 per cent. and more in cases of definite poisoning; increase in the platelets; slight diminution in the number of the red blood corpuscles).

Manipulation of the varnishes, dopes, etc., containing tetrachlorethane has set up eczema, especially of the fingers.

Diagnosis

This should be effected as early as possible, so as to remove the worker from the serious consequences of the poisoning. The history of the case is of the greatest importance.

Detection

The smell in a proportion of as little as 1 mgr. per litre is perceptible (like that of chloroform but more pungent) and such air may be held to be suspicious. To demonstrate the substance, allow air to be bubbled through an alcoholic solution of potash and test for the chlorine set free after a time. Examination of the viscera is work for the toxicologist.

Hygiene

As the vapour is heavy (six times that of air) it is of first importance that the system of ventilation should be by downward extraction. If localised ventilation is impracticable, the fumes should be removed by fans placed at the level of the floor. If it is not well planned, the condition may be made worse. During the war, before the use of tetrachlorethane for the doping of aeroplanes was abolished in Great Britain, 20 to 30 changes of the air of the room were required per hour, which did much to lessen incidence of poisoning. Rooms should be ventilated in such a way as to prevent perception of the smell, or permit not more than 0.001 grm. per litre (Kohn Abrest). Vapour even of mixtures containing tetrachlorethane should be prevented from escaping into the room, as serious illness may be caused to the workpeople thereby. Doping should be done in rooms set apart for the purpose, and equipped with the necessary means for preventing inhalation of the vapour, etc. A less solvent toxic should be substituted for tetrachlorethane in all "cements" or mastics.

All persons exposed to the fumes should be examined before employment and periodically afterwards. Individuals who are subject to gastric trouble (especially of the liver) should be rigorously excluded and all those showing the earliest symptoms transferred to other employment.

Legislation

A special Order concerning the use of tetrachlorethane was promulgated in Prussia on 30 April 1920. Notification of toxic jaundice was made compulsory in Great Britain in 1915 and also in the Netherlands and in the States of Minnesota and New York. Poisoning by tetrachlorethane is compensated in France, Great Britain, Switzerland, United States (Ohio) and Venezuela.

Tetra-Ethyl Lead

TECHNICAL DATA

Tetra-ethyl lead (Pb(C₂H₅)₄) is a colourless, clear liquid, specific gravity 1.62 at 15° C, boiling at 200° C, oily, with a sweetish odour, volatile at ordinary temperature, insoluble in hot or cold water, soluble in alcohol and acetone, miscible with fats and oils. When exposed to sunlight or evaporation it decomposes and one of the products of decomposition is triethyl lead. This is often found in crude tetra-ethyl lead or in old containers (Kehoe).

The product in question, though known since 1854, was not for a long time applied industrially. Recently it has found technical application, being used to eliminate the "knock" or detonation in internal-combustion engines, and it was its extreme toxicity, as noted in the course of its manufacture for this purpose, which drew the attention of scientists to this product.

Modern technical tendency has been towards the manufacture of smaller and less expensive motors, but having a higher compression rate with a view to increasing their efficiency. Commercial petrol as regards compression hardly permits of exceeding about 4.5 to 5 kg. per sq. cm.; above this limit the combustion is explosive and the motor knocks. Therefore, the addition of organo-metallic compounds soluble in the petrol, which would permit of a distinct increase above this limit, was proposed. The products which were suggested for this purpose are known under the name of "anti-detonants". It is claimed that they possess the property of retarding detonation and attenuating the over-violent shock to the walls of the cylinders and the piston head.

Generally, phenylated or methylated compounds, etc., as well as compounds of selenium, tellurium, arsenic, antimony, tin, and lead possess the properties in question. Yet all the products suggested as anti-detonants have co-efficients inferior to tetra-ethyl lead which, according to the experiments of Midgley, exerts a marked action in suppressing detonation in the proportion of one in 200,000 molecules of a combustible mixture of lamp petrol with air. The most effective products besides tetra-ethyl lead are diphenyl lead, dimethyl lead and diethyl lead, diiodised lead and dichlorated lead (see below).

The manufacture of tetra-ethyl lead involves difficult operations from the point of view of technical chemistry. The principle followed consists in making an alloy of lead sodium react on ethyl bromide in presence of a reducing agent and a catalyst. The product obtained is distilled and condensed. The process may be effected starting with a magnesium ethyl iodide on which lead chloride is made to react.

As reducing agent may be used silicon or ferrosilicon in presence of water or soda lye, etc. As catalyst may be utilised those generally used in the Gignard reaction such as: the ethers and primary, secondary and tertiary amines, aniline diethylarsine, toluidine, diphenyl amine, pyridine (the most frequently used), carbazol, etc.

Tetra-ethyl lead is placed on the market in the form of an "ethyl fluid", that is to say, a mixture of 60 to 75 per cent. of lead tetra with a solvent (at first carbon tetra-chloride was used, but now there is used chiefly an alkyl-halogen, mainly trichloroethylene or ethyl-dibromide, which are likewise poisonous). The solvents proposed for use in anti-detonants are pure alcohol, pure ether, benzene, xylene, etc., and they are used with the intention of facilitating the elimination of the lead after combustion. The ethyl fluid is added to the petrol in the proportion of 1 to 1,000 or 1,400.

The role of the tetra is to decompose, leaving tiny drops of metallic lead which are deposited in the accumulations of dust and on the salient parts of the motor, diminishing their catalytic capacity. According to other experts it acts by diminishing the degree of ionisation of the mixture. The tetra is held to constitute in some way a negative catalyst.

TOXICITY

The effect on the skin is corrosive and necrotic only after prolonged contact, as determined by experiments on animals.

The systemic effect closely resembles the action of triethyl and trimethyl lead as determined by Harnack in 1878 and confirmed by Mason in 1921. The most important features shown in these experiments are: a stimulating action on the central nervous system, mainly the medulla and medulla oblongata, a marked stimulation of the central motor nerve mechanism, evidenced by trembling, twitching, and, finally, con-
vulsions, but without loss of consciousness; an extreme fall of blood pressure, apparently central in origin, for it fails in pithed animals; changes in the respiration, which at first is stopped, and then accelerated and deepened; slowing of the pulse, and increased peristalsis with colic and diarrhoea.

Eldridge, of the United States Chemical Warfare Service, tested tetra-ethyl lead on animals. His findings are as follows: Experiments on six dogs showed that application of tetra-ethyl lead to the shaved skin of the abdomen resulted in a direct action on the intestinal tract, characterised by acute lead colic, followed by diarrhoea, the abdomen tense and painful to pressure; then depression, difficulty in getting up on the legs, tremors, coma, convulsions; and death. The lethal point for dogs by skin absorption was found to be 0.3 c.c. per kilogram of body weight. Death followed in four dogs after from 24 to 180 hours, two recovering. In 11 guinea-pigs the lethal amount was determined to be 0.6 c.c. per kilogram of weight, and death occurred in from 12 to 16 hours. Three of this group recovered. The symptoms were similar to those in the dogs.

Inhalation experiments were made on mice, five animals being used for each of ten concentrations of tetra-ethyl lead. The exposure lasted ten minutes, and during this time the mice showed activity, followed, after removal from the test chamber, by marked excitement, then depression, collapse, trembling, convulsions and death. The lethal dose averaged 5.11 mg. per litre of air.

To determine possible cumulative effects, a 4.08 kg. dog was chosen, and applications of 0.1 c.c. were made to his skin once a day. After the 12th application the dog became depressed and nervous, and increasingly so until the 18th, when he became unsteady on his feet and trembled. He died 40 minutes after the 21st application. The cumulative action was also tested on mice, by inhalation experiments, exposing ten of them to 0.05 mg. per litre of air for ten minutes a day. Five died, on the 14th to the 20th days.

Necropsies on the dogs dying with acute poisoning showed an acute inflammation of the small and large intestines, with numerous ulcers from 1 to 1.5 cm. in diameter, clean and punched out, with a smooth base. These were chiefly in the region of Peyer's patches, which were swollen and protruding, and with a similar ulcer near the pyloric end of the stomach; one had no lesions in the intestinal tract at all. There was no change in the heart, lungs, liver or spleen but a mild congestion in all zones of the kidney. Analyses were made of excretions, organs and bones of dogs and guinea-pigs, and lead was found in both urine and faeces, in skeleton, intestines, liver and lungs, by far the largest amounts being in the skeleton. Eldridge comments as follows:

"We are dealing with a highly lipoid-soluble lead compound, which is capable of skin penetration and which, furthermore, is comparatively stable. It is probably the only compound which absorbs through the skin, causes acute lead poisoning."

**SYMPTOMS**

In human beings the effects of mild and of severe poison have been reported by Kehoe, Gilman Thompson, and A. W. Schoenleber. According to Kehoe, the effect of tetra-ethyl lead differs clinically in marked degree from that of the ordinary compounds of lead, with the exception of those rare cases of acute lead encephalopathy, probably because it is more rapidly absorbed than any other compound and is also readily soluble in fats, which leads to its concentration in the central nervous system and in the liver. Poisoning in man takes place through inhalation or through the skin. The following is a description of the symptoms which follow slight and brief exposure: insomnia, anorexia, slight fall in blood pressure, and in temperature, stippled red blood cells and leucocytosis if the exposure is prolonged, though slight. Possibly there may be a lead line.

In cases with longer and severer exposure, the symptoms occur in the following order:

1. Insomnia, one of the earliest and most troublesome symptoms, with restless, excited dreams.
2. Anorexia, nausea and vomiting, especially early in the morning, and a sickening taste which increases aversion to breakfast. An attack of vomiting may be brought on by the odour of tetra-ethyl lead.
3. Vertigo and headache, but seldom severe.
4. Muscular weakness, a later symptom and probably due to loss of sleep and appetite.

The signs are: pallor, which is impressive and out of proportion to the anaemia; subnormal blood pressure, an early and reliable sign, the diastolic pressure being almost always relatively lower; subnormal temperature especially in the early morning, rarely above
97° F.; loss of weight; tremors, coarse and well-defined, with exaggerated reflexes and hyper-irritability of the muscles, which may be continuous and exaggerated by efforts at control; sometimes sudden violent twitchings; increased respiratory rate and decreased pulse rate.

Symptoms which are important in ordinary lead poisoning and not in this form are: gastric and intestinal cramps, constipation and diarrhoea, which are either absent or not severe. The blood findings are negative except in slow absorption when stippling may appear; but is not an early nor an important item in diagnosis. The lead may appear; but is not an early nor an important item in diagnosis. The blood findings are negative except in slow absorption when stippling may appear. The urinary findings are slight except for the presence of lead. There is no albumin even in severe cases. Excretion of lead by the kidneys and faeces is greater than in most cases of lead poisoning and may reach 3.4 mg. in 24 hours.

In May 1924, W. Gilman Thompson and A. W. Schoenlebei reported their observation of the severe and fatal cases which had occurred in the autumn of 1923 in the Standard Oil Company's works in New Jersey, as follows:

The first symptom noticed is a marked fall in blood pressure, sometimes 60 mm. of mercury below normal, an accompanying fall in body temperature, which has been as low as 94.6° F., and a low pulse rate, down to 48 a minute. Then symptoms of profound cerebral involvement appear, persistent insomnia, extraordinary restlessness and talkativeness, and delusions. The gait is like that of a drunken man, but there are no paralyses or convulsions. Finally, after a period of exaggerated movements of all the muscles of the body, with sweating, the patient becomes violently maniacal, shouting, leaping from the bed, smashing furniture, and acting as if in delirium tremens; morphia only accentuates the symptoms. The patient may finally die in exhaustion. In two fatal cases, the body temperature rose to 110° F. just before death occurred. One of these was a young man of fine physique who had been at work only five weeks. He is said to have suffered terrible agony.

There is no cyanosis or dyspnoea; there may be vertigo, and the acute outbreak may be preceded by a period of anorexia, vomiting and diarrhoea. Changes in the red blood corpuscles are noted, and the blood of one of the men who died failed entirely to coagulate. It had the colour typical of carbon monoxide haemoglobin. In one case the systolic blood pressure dropped from 190 to 112 mm. of mercury in three and a half hours, a fall commensurate with that following a severe haemorrhage. Convalescence is slow, and may take from six to ten weeks.

From the Pont de Nemours Company's physicians, Eldridge secured a report of the symptoms in 28 cases of tetra-ethyl lead poisoning. The most frequent finding recorded is insomnia (28 times); then follows a markedly lowered blood pressure (20); a sub-normal temperature (19); anorexia, nausea, and hyperacidity of the urine (18); bodily weakness (16); abdominal cramps (12); unaccustomed and annoying dreams (11); vertigo and morning vomiting (11); decided loss of weight and headache (7). Other less frequent findings were a metallic taste in the mouth, tremors, a lead line on the gums (in 4 cases), and itching of the skin. Lead was detected on the skin of 12 men.

Biondi and his collaborators during 1929-1931 studied poisoning by tetra-ethyl lead. Biasi found as a result of animal experiment that the symptoms chiefly affect the central nervous system, the organ most affected being the sight (marked mydriasis, hyperaemia followed by anaemia of the papilla). In the blood no stippled cells were found nor young red cells nor modifications of the leucocytic count. Mene-sini has proved that there is likewise no change in the acid-basic metabolism nor in the calcium content of the blood. It may be stated that, contrary to the other lead compounds, tetra-ethyl exerts no special action on the hemapoietic system.

It is impossible to say just how many cases of acute poisoning occurred between the autumn of 1923 and the early spring of 1925, because a good deal of secrecy was maintained. The deaths numbered 11 or 18. The cases including the mild ones are supposed to have reached over 100.

Diagnosis

The diagnosis, according to Kehoe, must be based on the history of exposure to tetra-ethyl lead, the presence of lead in urine and faeces, and the symptoms outlined above, but the latter are not in
TETRA-ETHYL LEAD

mild cases characteristic of tetra-ethyl lead; they are not to be distinguished from those of tuberculosis, syphilis, chronic myocarditis, or chronic, sub-acute infections with systemic intoxication, except through the history of exposure.

Eldridge found that the best agent for cleansing the skin after splashing was kerosene, followed by tincture of green soap. Animals so treated survived even if 30 minutes elapsed before washing the skin. Prevention depends on the use of fume-proof apparatus and the absence of splashing.

The treatment is the same as for ordinary acute, severe lead poisoning. Kehoe, finding that the urine is always hyper-acid, uses alkalkalisation by sodium bicarbonate or citrate, with magnesium oxide and calcium carbonate, sufficient to make and maintain neutrality of the urine. He warns against opium and chloral hydrate as dangerous for delirium.

ENQUIRIES

Autopsies were made on four cases of acute fatal poisoning, by Charles Norris, Chief Medical Examiner, New York City, and A. O. Gettler, Chief Toxicologist. The cases were young white men who died in acute delirium after varying periods, 12 1/4 hours, 21 hours, 3 days and 10 hours, and 5 days after admission to the hospital. In all there was a yellowish discoloration of the skin and haemorrhagic foci in the bone marrow. Three had haemorrhagic broncho-pneumonia with intense pulmonary engorgement, the lungs resembling those of malignant influenza. In one, the tissues were much desiccated and in another there was yellowish discoloration of the cerebral cortex and chronic leptomeningitis. The striking microscopic features were: intense engorgement with frank haemorrhage in the lungs, in two cases, a general visceral congestion except in the liver, and congestion of the vessels of the brain with red blood cell thrombi. The striking chemical finding was the isolation of a volatile lead compound in the brains of two of the four cases. The amount present at the time of analysis was, in Case 1, 4.25 mg. and, in Case 2, 4.77 mg. Lead in non-volatile form was also found in these brains. These were the two men who had died within the first 24 hours after admission. In the other two, no volatile lead compound was found. The fluids of the tissues had hydrolysed most of the tetra-ethyl lead to a non-volatile lead salt, for no volatile com-

The lead content of the lungs was also somewhat high, pointing to absorption through inhalation. 2.25 mg. to 6.71 mg. The liver contained a large amount, indicating attempt at excretion. 30.53 mg. to 61.47 mg. The kidneys contained from 3.48 mg. to 10.66 mg. All the organs, including the blood, contained lead, pointing to a very recent intake of lead.

Flinn took up the question of danger from splashing or spillage of tetra-ethyl lead, of ethyl gasoline 1-1,000 on the clothing or the skin, and the danger of fumes from spilling in garages. He used rabbits, guinea-pigs, rats, goats, pigeons, and monkeys, exposing them to contact with ethyl gasoline, and to the fumes, and he found that a deposit of lead in the body followed exposure to a 1/1,000 mixture, both by skin absorption and by inhalation, the latter mode of entrance being the more rapid.

The further danger to garage employees and to the public from the use of tetra-ethyl lead in gasoline being retained in the form of sulphate. A quantitative analysis made by the Bureau of Mines investigators of the deposits in the engine head, exhaust pipe, crank case, and drip pan under the exhaust outlet, showed that 95.2 per cent. of the deposit consisted of lead, of which 40.1 per cent. was in the form of chloride or bromide and 55.1 per cent. in the form of sulphate. The bromide is very soluble in water, and so is the chloride, the figures being 8.3 grm. per litre for the former, 9.6 grm. for the latter. No lead compound ordinarily used in industry is nearly so soluble.

The danger to the public and to the workers in garages of chronic lead

1 The word "petrol" has been retained in the parts of this article taken from European sources and the word "gasoline" in the majority of cases based on American data in accordance with the American practice.
poisoning from the fine lead dust in the exhaust gases was emphasised by Zangger, of Zurich, and was prominently exploited by some of the American newspapers. In consequence, the industrialists interested in ethyl-gasoline requested the U.S. Bureau of Mines to undertake experiments which might clear up this subject, and these were begun in December 1923, the results being published just one year later. The experimenters used ordinary motor gasoline, to which was added 3 c.c. of tetra-ethyl lead and 2 c.c. of ethyl dibromide or trichlorethylene, approximately 0.04 and 0.06 per cent., respectively, by volume. The apparatus used was a 1,000 cubic foot air chamber, through which air was driven at the rate of 30,000 cubic feet an hour, making a complete change every two minutes. Twenty-three rabbits, 15 guinea-pigs, 4 pigeons, 8 dogs, and 2 monkeys were exposed for three hours daily to exhaust gases generated by a Delco engine; an equal number of rabbits and guinea-pigs, 3 dogs and 4 pigeons were given six-hour exposures, and about half as many rabbits, guinea-pigs, and pigeons were kept as controls.

Of the animals, about a half of the rabbits, both test and controls, died and about 25 per cent. of the test guinea-pigs, but all deaths were attributed to accident or disease. No loss of weight was noted, no anaemia, no lead lines, no evidence of lead poisoning through symptoms or from analysis of tissues. Very insignificant amounts of lead were found in the carcasses of 7 guinea-pigs, 1 dog and 11 rabbits, examined by Fairhall’s method, the largest quantity being 0.33 mg. per 100 grm. of body weight. Lead was daily given to test animals, and the authors conclude that latent or delayed poisoning is not a possibility under these circumstances since no storage of lead took place.

This report was not accepted as truly convincing, partly because of the small number of animals that actually went through the tests, the mortality of both test and control animals being excessive. The material was also presented in insufficient detail so far as regards a study of the lead dust in the exhaust gases. Therefore, a request was made that the Surgeon-General, Dr. Hugh S. Cumming, should summon a conference for the purpose of deciding what further steps should be taken. Dr. Cumming called together on 20 May 1925, in Washington, D.C., a group consisting of manufacturers, industrial chemists, industrial physicians, hygienists, toxicologists, and specialists in internal medicine. It was agreed that a small body of impartial experts should undertake the enquiry, and the manufacturers voluntarily pledged themselves to suspend the distribution of ethyl gasoline until the report of these experts had been made.

Dr. Cumming appointed the following men as a committee:

W. H. Howell, Johns Hopkins University, Chairman.
D. L. Ebsall, Harvard Medical School.
Reid Hunt, W. S. Leathers, Vanderbilt University.
Julius Stieglitz, University of Chicago.
C. E. A. Winslow, Yale University.

Their report was presented to the Surgeon-General on 17 January 1926, and may be briefly abstracted as follows: The committee felt that while animal experiments had yielded important results, the crucial test must be derived from actual experience in the use of ethyl gasoline under practical conditions of operation. They therefore undertook the examination of five groups of men. Group A was a control group of chauffeurs using gasoline without lead. They had never used leaded gasoline. Group B had for almost two years used ethyl gasoline. Group C served as control for Group D. Both groups were garage workers who either had not used ethyl gasoline at all (Group C) or had worked in garages handling ethyl gasoline for almost two years (Group D). Group E consisted of men employed in two industrial plants where there was known to be serious exposure to lead dust. This group was selected for what might be called a positive control or check in regard to the validity of the clinical and analytical methods used, in the study of the other groups.

Each individual was subjected to a careful clinical examination, an examination of a blood smear was made by a skilled observer, and an examination of the faeces for lead was made by a specially trained chemist. Neither of the two latter knew whether the specimen in question came from a control or from a man supposedly leaded. Special attention was given to three methods which it was hoped would yield data of an objective character. These were, first, the determination of the amount of lead in the faeces, as an index of lead ingestion or absorption; second, the estimation of the number of stippled red cells, which, in the absence of other causes,
might also be considered as an index of lead absorption; third, measurements of the strength of the extensor muscles of the forearm, as an index of lead poisoning. The first two methods yielded results of positive value, but the last was practically negative so far as the present investigation is concerned.

The clinical examinations failed to give any decisive indications of lead poisoning among the chauffeurs or workers in garages in which ethyl gasoline was used as a motor fuel. The median time of potential exposure among these men approximated two years, and this negative result, therefore, holds good only for a period of that duration. It should be added that in Group E, comprising workers in industrial plants in which there was a known and serious exposure to lead dust, definite clinical symptoms of lead poisoning were revealed, although these workers had been exposed for shorter periods of time.

The analysis of faeces revealed practically no difference between Groups A and B, and it was also found that ten of the workers in the Hygienic Laboratory of the U.S. Public Health Service who had had no known exposure to lead had small amounts of lead in the faeces. In both the garage groups the amount of lead was larger and Group D showed a larger amount than the control Group C.

The blood examination also showed no difference between the two groups of chauffeurs while the number of stippled cells in Group C was higher than in the first two groups and Group D was higher still. These results therefore indicate an incipient storage of lead in Group C and D. The findings in Group E were far more pronounced than in any of the others, over 90 per cent. of Group E showing distinct stippling.

The committee endeavoured to discover whether any cases of lead poisoning had occurred in the region where the investigation was made and where ethyl gasoline had been employed as a motor fuel for the longest time. No cases came to light after the most careful enquiry.

The presence of lead and of stippled red cells in the control garage group showed the need of an examination of the dust in that group. It is evident from the results obtained that lead is present in the air and in the dust, even when the gasoline contains no lead. The figures found ran from 0.82 mg. to 22.31 mg. per gramme of dust.

On the basis of this investigation the committee felt that the following general conclusions were justified:

1. Drivers of cars using ethyl gasoline as a fuel and in which the concentration of tetra-ethyl lead was not greater than one part to 1,300 parts by volume of gasoline, showed no definite signs of lead absorption after exposures approximating two years.

2. Employees of garages engaged in the handling and repairing of automobiles and employees of automobile service stations may show evidence of lead absorption and storage, as indicated by the lead content of the faeces and the appearance of stippled cells in the blood. In garages and stations in which ethyl gasoline was used, the amount of apparent absorption and storage was somewhat increased, but the effect was slight in comparison with that shown by workers in other industries when there was a severe lead hazard (Group E) and for the periods of exposure studied was not sufficient to produce detectable symptoms of lead poisoning.

3. In the regions in which ethyl gasoline has been used to the greatest extent as a motor fuel for a period of between two and three years, no definite cases have been discovered of recognisable lead poisoning or other disease resulting from the use of ethyl gasoline.

In view of these conclusions the committee reports that in their opinion there are at present no good grounds for prohibiting the use of ethyl gasoline of the composition specified, as a motor fuel, provided that its distribution and use are controlled by proper regulations.

The committee feels conscious of the fact that their conclusions, although based upon most careful and conscientious investigations, are subject to the criticism that they have been derived from a study of a relatively small number of individuals who were exposed to the effects of ethyl gasoline for a period of time comparatively brief when the possibilities in connection with lead poisoning are taken into consideration. A more extensive study was not possible on account of the limited time. It remains possible that, if the use of leaded gasoline becomes widespread, conditions may arise very different from those studied by them which would render its use more of a hazard than would appear to be the case from this investigation. Longer experience may show that even such slight storage of lead as was observed in these studies may lead eventually in susceptible individuals to recognisable lead poisoning or to chronic degenerative diseases of a less obvious character. In view of such possibilities the committee feels that the investigation begun under their direction must not be allowed to lapse. The respective States would be dependent upon the findings of such investigations for changes in their regulations. With the experience obtained and the expanded methods now available, it should be possible to follow closely the outcome of a more
extended use of this fuel and to determine whether or not it may constitute a menace to the health of the general public after prolonged use or under conditions not now foreseen.

Apart from the question of ethyl gasoline, it would seem from this investigation that wherever automobiles are housed together, there is an accumulation of lead dust which may prove to be a source of danger to the workers involved, in addition to the hazards arising from the production of carbon monoxide gas. The vast increase in the number of automobiles throughout the country makes the study of all such questions a matter of real importance from the standpoint of public health.

As a result of this report agreements were entered into between the producers and blenders of tetra-ethyl lead on the one hand, and the Public Health Service on the other, whereby the distributors of ethyl gasoline and the retail sellers. Tetra-ethyl lead is produced by one company only and in a factory inspected and approved by members of the Surgeon-General's Committee. The blending of tetra-ethyl lead with gasoline is done by the oil companies and only blended gasoline is sold to the trade. Every supply pipe in a filling station which delivers ethyl gasoline bears a warning sign, stating that the gasoline contains lead, is fit for no purpose except motor-car fuel, must not be used for cleansing, and that it is dangerous if spilled on the skin. Between 1918 and 1926, 94 illnesses in 72 individuals have been reported in compliance with contracts between distributors of ethyl and filling stations as to notification of all cases of illness. These cases are referred to Professor Surgeon J. P. Leake, of the Public Health Service, and the more suspicious ones have been personally investigated by him or by R. A. Kehoe. The conclusion of these two authorities is that lead was not a factor in these cases, a matter of surprise to the investigators who had expected to find some cases of lead poisoning.

Dr. Leake writes that there were 25 cases of skin disease, burns, fungus infection, eczema and dermatitis; 30 of pyogenic infection; 9 of gasoline intoxication; 5 of carbon monoxide poisoning; 2 of nephritis; 3 of arthritis; 4 of upper respiratory infection; 5 of affection of the teeth and gums; and 4 pulmonary cases; 1 bronchial pneumonia, 1 asthma, 1 tuberculosis and 1 pleurisy. There were 7 cases of inflammatory disease of the eye or the conjunctiva. The cases involving the central nervous system were 8, namely, 4 of neuritis, 1 melancholia, 1 paralysis agitans, 1 acute temporary delirium, 1 encephalitis lethargica. Finally there were 4 cases of cardio-vascular disease and 1 each of hepatitis, tonsillitis, intestinal stasis, lymphatic leukemia, and purpura hemorrhagica.

Toward the end of 1927 tetra-ethyl lead began to be imported into England and there blended with gasoline (petrol). A Departmental Committee on Ethyl Petrol of the Ministry of Health was appointed to make an exhaustive study of the possible hazards attending the various processes involved in the preparation, distribution and use of ethyl petrol and the Committee delivered its final report in 1930. The conclusions are in harmony with those arrived at by the United States Public Health Service.

Much experimental work was carried out, with regard to the detection of lead in petrol, the possibility of absorption through the skin and the danger of fumes in street traffic. The results of these experiments show that:

1. Small amounts of volatile lead and significant amounts of non-volatile lead are present in the lubricating oil of the crank cases of motor vehicles using ethyl petrol as fuel, the maximum amount of volatile lead found being approximately one-sixteenth by weight of the amount of lead tetra-ethyl in ethyl petrol. In view of the experiments conducted by Professor Dixon, there is no danger of the absorption of lead tetra-ethyl through the skin, should oil of this character remain on the hands.

2. Cylinder and exhaust pipe deposits from cars run on ethyl petrol contain only negligible traces of volatile lead, but large quantities of non-volatile compounds. Owing to the coherent nature of these deposits, there is little danger of the lead from this source getting into the atmosphere as dust.

3. There is no serious danger to health from the spillage of ethyl petrol, even in the case of confined spaces such as closed garages and repair shops, and if adequate ventilation of such premises is secured the danger from spillage is negligible.

4. If ethyl petrol were used universally the quantity of particulate lead which would be retained in the air passages and lungs of drivers under very severe traffic conditions would not be likely to exceed 0.2 mg. per day; pedestrians would retain daily in their lungs and air passages a much smaller quantity than this. On these figures, and having regard to existing
knowledge, neither pedestrians nor drivers would be likely to inhale dangerous quantities of lead even when "puffs" were blown out of the exhaust pipes of motor vehicles during the acceleration of their engines.

5. In view of the fact that a mixture equivalent to 7 c.c. of ethyl petrol was applied daily to the shaved skin of rabbits for 180 days without the occurrence of ill effects, even garage workers who are engaged on repair works or on filling petrol tanks and whose skin is therefore most likely to come into contact with ethyl petrol, cannot be regarded as subjected to any danger.

6. There is no danger in streets from the lead or the carbon monoxide emitted from the exhausts of motor vehicles.

7. The calculated amounts of lead in the air of streets and garages, based upon the amounts of carbon monoxide found by analysis therein, are in general agreement with the amounts of lead found by experiment under conditions representing a traffic block.

8. The proportion of particulate lead retained by the lungs depends upon the depth of breathing. The proportions are 16 per cent. when breathing while at rest (sitting), and 32 per cent. when breathing during gentle exercise; American investigators found that 15 per cent. of the particulate lead was retained by the lungs of men breathing normally at rest.

9. The odour of the exhaust gas produced by the combustion of ethyl petrol when diluted with air is not distinguishable from that produced by other fuels used for internal combustion engines.

Based upon these results and the experiments carried out in the United States the Committee concludes that:

1. The widespread use of ethyl petrol as a motor fuel for motor vehicles would not increase the proportion of particulate lead in the atmosphere of streets to such an extent as to constitute a risk even to the health of that part of the population which is most exposed — namely, police officers on traffic control duty and drivers of motor and other vehicles.

2. In a properly ventilated garage there would be no danger to health from the exhausts of motor vehicles, or from the evaporation of ethyl petrol owing to spillage. Even in a badly ventilated garage the danger due to spillage would not be serious. It should be stressed, however, that adequate ventilation of all garages, whether or not ethyl petrol is used, is a matter of considerable importance, and that the danger from carbon monoxide in an unventilated garage is very serious.

3. The risk arising from the absorption of tetra-ethyl lead owing to the contact of ethyl petrol with the skin is so small as to be negligible.

4. While the deposits from cylinder heads, etc., of cars using ethyl petrol contain a high percentage of lead, the quantity and nature of these deposits are such as to make them of little significance to garage workers, if due regard is had to ordinary cleanliness.

5. There is no danger to water supplies from the use of ethyl petrol.

Finally the Committee holds that there are no reasons for prohibiting the use of ethyl petrol so long as the following precautions are observed:

1. Cans and pumps should be labelled to indicate the presence of lead in the fuel and to warn the user to avoid spillage and not to use the fuel for other purposes than motor fuel.

2. The fuel should be dyed as an additional check against its use otherwise than as a motor fuel.

3. The amount of tetra-ethyl lead in the fuel sold for ordinary commercial purposes should not exceed 1 part in 1,300 parts by volume or about 1 in 650 by weight.

The most recent work (1931) on lead tetra-ethyl has been done by Kehoe, of Cincinnati, and his colleague, Thamm. In 1927 Kehoe published a paper giving the results of experiments on rabbits to compare the action of lead tetra-ethyl with that of an inorganic lead salt. He concludes that the toxicity of the former is a function of its lead content. He suggests that lead tetra-ethyl owes its toxicity to a decomposition product or products which are water-soluble and capable of coagulating proteins.

The latest work by Kehoe and Thamm discusses the absorption of lead tetra-ethyl through the skin and the fate of this compound in the body. The investigators conclude that the latter differs little from that of water-soluble lead compounds, although it does differ greatly in its ability to pass through the skin. Absorbed in this way it circulates as lead tetra-ethyl, but the greater part is rapidly decomposed by the tissues and after three to fourteen days the distribution of the lead is similar to that of other lead compounds and in its mode of excretion it does not differ from these other compounds.

Kehoe and Thamm used rabbits and applied lead tetra-ethyl to the shaved skin, preventing the animal from breathing the fumes by placing its head under a hood in a current of
air. They analysed the tissues in a steam-distillation apparatus with bromine water vapour because of the volatility of lead tetra-ethyl and its easy decomposition in the presence of bromine.

Lead was found in the carcass exclusive of the treated area of skin in amounts running from 0.96 mg. after one half-hour of skin application, to 8.24 mg. and 9.27 mg. after four hours' application. If the animals were killed promptly the greatest proportion of the lead was found in the bile and the liver, next in kidneys and spleen, but if killed after a longer period (from one to 205 days), the lead was found to have disappeared largely from the blood and organs and to be concentrated in the bones. This is similar to the fate of water-soluble lead and they believe that lead tetra-ethyl has been converted to this form. There are, however, two distinctions which may be important in human cases. More lead is found in the muscles and in the brain than is true of water-soluble compounds. The brain of an animal that lived 205 days after the experiment contained as much as that of an animal dying much earlier. Afterwards a lethal dose of lead is found in the brain, but not after small doses, for lead tetra-ethyl seems to lose quickly in the body its affinity for fatty tissue. They found it decomposing rapidly to non-volatile compounds, within the first thirty days and over one-half in the first week. From one-quarter to one-third is eliminated by the kidneys.

**Detection**

It should be fairly easy for customs authorities to detect tetra-ethyl lead in imported petrol. Similarly, it should be easy for the factory inspectorate to ascertain whether the product in question is manufactured in the country.

Different methods have been suggested by Dr. Fallenberg for this investigation and for estimating the amount of organic compounds of lead in the petrol. The most practical are the following:

**Qualitative research:** The petrol to be examined is burnt in a small lamp, the wick of which consists of a cotton thread. A large test tube full of water is held above the flame. At the end of about ten minutes there may be noticed a deposit on the foot of the test tube. This deposit is dissolved in acetic acid diluted to 30 per cent., and the solution is treated by a current of sulphuretide hydrogen. A black precipitate indicates the presence of lead. It is thus possible to detect 1 part of lead in 20,000 parts of petrol, which corresponds to 0.05 mg. of tetra-ethyl lead.

**Quantitative research:** (a) Sulphuric acid and nitric acid method: 10 c.c. of petrol are introduced into a Kjeldahl balloon flask with 0.5 c.c. of sulphuric acid and 2 c.c. of concentrated nitric acid. The flask is heated over a naked flame. After cooling the upper layer is decanted and the watery layer diluted with water. The contents of the flask are then evaporated over a naked flame. The sulphate of lead is then separated and weighed in the ordinary way. Dr. Fallenberg, however, advocates that the separation of the precipitate be effected by centrifugation in order to avoid filtrations which would be difficult in view of the very small quantities of lead involved.

(b) Permanganate of potassium and sulphuric acid method: 10 c.c. of petrol are treated in a Kjeldahl flask by 2 c.c. of a saturated solution of potassium permanganate of potassium and 1 c.c. of concentrated sulphuric acid. It is shaken vigorously while being heated for from two to three minutes in boiling water, then sodium bisulphide is added to excess. The petrol which floats on the top is removed by a separating funnel. The watery layer is transferred again to the Kjeldahl flask and evaporated. The nitrous fumes are driven off and the residue is treated with water. The lead sulphate alone remains insoluble. It is separated by centrifugation washed in alcohol, transferred to a calibrated receptacle, calcined and weighed.

It must be stated that the quantitative estimations must always be preceded by the qualitative research carried out as indicated above, that being the only method which permits of ascertaining the presence of an organic derivative of lead. It would be equally useful to ascertain the presence of chlorine or bromine which enter into the composition of liquid tetra-ethyl.

Ferreri (1928) determines the quantity of tetra-ethyl lead in the fuel by decomposing the anti-detonating agent by means of hydrochloric acid. The lead chloride formed can be weighed directly. It is also possible to transform the PbCl₂ into sulphate of lead which is then weighed.

**Hygiene**

From the hygienic point of view it would be essential so to organise production that the worker is removed as far as is possible from inhalation of toxic fumes, and to draw the attention of garage workers and mechanics to the danger of escape of gas, which makes it necessary to ensure adequate ventilation in repair shops and garages. It is, however, important to draw the attention of health experts in the various countries to the problem in question in order that they may follow...
closely production of tetra-ethyl lead where such occurs as well as the commercial manipulation of petrol containing this product. It is commonly known that the latter is now sold in a concentrated form and under fancy names invented by the selling agents who may themselves mix the product with the petrol.

In Germany there is now found on the market petrol mixed with iron carbonyl (see that article) under the name of "Motylene".

In Russia olate of lead is used and has been successfully employed during an aviation race. This product, however, must be mixed with petrol in the proportion of 1 per cent., which would increase the efficiency of the motor from 5 to 7, but also increases the danger to the public. The product in question is easily prepared and is affirmed to be non-poisonous (?)

R. A. Kehoe, Medical Director of the Ethyl Gasoline Corporation, U.S.A., has formulated the following rules for refineries and depots where the blending of tetra-ethyl lead with gasoline is done.

"Ethyl fluid is poisonous when it enters the body: it may enter by contact with the skin, through the mouth, or by inhalation through the lungs. It is essential that workers be equipped with a separate and complete change of working clothes including boots or shoes, rubber and canvas gloves, and a rubber apron, and that these clothes should be laundered daily. It should be insisted upon that at the end of the working period each employee bathe thoroughly with soap and warm water. He should be supplied with an individual cotton towel. If there is contact with ethyl fluid he should at once wash the skin with kerosene and then with soap and water. Respirators containing activated charcoal are to be used whenever the vapour of ethyl fluid is present in the air. Mixing operations should take place in an open place or in one provided with forced downward ventilation and on a floor which can be flushed immediately in case of spilling. The same men should be employed on each operation at all times."

"No cars of ethyl fluid should be unloaded until they have been inspected for leaking drums or spills. In case these are found they should be carefully cleaned up and the car properly ventilated until free from ethyl vapour. Drums should be stored with the opening up and should be carefully inspected for leaks before storing. Operations should cease immediately when leaks occur and repairs are to be made. Spilling of ethyl fluid should be avoided, and if it occurs the fluid should be immediately dissolved in kerosene and then flushed with water or else neutralised with kerosene containing 2 per cent. sulphuryl chloride or a thin paste of bleaching powder in water."

Recently (1926) Ferreri suggested the use of metallic naphthenates which are easily soluble in petrol. During refining of Russian petrol, treatment by sulphuric acid is followed by neutralisation with caustic soda and washing in alkaline water. After being left for some time the lyes separate out in three layers; one, the lightest, consists of mineral oil, and the two others of a paste-like soap and a solution of sulphate of sodium. The soap is a mixture of sodium naphthenates which easily furnish free naphthenic acids utilised in the preparation of different naphthenates. They are used as drying agents (varnish), for the preparation of imitation objects, for impregnating wood, and mordanting in the dying industry, etc.

There has also been proposed diethyl of selenium or of tellurium which, like tetra-ethyl lead, are dissolved in the same substances. It is, however, probable that their toxicity is as high as that of tetra-ethyl lead.

**LEGISLATION**

As regards legislation, the only measure passed so far is the Swiss law (Ordinance of 7 April 1925), in accordance with which petrol may not contain any compound of lead tellurium, selenium, or other compounds possessing harmful properties.

As regards notification or legal compensation for poisoning by this lead compound, the measures passed in regard to lead poisoning in general apply when the formula is that adopted by English law or when it comprises the expression "lead compounds".

**BIBLIOGRAPHY**

Textile Industry

A rapid survey of problems connected with weaving and knitting is given in this article. Spinning is dealt with in articles "Wool", "Cotton", "Silk", "Flax" and "Jute".

The manufacture of textile fabric is simply the regular interlacing of two series of perpendicular, longitudinal or warp, and transverse or weft threads. The operation takes place on the weaving loom, on which the warp threads are stretched, parallel, between two cylinders, one of which supplies the thread for weaving, while the other is for rolling up the fabric. When weaving the fabric each weft thread is passed alternately above and below various warp threads across the whole width of the fabric. In order to accomplish this, the warp threads are drawn into two series, so forming an angle, along which is thrown the shuttle containing the weft thread which unwinds as the bobbin containing the thread is made. When weaving, the fabric is passed alternately above and below various warp threads across the whole width of the fabric. In order to accomplish this, the warp threads are drawn into two series, so forming an angle, along which is thrown the shuttle containing the weft thread, which unwinds as the bobbin contained in the shuttle unrolls. After each passage of the shuttle the warp threads are combed by a comb or beam, which acts in such a way as to thrust home the weft thread into the angle formed by the two series of warp threads.

The weaving loom in use to-day in the industry is machine driven; it considerably lightens the work of the weaver, which now consists in supervising the working of the loom, piecing broken threads, and replacing the cops in the shuttles; these last two operations necessitate stopping the machinery. However, there are more up-to-date machines in which a mechanical device automatically replaces the cop in the shuttle without stopping the machinery, should a weft thread break or the shuttle become empty. The quality and appearance of a tissue depend on the nature and fineness of the warp and weft threads, and on the closeness of their apposition, as well as on the various arrangements for interlacing the warp and weft threads, so producing patterns which result from the way in which the warp threads are drawn upwards or downwards before the interweaving of the weft threads. Certain so-called fundamental patterns in linen, batavia or twill serge or satin, are obtained by means of combinations which may be endlessly varied, to produce a diversity of patterns, either striped, check, damasked or ribbed. Special machinery is employed for weaving complicated and figured patterns.

Figured fabrics, which need a great number of strips, are made to-day automatically on the jacquard loom, which has taken the place of the draw loom. In the jacquard loom the pattern desired is obtained by means of cards, perforated beforehand according to the pattern required; they form a continuous belt, which unrolls on a quadrangular block, making one-quarter of a revolution for each weft thread, so bringing the desired pattern into being. A machine fitted with needles and a spring coaxes the drawing upwards and downwards of those warp threads which correspond to the perforations of the card, and prevents displacement of those weft threads which correspond to the non-perforated parts of the card.

Weaving is preceded by a number of preparatory operations, which include making ready or spooling the weft threads on the cops in order to prepare the weft; moistening the cops with clean water or soapy water so as to obtain closely woven fabrics; winding skeins of thread on to bobbins in order to prepare the warp; twisting or warping by simultaneously winding and gathering together threads supplied by a certain number of the bobbins; and dressing or sizing the warp threads. Mention should also be made of the operation of punching the cards which are used on the jacquard loom.

Fabrics, when taken off the loom, undergo a process of repair to remove any defects in the woven piece, such as tears or rents, flaws in the weaving, or irregularities of design.

The fabrics next pass on to other operations, the object of which is to give them the quality required by the use to which they are to be put; dressing, properly so called, which includes the incorporation with the fabric of various thickening substances, such as starch, faecula, dextrin, animal glue, fat substances, oil or glycerine, in order to give a substantial feel to the fabric; or kaolin, talc or barium sulphate, to give weight or resistance; preparation, by means of mechanical operations, such as pressing in the hydraulic press, between calender rollers, trimming, goffering, humidifying, steaming, sponging, or drying on tenterframes.

During the last few years, the chemical industry has put on the market certain moistening agents prepared by synthetic means, used to accelerate the operations of bleaching, carbonisation, mercerisation and dressing.

Hosiery includes the manufacture of articles in knitted fabric or in tubular fabric (jersey), from a few inches in diameter to two or three yards, made on a frame the needles of which are arranged round a circular disc. Knitted hosiery is now made on a knitting machine, which can turn out the knitted fabric either in strips or tubes as desired. For the manufacture of fancy articles the machines are fitted with mechanical devices, e.g. fringing apparatus.
They go back to the year 1910, and cover a total of 4,950 wage earners, of whom 1,335 were men. The frequency of various kinds of sickness among the men and women is indicated in the two following tables:

As regards mortality, the most important statistics are those published in Great Britain referring to the period 1921-1923. These statistics are based on the assumption that the general mortality of all occupied and retired males, taken as the standard, is represented by 1,000. The various categories of workers dealt with include weavers in the cotton industry, those in the wool and worsted industry, and weavers of other textile fabrics, hosiers and knitters, dyers, scourers, calenderers and finishers.

The following table indicates the death rate for these various categories of workers from certain causes:

<table>
<thead>
<tr>
<th>Causes of death</th>
<th>Total number of deaths from all causes</th>

PATHOLOGY

No important occupational condition of ill-health derives from the operations of weaving and accessory processes. This is particularly true in regard to those who work in factories where up-to-date technical installations create a satisfactory and hygienic environment, especially as regards temperature and humidity.

The general health of these workers is a reflection of their social surroundings and their living conditions, but especially of the technical organisation in the factory where they work. Indeed, it is quite usual to find different hygienic conditions in the same industry according to whether the situation is in the country, in a big industrial centre, or in a semi-industrial and semi-agricultural area.

Weaving, and particularly its accessory operations, may cause dermatitis, complicated or not with eczema, among which may be mentioned dermatitis due to tartrate of potassium and antimony, characterised by a papulo-pustulous type. The radical antimony combines with the tannin contained in the solution used as a mordant before the dyeing of the fabrics, and eliminates the tartrate (Selisskij, 1927; Lagoviner, 1928). In the cases under observation there was cyanosis of the skin, and the dermatitis, as a rule follicular, developed into atrophy and sometimes necrosis. The lesion was situated on the extremities, the penis and sometimes the upper lip. In the course of eighteen months, Selisskij noted 290 cases of dermatitis, including relapses. In Japan, Bogo Koinuma in 1926 described a form of eczema (Mizumushi) peculiar to weavers; cutaneous troubles caused by chromates have been reported among fabric dressers and dyers.

Oppenheim draws attention to the formation of callosities, due to the handling of rough fabrics or irritant colouring agents.

Dust, high temperature and humidity explain the frequency of respiratory and rheumatic affections and disorders due to "chills".

A disease considered to be peculiar to cotton weavers was reported in 1913 by Collis. A great number of workers in Lancashire suffered from coughs, feverishness and attacks of asthma in mills where chloride of zinc was not used for preventing the formation of moulds on the warp threads. Moulds of the "aspergillus" group were thought to be the cause of the outbreaks; the cases recovered after a period of varying duration of absence from work, or else persisted in a chronic form. Middleton reported as a complication of this pulmonary affection a form resembling tuberculosis. In other cases the symptoms were so similar to the clinical picture of tuberculosis as to make a differential diagnosis with tuberculosis a difficult matter.

A noteworthy incidence of cortico-pleuritic forms was reported by Lo Caso in 1929. Badham in 1928, as the result of an enquiry into the conditions of health among textile workers in Sydney, recommended revision of the regulation in force at that time regarding the degree of humidity and heat to be permitted in the industry in question.

Standing while at work may easily bring about disorders of the venous circulation, causing varicose veins; Suguiria in 1930 and Konishi in 1929 studied in Japan the frequency of varicose veins among weavers.

Anaemia appears to be equally common (Konishi, 1929); as are also lesions of the locomotor apparatus among the young men who have to do strenuous work; tenovaginitis occurs among the women workers in the hosiery trade employed in drawing the stockings out of the frames, due to this work constantly bringing into action the long adductor and short extensor muscles of the thumb; modifications of the foot and of the knee have also been reported by Aisenstein in 1927-1928.

Workers who have to carry or push heavy weights — especially women workers, including those in the hosiery trade who handle the hot metal or wooden moulds with which they push with the abdomen against the table — often complain of various troubles such as enteroposis, and, in particular, disorders of the abdominal organs.

Supervision of several looms at once, especially in the weaving of ribbons and lace-making, requires close attention, which is generally very exhausting and may in time set up nervous disorders. Observations made in Russia on workmen who have passed from tending two looms to tending three have brought to light facts which demonstrate the early development of the phenomena of fatigue, the cause of which is favoured by bad lighting arrangements, by unhealthy temperature, humidity in the workplaces, and also by exhaustion resulting from accessory forms of work. But the adoption of hygienic precautions would appear to prove that the change over to the tending of three looms need
not necessarily be attended by any serious risk of over-strain for the worker (Rosenbaum, Riwelina, Belogorets and Seletzkaja).

Tending a number, sometimes very considerable, of looms—twenty, or thirty, or even forty, rendered possible by the most up-to-date technical plant—may lay the foundation of various disorders, chiefly fatigue. However, Koelsch considers that the movements required for tying the threads do not cause any increase in invalidity, and especially in gastro-intestinal troubles, reported among weavers.

In 1930 Kopelowitsch described numerous cases of nervous diseases among the workers in a stocking and fabric factory. They included forms of hyperthyroidism, chiefly among the women; and of goitre, which he correlated with the conditions of the individual workers, as regards constitution and sexual life, and with their working conditions, lack of hygienic measures and fatigue.

Another source of nervous fatigue is noise, which is considerable in weaving sheds, and also vibration caused by the movement of heavy and noisy machinery.

Cases of conjunctivitis have been observed in weavers, and attributed to certain colours used in dyeing.

Although Waither has emphasised a heavy incidence of cases of short-sight among weavers, amounting to 75 per cent., few of whom had suffered from short-sight when they started as weavers, Roth, on the contrary, only reported an incidence of 7-8 per cent. Both acknowledge that it was only a question of short-sight of a medium degree—3 D at the maximum. Obviously short-sight is aggravated by bad lighting, which is more often than not the case when work is carried on at home (Netolitzky and others).

Ocular fatigue in the hosiery industry was the subject of an extremely interesting article by Weston in 1927.

Disorders of hearing are represented by diminution in auditory acuity, which may be so serious as to develop into deafness, due to noise, and by otitis caused by certain fungi conveyed in tiny drops of starch thrown into the air and localised in the external auditory meatus.

This bad habit of shuttle kissing, called in French "baiser de la mort", — the kiss of death — should be mentioned. It consists in drawing the thread into the mouth through the eye of the shuttle, when a new thread is put into the shuttle, or when the thread breaks, especially in mills where a fine thread is used. This habit has long been regarded as constituting an important source of risk to the worker. A little wire hook should be used to pass the new thread through the eye in the shuttle; but the worker finds it quicker and more convenient to have recourse to aspiration with the lips. Since this operation may take place every ten minutes, this habit, which must be considered as distinctly unhygienic, becomes a source of such cutaneous and buccal diseases as tuberculosis and syphilis, when different workers succeed each other at the loom.

Various new types of shuttle with mechanical aspiration, and especially the introduction of automatic weaving are fast doing away with manual operations in charging the shuttles and drawing the threads into position.

Risk of lead poisoning may be so common in work on the Jacquard looms with lead counterpoises, has now become very rare. Cases of lead poisoning have been reported among the lace makers who handle products impregnated with such salts of lead as the acetate or chromate.

In the accessory operations of dyeing, dressing and printing, the workers are exposed to the harmful effect of air which is hot and damp, or to that of certain substances which are used. During bleaching, a source of danger may be represented by acid fumes (sulphurous anhydride); during gassing by carbon monoxide if the operation is not carried out with complete aspiration of the gases of combustion.

Injuries which may be attributed to colours are fairly rare, as the use of toxic products, with a lead or arsenic basis, has now been almost completely suppressed. Besides, the colours are used nowadays in very weak solution. Yet in persons who are specially predisposed it is sometimes possible to observe injuries to the skin, such as eczema, or to the teeth, or cases of conjunctivitis.

Mention should be made of the special work of repairing, which is liable to cause ocular fatigue, with accommodative asthenopia, watering of the eyes, photophobia, conjunctival congestion, and, often, sub-orbital neuralgia. The sitting position which the women are obliged to maintain exerts an injurious repercussion on the neuro-muscular system, setting up fatigue, spasms and muscular cramps, of which cramp of the fingers is the most frequent. This is characterised by a painful contraction, involuntary and temporary, of the muscles of the
The social question of women's work in the textile industry has resulted in a large number of enquiries in which there is some divergence in the conclusions drawn. Although the writings of Hirsch and others (see article "Women's Work") emphasise the injurious effect of this work on the female organism, on pregnancy and on the offspring, the contributions of Holtzmann in 1928 and of Geller in 1929 arrive at less unfavourable conclusions.

Holtzmann, who carried out his observations at Lorrach and at Friburgh reports that premature confinements and miscarriages are less common among these women workers than among the rest of the female population of the same town. It is undeniable that these favourable results are accounted for by the benefits of social insurance, with help during pregnancy and at confinement. The average life of women who are employed in the textile industry is shorter than that of the agricultural population, for the reason that persons who have not got a robust constitution turn to industry. The average age at death for women who have been engaged in industry and in agriculture is lower than that for men similarly engaged, because in the case of women the fatigue of housework is added to occupational fatigue. But women in industry have better social conditions than women employed in agriculture. This fact also exerts an influence on the probability of survival for infants. Gynaecological diseases which might be attributed to occupational strain are not unduly frequent.

Geller has made a study of the morphology of the pelvis in women employed in the textile industry, including 2,073 women workers between the ages of fourteen and twenty, and 633 who were pregnant. The work would appear to have no effect on the diameter of the pelvis, nor would it seem that the pregnancy was affected. Women employed in the textile industry had fewer still-born children. Geller considers that it is not hard work which is a danger to these women, but rather the fact that the pregnant woman stands too long, in hot, moist, noisy surroundings, employed on work which requires close attention. Among the women who are pregnant Geller often found a poorer state of health than among the others. Whereas the work does not have a directly injurious action on the product of conception, it certainly does have an injurious effect on the woman herself, in lowering her capacity for child-bearing and for nursing her child at the breast. Finally, in 1927, Alesker, Slatopolskaja and Korolev observed among the young Russian women who worked at weaving a hypo-evolution of the genital organs.

It must, however, be admitted that, in comparison to what went on in the past, the sanitary conditions for weavers, especially women and young workers, have been greatly improved, thanks to progress in industrial technique with mechanical devices, and to the measures of social relief adopted.

The risk of accidents should not be overlooked, although as a rule the textile industry ranks almost lowest among factory occupations classified in order of accident frequency.

In one factory it was the duty of a workman to nitrate a fabric which had been dyed with "oxydiaminogen OT". Contrary to the instructions received, he used a concentrated solution of nitric instead of a dilute solution, thus causing a liberation of nitrous fumes, with fatal poisoning for the worker.
Weaving sheds, and places where accessory operations take place, must fulfill the requirements laid down for the general hygiene of factories (see article "Industrial Hygiene (Workshops)"). Four points are of particular importance, viz., ventilation, cooling, and humidification of the air, and lighting.

As is well known, textile fibres are hygroscopic, and, in order to work them easily, the temperature and hygroscopic condition of the atmosphere must be just right. It is likewise known that work on rough fibres, in an atmosphere that is too dry, causes static electricity, which, besides making the fibres stand erect, may also be the cause of very serious accidents from fires and explosions.

For these reasons artificial humidification of the air in textile mills is necessary if the air of the district in which the mill is situated is not sufficiently damp — and it is not, as a rule, during the hot season. The disadvantages of such an atmosphere and its effects on the human organism are referred to in the article "Air: Hot and Humid Atmospheres". These have led the legislator to demand adequate ventilation in weaving sheds in order to prevent any excessive rise in the temperature.

It is also noted in those articles dealing with the various textile fibres that formerly, in the fear of draughts, special arrangements were made to avoid all contact of the sheds with the exterior air. At this period the sheds were under plus pressure because damp air was introduced into them, instead of being under minus pressure, due to evacuation of the hot air to the outside.

The solution of the problem of humidification has thus become a more difficult matter, for the engineer must consider simultaneously ventilation, humidification and cooling.

Modern technique has nevertheless provided a solution of the problem; and it is now possible to obtain ventilation and the evaporation of water necessary for cooling and humidification by means of systems which may be briefly stated to be based on the following principles:

- Incorporation of water with air by prolonged contact with the liquid and vapour, either by stirring or by close mixing; the air is then distributed in the sheds from saturators, atomisers or supersaturators;
- Production of humidification and ventilation by various vaporising apparatus.

Saturators for humidification and cooling utilise air which only carries the quantity of water corresponding to its point of saturation. Atomisers combine the two operations in one: in a first stage a preliminary preparation analogous to that of the saturators takes place, wherein the air evaporates a quantity of water corresponding to its point of saturation; in a second stage the completion of the preliminary stage takes place in the weaving shed, for the air carries along, in the form of vapour, atoms of water which are ready for a second evaporation.

Where vaporisers are employed, the humidification is carried out in the shed. Ventilation accompanies and precedes the evaporation of the water. The work is carried out by quite distinct apparatus.

It is known that each textile fibre possesses a maximum hygrometric state, and that inside a weaving shed it is forbidden to exceed a temperature corresponding to that which exists outside, in the shade, with northern aspect and at 2 o'clock in the afternoon, when this temperature reaches at least to 28° C. and a humidity of 45-50 per cent.

The amount of fresh air required and the quantity of water which must be evaporated depend: on the maximum humidity which the textile work can bear; on the temperature, which must not be exceeded inside the shed; and on the external conditions of warmth and humidity under which these required results have to be obtained.

At the present time, there are available apparatus which make it possible to obtain humidification without ventilation, or vice versa, or even ventilation and humidification combined. The air is at the same time washed and then passed in at the desired degree of humidity. The humidification also can be modified, according to requirement, as well as the speed of the incoming air. It is even possible to unite in a single process heating by ventilation and humidification. A quite simple apparatus provides a record at any moment of the degree of humidity by using psychrometers, of the amount of carbon dioxide in the air of the weaving shed, or even of the degree of comfort by use of the katathermometer.

Humidity is definitely recognised as essential in the textile industry; a condition which is hygienically favourable facilitates the formation of "grains" in the classic fabrics; the
fabric has a better appearance, and is thick; the warp unrolls more easily, and the threads are less brittle; thread that is sized or taped breaks like glass if it is too dry; on the other hand it must not be too damp.

Temperature does not play an important part in weaving, which is contrary to what holds good for spinning; a temperature of about 18°C is necessary for assuring the best output from the worker. It might be said in a general way that a relative humidity of 70–80 is indicated for weaving cotton on the ordinary looms, and a temperature of 75–80 is indicated for weaving cotton, flax, hemp and jute.

According to Neu, in places where cotton, flax, hemp and jute are prepared, on an average, a temperature of 18°C may be required with a relative humidity of 65; in weaving sheds, a temperature of 18°C with a humidity of 70–85, for cotton according to the kind of loom used, of 75–85 for flax, and of 80 for jute and hemp. For both wool and silk, a temperature of 18°C and a humidity of 60 during preparation, and of 65–70 for weaving is required.

As regards lighting, a general uniform system of lighting should be insisted upon, with luminous sources of 100–150 W. for sheds where cops and bobbins are wound, work at weaving looms, hosiery knitting machines, and other machines. Lighting must be concentrated for places like warps, bobbins are prepared, or sizing and taping machines, and for Jacquard looms.

The best lighting is that of 40–50 lux for the tapping machines; 50–60 for winding cops and bobbins; 50–80 for warp beams and other machines; and 50–100–120 for the weaving machines.

Concentrated light should be distributed after a very careful study of the particular conditions of the workplace. The arrangement of the machines — such as taping and sizing machines — must be taken into account, considering on the level as well as in elevation and likewise the vertical and horizontal surfaces of Jacquard looms, in order to prevent production of shadows, unequal lighting, hard shadows and dazzling.

Account must be taken of the delicate nature of the work done, e.g. on the Jacquard looms, of the colour of the fabric, since with black tints stronger light is required, and of the presence of great cumbersome machines liable to intercept a large part of the luminous rays.

Whereas for hosiery, general, uniform, but intense lighting may be right, for extremely fine work and mending concentrated light is necessary.

Weaving sheds as a rule have natural lighting coming from the roof — saw roofs; but up-to-date systems tend more and more to attain this end with rows of windows. In this case, suitable measures must be taken to assure for the workers a stable, constant, soft and restful light.

In brief it is essential to recall provision of measures for preventing shuttle kissing; for assuring good individual hygienic conditions for the workers, conditions which must vary according to the different kinds of accessory work and are too numerous to enumerate here. Fatigue due to standing may be overcome by placing seats at the disposal of the workers whenever it is possible. For those engaged on repairing of fabrics, tables or benches should be provided, and special devices (Blin and Blin) calculated to reduce troubles arising from bad posture and manner of working.

Suitable measures must also be taken for the evacuation of residual water (see article "Industrial Waste Waters" and the articles dealing with the various textile fibres).

LEGISLATION

In Germany, youths under sixteen are excluded from workshops where combing is done, and from other premises where dust is liberated; in Belgium, those under fourteen are excluded from spinning-mills, cotton-wool factories, and from accessory processes connected with filamentous material, from workplaces where dust is liberated and there are no mechanical means for its elimination; in Spain, boys under sixteen and women under twenty-one are excluded from the process of singeing threads, if the products of combustion are given off freely into the workplace; in the United States (New Jersey), youths under sixteen are excluded from every industry where vegetable dust is liberated in harmful quantities; in France, women and boys under eighteen are excluded from the singeing and gassing of threads; the gases of combustion are given off freely in the workplaces; from the manufacture of painted fabrics in workplaces where toxic materials are employed; from the carbonising of wool and cloth by the damp process, where there is liberation of acid fumes; boys under eighteen from dye works where toxic products are used; and from bleaching linen, when chlorine or sulphurous acid is given off.
In Great Britain, the Regulations of 1929 on artificial humidification in cotton weaving permits as the maximum limit of temperature 72.5° F. (22.3° C.) with the wet-bulb thermometer, corresponding to a relative humidity of 75-80° F. The previous Regulations allowed a maximum limit of 75° F. (24° C.) and it is of interest to emphasize the fact that this limit had previously been 28° C.

The new Regulations provide for the cessation of all work when the wet-bulb thermometer reaches 80° F. (26.6° C.), and authorise the workers to leave the sheds until the temperature of the air can be adjusted to the maximum limit allowed.

Pulmonary affections, and cases of poisoning by arsenic or mercury among printers of fabric are subject to compulsory notifications in the Netherlands. Deafness caused by noise, and short-sightedness due to inadequate lighting are compensated in Bulgaria; diminution in auditory acuity on account of noise, varicos veins and ulcers on the leg, flat foot and knock-knees among weavers, are compensated in the U.S.S.R.

Deafness caused by noise, and short-sightedness are especially prevalent in the General Public Health Department, In a pure state it is a silvery white metal, soft and malleable like lead, which melts at about 300° C. It becomes volatilised slightly above its melting point, and boils at about 1,700° C. In the molten state it is black on account of formation of oxide.

Buschke has drawn attention to the similarity between thallium and lead, both from the point of view of atomic weight and from that of biological reaction (acetate of lead, like acetate of thallium, produces amongst rats whitening of the hair, as well as allergic reactions and derangements of growth). Thallium is readily oxidised on exposure to air, and liable to attack by carbon dioxide. It dissolves easily in nitric and sulphuric acid and less readily in hydrochloric acid. It combines with chlorine, bromine, iodine, sulphur, selenium and tellurium. It is attacked by alcohols (amyl-alcohol and methyl-alcohol), and the ethers, with formation of organic combinations. It provides two series of salts: thallous and thallic salts.

The raw materials required for the preparation of thallium are especially the residues of zinc, pyrites and sludge from lead chambers. In roasting pyrites in order to obtain sulphur dioxide, thallium passes into the sludge and dusts of the lead chambers. Zinc-bearing pyrites also contain thallium, which passes off in solution with zinc sulphate, when the product is washed with sulphuric acid for the recovery of zinc. The sludges and dusts are extracted by means of boiling water and the clarified liquid is treated with concentrated hydrochloric acid, which precipitates thallium chloride. The latter is finally transformed into sulphate, from which the thallium is pre-

**Thallium**

French and German: **Thallium.** — Italian: _Talio_. — Spanish: _Talio_.

**Technical Data**

This product (symbol TI), discovered in 1861 by means of the spectroscope by Crookes, and in 1862 by Lamy, in the sludge from lead chambers, is a fairly abundant metal: found in nature in small quantities, in a state of salts in combination with other metals in various ores: _Crookerite_ (copper, silver and thallium selenide), _Lorandite_, the _Hutchtsonite_ of Lengebach, etc. Small traces of thallium are still found in the potassic salts of Stassfurt, in hematite, in manganese, zinc, cadmium, bismuth and platinum ores, in native sulphur, and especially in pyrites, etc.

In a pure state it is a silvery white metal, soft and malleable like lead, which melts at about 300° C. It becomes volatilised slightly above its melting point, and boils at about 1,700° C. In the molten state it is black on account of formation of oxide.

The raw materials required for the preparation of thallium are especially the residues of zinc, pyrites and sludge from lead chambers. In roasting pyrites in order to obtain sulphur dioxide, thallium passes into the sludge and dusts of the lead chambers. Zinc-bearing pyrites also contain thallium, which passes off in solution with zinc sulphate, when the product is washed with sulphuric acid for the recovery of zinc. The sludges and dusts are extracted by means of boiling water and the clarified liquid is treated with concentrated hydrochloric acid, which precipitates thallium chloride. The latter is finally transformed into sulphate, from which the thallium is pre-
pared either by means of zinc or by electrolysis. Thallium may be obtained in the same way from solutions of zinc sulphate.

Thallium is especially utilised in the state of salts. Whilst the acetate is very much used as a depilatory in ointments and as a product for destruction of rats (Céliopaste), the carbonate of thallium is used in the glass industry, in the manufacture of lenses, coloured glasses, and imitation precious stones; in the making of fireworks, manufacture of Bengal lights, etc. The chloride is utilised in the manufacture of Tungsten lamps, and as a catalyst for the chlorination of organic substances. The nitrate is used with barium sulphate to give phosphorescent colours (greens and yellows). The hydrate serves for impregnation of paper utilised in detection of ozone and sulphuretted hydrogen. The nitrate and sulphate are also utilised in chemical analysis in order to separate and measure chlorides, bromides and iodides.

**TOXIC ACTION**

Thallium is excessively toxic, and the acid is more toxic than the salts. This toxicity has for long been known, thanks to the experimental researches of Stricker (1865), Marmé (1867). Rabuteau (1874), Blake (1890), and Richet (1899). Lutz, resuming this research in 1928, has, with a daily injection of 0.2 c. cm. of a 1 per cent. solution of commercial salts of thallium, caused the death of animals in a week with cramp and diminution of weight (two-thirds of the original weight).

Lesions obtained by various research workers are as follows: atrophy of the skin and subcutaneous tissue, of the sebaceous and sweat glands, with hyperplasia of the corneal layer, degeneration of the roots of the hair (Manioli) and alopecia (Olivier, 1927; Insabato, 1927), bronchitis, bronchial pneumonia, stomatitis, venous stasis of the stomach, formation of hyperkeratotic papillomata of the cardiac region of the stomach (Olivier, 1927; Hecke, Leigheb, 1928), catarrh of the digestive system, vomiting, diarrhoea, digestive hemorrhage (Greving, Gagel, Hecke), degenerative and necrotic changes of the kidneys, oligocytthesis, pseudo-leucocytosis and eosinophilia, changes in the cell islets of Langerhans, in the suprarenal, sexual and thymus glands, congestion of the ovaries, of the hypophysis and of the meningeal membranes, with meningeal and ventricular hemorrhage. Experiments effected by Landaour (1931) on hens have shown that intoxication of the animal by thallium may exert an influence on its descendants.

Buschke and his pupils have likewise noted derangement of the growth of the bones and changes in the calcium metabolism. At the end of a certain time after the onset of the experimental poisoning a veil appears over the crystalline lens and even a form of cataract due to inflammatory change of the iris and intra-ocular hemorrhage, followed by troubles of the base of the eye and atrophy of the optic nerve. Other experts have noted also an extra-pyramidal hepatolenticular syndrome, and certain authorities a syndrome resembling the pseudo-sclerosis of Westphal-Strümpell, with an enlarged and painful liver (Insabato). This author thinks that acetate of thallium exerts an elective action on the anato-mo-functional extra-pyramidal complex, which accords with a case described as a choreiform syndrome due to thallium. Greving and Gagel (1929) found typical modifications of polyneuritis, degenerative changes in the Purkinje cells, in the medul-geniculate body and in nucleus of the oculomotor nerve. The vegetative nervous system does not appear to be affected.

The mechanism of the toxic action is not very clearly understood. It is thought to consist of a local effect and a nervous effect, or, again, of an endocrine action.

Absorption of the poison occurs by way of inhalation of dust liberated in the course of various operations either of manufacture or of manipulation of the product. There is a cumulative type of action, the product accumulating especially in the hair and on the skin.

Teleky considers that repeated doses are more likely to be harmful from a permanent point of view than one initial and single dose, as in the case of accidents connected with therapeutic treatment. From the industrial point of view, it must be remembered that the limit between harmless and dangerous doses is excessively small and is connected especially with individual susceptibility.

**STATISTICS**

Though the toxic action of thallium and its salts has been known for a long time, it is only recently that the importance of thallium from an industrial point of view has been adequately realised. Symptoms.
caused by it have perhaps been confused with lesions attributable to arsenic and lead. However that may be, available statistics are not numerous. In the annual report of the Prussian Factory Medical Inspectorate for 1927 Teleky drew attention to cases of intoxication by oxide and sulphate of thallium. These cases were also studied by Rube and Heindrik (1927) in two factories engaged in the manufacture of celiopaste. In 1928, Teleky reported that out of 14 workers in a factory for the manufacture of thallium or its salts, 3 only were free from effects. A case of thallium poisoning has also been reported as affecting an apprentice hairdresser.

PATHOLOGY

Industrial poisoning by thallium generally assumes the form of chronic poisoning with symptoms typical of the acute form. At the onset there is often interference with sleep and excitement (Teleky), which may pass unnoticed at times and the importance of which is only recognised later when further symptoms make their appearance. The first of these occur either a few weeks after commencement of work or at the end of several months (Teleky) and consist in pains located in the joints of the lower limbs, with weakness of the limbs, accompanied by muscular cramp, disappearance of the rotular reflex and that of the tendon of Achilles and sometimes even polyneuritis. At the end of a few months (Teleky) there is noted falling of the hair, gastric symptoms (profuse saliva, loss of appetite, vomiting, diarrhoea accompanied by loss of weight); nervous troubles (depression, fatigue, loss of consciousness, at times excitement, muscular spasms, attacks of hysterical laughter). As regards cardiac symptoms there are noted cyanosis, tachycardia, at times slowing down of the pulse, and in the renal system albuminuria develops at times fairly late (at the end of three months) and only disappears on cessation of work. Examination of the blood reveals characteristic lymphocytosis (over 40 and sometimes over 58 per cent.: Teleky), eosinophilia (7 per cent.: Buschke). These symptoms appear, moreover, very early, and have even been noted on one occasion to have affected a worker four days after commencement of work (Buschke). According to Testoni (1929) no punctate basophilia of the red corpuscles has been noted. At times symptoms of purpura have been noted.

Ocular lesions are very important, and may occur at an early stage: in a case described by Teleky, four months after appearance of the first symptoms.

Besides lesions of the iris and crystalline lens, there has been noted total central scotoma, bilateral, for red and green. In another case there was optic atrophy which did not improve. This constitutes the grave danger of thallium.

It should finally be stated that Egli has reported lesions connected with irritation of the nose and eyes due to liquid combinations of thallium.

The spectroscope enables detection of up to 2 mg. of thallium per litre in solution: a beautiful green ray is given.

HYGIENE

In 1920 the use of a product with a salts of thallium basis was recommended in the campaign against rodents. Tests (1925) were undertaken in the United States with a view to establishing whether salts of thallium might be effective against rodents and might be employed without danger to man. It was found that thallium is the most toxic and the most effective of all substances which can be used in an anti-rat campaign, since it is more active than strychnine and four times more active than arsenic.

As there is no warning sign accompanying its presence, use of the product should be reserved for those trained in its use.

Buschke, as well as Teleky (1931), has drawn attention to the necessity in those industries which utilise thallium and its salts for adopting adequate measures of prevention: general hygienic conditions; means of capturing and removing dusts which may be liberated; wearing of gloves or special working clothes. Periodical medical examination of the workers is also of importance (Teleky), and they should further be informed as to the risk to which they are exposed. Well-thought-out and well-applied prophylactic measures are quite sufficient. This is proved by the fact that Buschke and his collaborators, who worked for twenty-seven years with thallium, never suffered from any symptoms.

Thorium

French and German:Thorium. — Italian and Spanish: Torio.

Thorium (symbol. Th.) is found in the natural state as a constituent of numerous salts: silicates, niobates, tantalates, titanates, phosphates—as, for example, Aeschynite (niobotitanate of cerium, of yttrium, etc., containing 23 per cent. of oxide of thorium), Ceylon thorianite containing up to 70-80 per cent. of oxide of thorium. In industry it is extracted from thorite, which is a hydrated silicate, and especially from monazite.

The latter consists to a great extent of phosphates of cerium, of didymium and of lanthanum, and contains mixtures of various quantities of thorium ore (3 to 10 per cent.). Deposits of monazite exist in the Transvaal and in Brazil. Monazite sands are produced in the United States.

In the pure state, thorium is a silver-blue metal, which melts at 1,700° C. and is ductile and malleable. It burns easily in air, becoming transformed into oxide, and is readily dissolved in hydrochloric acid and less so in sulphuric and hydrofluoric acids. Thorium is considered as the first element of one of the three families of radioactive substances. It emits α rays and an emanation (Toron) of very short duration. Like radium and actinium, it disintegrates into radioactive substances of less atomic weight, and gives rise to the following substances: mesothoriums 1 and 2; radionium, thorium X, Toron (emanations), thorium A, B, C, and omega, this latter being the isotope of lead.

Mesothorium is obtained from the residues got in extracting thorium from monazite by processes similar to those engaged in in the extraction of radium. A ton of monazite may give 2 to 5 mg. of mesothorium in a state of bromide.

The extraction of thorium in the state of a salt involves various complex operations. The ordinary concentrated monazite ore is ground down, treated with sulphuric acid in order to dissolve the phosphate of thorium and other metals it may contain (cerium, lanthanum, aluminium, iron). The sulphuric solution is neutralised by caustic alkalis, or ammonia or magnesium, by simple dilution with a given quantity of water, in order to cause a reprecipitation of the thorium in the state of a phosphate. The latter is purified by transformation into oxalate, which in its turn may be purified or transformed into hydroxide. In starting with thorite or thorianite, the series of operations terminates with hydroxide of thorium. The oxalate or hydroxide thus obtained are finally purified by transformation into the sulphate, which is then subjected to successive crystallisations. The sulphate is then transformed into a nitrate, which is the salt most commonly used, and from which may be obtained either pure thorium, prepared also by electrolysis of chloride of thorium or other salts of thorium: acetate, chloride, fluoride, sulphate, etc.

The preparation of powdered thorium was achieved in 1829 by Berzelius, who caused sodium or potassium to react on thorium chloride. Calcium is chiefly used for this purpose now. It is almost impossible to produce powdered thorium of a high grade by distillation of tetrachloride thereafter reduced by sodium, since the thorium becomes oxidised during the process of disintegration. The preparation of the chloride by distillation in chloroform, carbon tetrachloride or sulphur fumes has not met with success. Reduction of the tetrachloride by calcium has given better results.

Thorium is used in the manufacture of tungsten filaments for electric lamps. In the manufacture of the cathode for X-ray lamps; the acetate, and especially the nitrate, are used in the impregnation of incandescent mantles (see article "Incandescent Mantles"); in the manufacture of other salts and compounds of thorium; as a mordant in dyeing (nitrate). The chloride of thorium is utilised in the manufacture of pure thorium; the fluoride is used with other salts as an agglomerate for carbon electrodes during stages of electrolysis. The nitrate likewise enters into mixtures intended for the provision of luminous colours.

Mesothorium in the state of bromide or other preparations is chiefly used in obtaining luminous colours and varnishes which are phosphorescent in darkness (see article "Radium and Radioactive Substances").

The emanations of thorium are toxic. Animals (guinea pigs), after long ex-
posure to their action, die in about eight days. On post-mortem examination there is found hyperaemia of the liver, of the bone marrow and of the lungs, which show also infarcts here and there.

The influence of thorium X on the human body has been the object of study by Emile Weil and Lacassagne (1915), and by Averseng, Delas, Jaloustre and Maurin (1924), amongst workers handling thorium X, one of whom died of aplastic anaemia and another of myelogenous leucæmia. Another case of pernicious anaemia due to thorium X formed the subject of a communication presented by E. Weil, P. George and Laignel-Lavastine to the "Société de Médecine des Hôpitaux de Paris" (November 1926). There have also been reported cases of dermatitis, especially amongst workers engaged in the manufacture of incandescent mantles.

Friedlaender (1912) met with a case of generalised eczema, affecting a woman worker who had been engaged for two years on the operation of dipping incandescent mantles in a 30 per cent. solution of nitrate of thorium.

In 1913 he found in the case of another woman worker a form of eczema affecting the back of the hands, and especially of the right hand, with small patches on the forearm; the nails were sunken into the flesh as a result of swelling of the finger ends, and the skin of the palm of the hands showed ridges separated by deep cracks.

Lesser (1912) has also described a form of dermatitis due to mesothorium.

Measures of general hygiene and of cleanliness are requisite for the prevention of dermatitis and as a protection against troubles connected with radioactive properties. (For these, as likewise for legislation, see article "Radium and Radioactive Substances").

***

Timber Industry

INDUSTRIAL OPERATIONS

In many countries forestry work is an industry of great importance, especially in regions with temperate climates, where very extensive forests exist.

In the first place the forest was made use of to supply wood for heating or building, or for agricultural or domestic implements which were made by hand. The trade developed when the sawing industry appeared, which used water falls and rapids for power, and later steam and electricity. Some time afterwards came the development of the wood pulp, cellulose, paper, artificial silk, etc., industries for which it has been possible to utilise trees too small to be sawn as timber and previously only fit to be used as fuel. Forestry is essentially of a seasonal nature and has often to be carried on far from centres of habitation, and, year in year out, in different parts of the forest. The work includes first felling the trees, clearing and lopping, then felling, and transport in the forester's district. The sale of timber for fuel is also carried out chiefly in the forest at the place where the trees are felled. The timber is piled up to dry and then, when dried, is transported. Sawing into baulks and planks is also partly done in the forests by portable motors which use traction engines or motors for power. This method of working seems to be making great progress.

In addition to the felling, afforestation also takes place in forestry districts: the improvement of the forest soil by drainage and the appropriation of ground. Numbers of trees are then sown and planted. This work, as regards hygienic conditions and comparing the actual work, can be placed on a par with agricultural employment, especially with that of breaking up land for tillage.

The felling of trees is still often done by bill-hook, hachet and hand saw. But, as this work is slow and costly and necessitates a considerable amount of manual labour, inventors in all countries have been stimulated to devise practical cutting machines.

There are several quite distinct operations: clearing or removal of undergrowth, which consists in the removal of thickets, straggling shoots and thorn bushes; cutting small timber and large trees; topping off branches from trunks; and cutting them up into pieces. Each of these operations necessitates a special machine.

Cutting by burning with a metal wire, heated to a high temperature, has been tried, and also this method combined with movement of the wire. But these attempts have always failed, and cutting by actual removal of material seems to present the best solution of the problem. Felling on this principle may be carried out by saws with to-and-fro or circular movements; by hand saws;
by axes or mechanical cutters; by wire or chain ecraseurs; by drills making holes close together; or by the undermining action of ecraseurs of different shapes.

This work is done chiefly in the autumn and in winter before the rising of the sap. In cutting the face of the trunk is removed on the side towards which the tree is to fall. Then sawing is proceeded with at the same height on the other side. This operation is often done by two men working together. Often, for instance, if the weather is stormy, the tree may fall differently to what has been intended, and the workmen are liable to be injured, sometimes fatally, by the trunk or branches. During trimming and removal of the bark, the axe, especially during winter when the tree is frozen, may easily glance off and wound the worker or tear the clothes. These accidents are common and can only be avoided by using good tools and exercising care. The trees are often placed in such a manner that it is necessary to slide and roll them down steep inclines with a view to their further transport. The workmen are then exposed to contusions and wounds of various kinds.

In forest districts the ground is often rough: blocks of stone, stony ground, beds of streams, marshy ground, all these make transport impossible in the hot season. When, on the other hand, the ground is frozen and the uneven parts are covered by snow, it is possible to use horses as draught animals, which are almost everywhere indispensable in the forest. Only horses resistant to fatigue and cold and specially suited for the work can be employed. In the most northern parts of Scandinavia refrigeration is necessary.

Logs and wood fuel are conveyed for long distances over ice and snow.

In countries where there may be no snow it is possible to arrange for transport by rail or lorries, as in Canada and the United States of America.

In Norway, logs are often drawn in the following way: a hole is made at the thin end of the log and tackle is attached thereto. The position of the log is sometimes such that the tackle must be attached to the thick end. When horses are used for traction, if the tree gets jammed between stumps or large rocks, it may fly back when set free, and so hit and break the leg of the driver if he happens to be so placed that he can be struck. If the tackle is attached to the thin end of the tree, this may also cause a recoil, if the tackle or the hole in the timber give way. In this way the driver may sustain a fracture of the tibia or fibula, an accident which is typical of this kind of work (Th. Ansteensen). The tackle may also be fastened to a hook screwed into the tree. The logs are collected in a pile near to the forest tracks which are most suitable for transport. Later the transport is carried out on sledges specially constructed. The logs are transported to centres where they are all collected and from thence by road, rail, or river (floating) — this last being the most economical means of transport. When flotation is made use of, the timber must be sufficiently dry; otherwise it may sink when thrown into the water. That is why timber is deposited in a dry place and is never thrown during the autumn or winter into open water, nor put in a place where it may be covered with ice. It is only in early spring that it can be floated. The ice breaks up about the time of the melting of the snow, even the rivulets of forest districts contain sufficient water to float the timber to the large water courses and lakes, where it is collected by barriers formed by poles chained together, or gathered together as rafts which are then towed. Logs which have not been drawn over the ice are thrown down river banks into the water when the snow melts.

During flotation some logs become caught and remain fast, thus forming an obstacle which stops the logs floating behind. Thus in a short time a considerable obstruction may be caused. The lumbermen, furnished with long boat-hooks, have then to try to clear the entanglement. If the freeing takes place suddenly and unexpectedly the lumbermen are often drawn with the logs into the rapids; it is quite common for drowning accidents to occur in this way. Steel cables are often used in flotation work on rivers, and these may become worn and easily cause abrasions of the palm of the workers' hands. Cases of pyaemia have been reported as the result of these accidents.

Another wood industry which is very often set up in the depths of the forest is that of carbonising or distilling wood.

The plant and equipment vary according to the aim and object of the undertaking, whether for producing from the wood gas, charcoal, or volatile condensable products.

Such a factory always possesses a timber yard for the wood to be used during the year; the wood should be well air-dried, and, before it is used, at least twelve to eighteen months should elapse from the time of cutting. The yard may or may not have a saw-mill attached. The wood when piled up is
loaded on trucks or rails, which carry it to the carbonisation. Sometimes the transport is carried out by aerial transporters on cables or rails or by transporter elevators with an endless rope.

Artificial drying is carried out in horizontal tunnel-ovens heated by waste gases from retort furnaces. The trucks enter the retorts, from which they come out after carbonisation and then, after a pause in extinguishers, pass again to the timber yard after the charcoal has been emptied out.

The driers, retorts, and extinguishers are generally arranged in series.

The other buildings of the factory may be arranged in various ways: the removal of tar, the saturation, the de-alcoholisation of pyroligneous acid, and the preparation of acetic of lime and of soda take place in workshops in the immediate proximity of the retort building. As a measure of safety rectification of residues and treatment of tar are carried out separately.

Carbonisation can be carried out:

(a) In the forest, by the classical pile of the charcoal burner, still frequently used at the present time. This method has naturally been modified and modern mobile apparatus enables volatile products to be recovered.

(b) By furnaces called kilns composed of a large mass of masonry, which is, however, of less efficiency than other apparatus.

(c) By vertical retorts. They constitute the classic model used in Central Europe; although it presents some disadvantages, it still has its supporters.

(d) By horizontal retorts with trucks; in use in the U.S.A. and also adopted in Europe: this is the most advantageous solution for a big concern. There are many models of these retorts. They are generally of sheet steel, with pipes at the top for the escape of gas, and of cylindrical or rectangular form. They hold a train of trucks.

(e) By other types of apparatus which resemble more or less the types described, but present special features.

(f) By apparatus for the carbonisation of waste wood: a complex technical problem which has led to the production of numerous plants which are employed according to the bulk of the waste, in order to obtain condensable volatile products, or briquettes of charcoal.

(g) By gazogenes burning wood for the gasification of wood.

If wood is heated progressively in a retort connected with a cooling apparatus, it is found that at about 100° C. the water contained in the wood distils over. If a resinous wood is being treated it will be seen from the start that there is a slight layer of spirit on the condensed water. At about 150° C. this water takes a deep coloration and undergoes an acid reaction, whilst the wood begins to go brown. At about 250° C. the wood is in full pyrogenetic decomposition; this decomposition increases further towards 270° C.; it continues even if the heating of the retort ceases. The liquid obtained separates after standing into a lower layer of intensely black tar and an upper aqueous layer of a deep red colour which is known under the name of "pyroligneous juice". The gases which come off in clouds from the cooling apparatus consist chiefly of carbonic acid and carbon monoxide.

Above 300° the distillation proceeds more slowly; it is practically complete at about 400° and then only small quantities of gas and condensable vapours are given off. A residue of black and shining wood charcoal is found in the retort.

To sum up, the distillation of wood gives the four following products: wood charcoal, crude pyroligneous juice, wood tar, and gas. The proportion of these different products varies according to the kind of wood treated and the method employed in distillation (see diagram, fig. 154).

Pyroligneous juices consist of an aqueous solution of organic products of which the principal are acetic acid (3-10 per cent.), methyl alcohol (1.5-3 per cent.), acetone (0.1-0.2 per cent.). In addition to these products are found the homologues of acetic acid, allylic alcohol, furfurol, acetic aldehyde, methylethylketone, etc., and of dissolved tars as well.

The combination of the acid products extracted from this juice forms what is known commercially as pyroligneous acid: the combination formed by the other volatile products, among which methyl alcohol and acetone predominate, forms what is known as methylene. The tars are very complex products; those from non-resinous woods contain "caramels" more or less soluble in water, various neutral products, phenol products such as creosote, among which guiacol is the chief. In the case of resinous woods the oils of resin abound according as the wood contains more or less resin: these products are over and above the normal tars of the wood.
Industrially the distillation of hard wood gives a result approximately as follows: charcoal, 23-30 per cent.; gas, 18-25 per cent.; tar, 4-6 per cent.; pyroligneous acid, 4-5 per cent.; methylene, 1.2-1.5 per cent.

Integral distillation is carried on in retorts heated by an external furnace. In place of small mobile retorts, large fixed horizontal retorts have now been substituted, the charging and discharging of which are done from metal trucks which are filled with wood outside the furnace and are passed on complete trains into the retort house, whilst a train containing glowing charcoal from the preceding charge is rapidly drawn out from the retorts and removed to an extinguishing chamber.

In modern installations distillation of wood is done indirectly by the circulation of hot gas previously obtained from the gases of distillation as they leave the cooling apparatus, and heated by being passed over radiators.

For the distillation of such things as sawdust, shavings, and fruit stones, cylindrical rotary ovens are used.

The condensing apparatus placed at the exit of the retort house generally includes: a tar remover, which retains the tars without condensing the pyroligneous juice; a cooler for condensing the pyroligneous juice in bulk; and a "scrubber" to catch the vapours of methylene and acetic acid which are carried over in the gas from the distillation. The gases coming from this apparatus are combustible; they are passed under the furnaces of the retorts.

Among the products of distillation, charcoal alone, after rapid screening, is ready for immediate sale. As regards the rest the liquid products require first to be subjected to various processes.

The decanted pyroligneous juice contains acids, pyroligneous acid, methylene, and tars. These last, which are non-volatile, are separated by distillation; the pyroligneous acid is separated from methylene by making the mixed vapours pass to and fro through boiling alkaline solution (milk of lime). These processes are carried out by what is called the triple boiler method (méthode des trois chaudières). The pyrolignite of lime is evaporated and eventually gives a viscid mass which is dried to obtain the grey pyrolignite of lime, a deliquescent salt with 80 per cent. of pyrolignite of lime, which is generally sold in that form.

The methylene derived from the methylenic residue (phlegma) is recovered at 90° C. and is also saleable in this form.

Tars from resinous woods are generally directly saleable after a simple dehydration; tars from non-resinous woods are often used as fuel, but creosote can be obtained from them by treating the fractions of tar collected at about 200° C. with soda, which dissolves the phenols, which in their turn are precipitated by acids. The tars of resinous woods are used in rather interesting ways for the impregnation of marine cordage and fabrics. Purified oils from pine wood are used as inexpensive solvents. Tars from non-resinous woods give, besides creosote, guiacol, and their derivatives, some solvents, or low-priced burning oils (carburants).

Modern processes for the preservation of wood may be classed in two categories — in one process products with a tar base are used, and in the other process saline solutions.

In the first category the best process is that with a base of tar oil. A modification consists of a bath of heavy oil of tar at 140° C. followed after three
of or four hours by a bath of the same oil, but at normal temperature; and finished by a bath of chloride of zinc.

In the second category are classed processes using zinc or sulphate of copper, which, however, are being replaced more and more by processes of kyanisation. By this process, invented in 1838 by Kyan, a solution of bichloride of mercury and fluoride of sodium is used to impregnate the dry wood. The timber was steeped for twelve days in a 2-3 per cent. solution of bichloride. This solution is nowadays replaced by a mixture of fluoride of sodium and organic compounds (10 to 20 per cent.) generally of dinitrophenylamine, known under the name of "basilite".

It has also been found that bichromate of copper brushed or sprayed on is very efficacious for the preservation of timber, whether soft or hard and whether exposed to the weather or not. This solution is prepared by mixing warm solutions of potassium or sodium bichromate and copper sulphate.

The problem is a very important one in connection with the preservation of timber used for sleepers and telegraph posts.

It is very difficult to reach the heart (the central part) of timber with injections; hence timber which shows sap wood (young exterior part) and heart cannot be made completely aseptic. This is the reason why the injection of such antiseptic fluids as creosote and sulphate of copper is carried out under pressure in large watertight cylinders containing stacks of prepared sleepers. In order to obtain a better result a jet of steam is driven into the cylinders so as to remove the air: heating the timber opens up its pores; a vacuum is then created and it is only when this has occurred that the antiseptic solution is put in the cylinder. In order to obviate certain disadvantages timber is nowadays submitted to a "rapid artificial ageing" by which it is sterilised by eliminating air from the pores. This operation is carried out in an oven in which the timber is submitted to the action of a current of vapour from an organic material possessing a constant boiling point.

Very expensive and rare woods, either on account of the selling price or of the costs of transport, are not worked as solid beams, but are cut into very thin sheets for covering furniture made of common wood. This is the industry of veneering wood.

A slicing machine cuts a trunk into a sheet with a thickness of about two to three-tenths of a millimetre, which rolls off in one piece like a roll of photographic film. The machine is actuated by very exact clockwork movement, which has to be adjusted most accurately.

The thin sheets are next submitted to slow drying and then cut up and prepared for use.

It is interesting to consider the importance of the nature and composition of the glues used in veneer work, for they must ensure a close and definite solder between the sheet of veneer and its support.

In modern carpentry wood is worked by a large number of machine tools, although these have not been brought to the same state of perfection as the machine tools used for working iron. It will suffice, however, to mention here: to-and-fro saws; saws for carrying and cutting wood in pieces; machines for splitting, slicing, smoothing, planing, scooping out, drilling, morticing, carving, and copying; machines for making grooves, mouldings, discs, wheels, etc. Wood for brushes, casks, wheels of vehicles, wooden clogs, shoe lasts, etc.

**Pathology**

For forest workers the forest is their factory. The work is done in open air, and from this point of view under the best of hygienic conditions. It is animated, but is hard and tiring, for it is generally done in the cold season and in regions where the temperature may be very low. Frostbite, which naturally makes its attack on such prominent parts of the body as the ears, nose, cheeks, fingers, and toes, is very common.

Forest labour is often associated with accidents; sprains, contusions and wounds from blows are of course the most frequent; next come fractures of the legs and arms. These accidents occur while hewing, topping, and barking trees, when the workmen throw down, load, drag, or unload the timber on rough ground. Then again, frozen ground increases the risks of these accidents. In Norway where insurance against accidents is compulsory, the premium for work in the forests is average.

Such rheumatic affections as lumbago and sciatica are common among forest workers. So also is dyspepsia, while cases of phthisis are not uncommon.

As has already been mentioned, forest work is often carried out at great distances from inhabited centres. The housing provided for the workers in the forests is usually unsatisfactory. They have (although in some countries this happily is only a memory of the past) to be content with small damp huts,
badly constructed, exposed to draughts, consisting of a single room, in which the workmen sleep, prepare their food, eat, and live.

In the district of Frankfort some cases of poisoning by mercury were reported in 1921, as well as in 1922 in Saxony, among workmen employed on the impregnation of timber with bichloride solution.

In Austria workmen employed on the impregnation of timber with chloride of zinc (1920-1922) were troubled by the irritating gases given off during the operation. Into the tanks in which the timber was stacked zinc slag was placed and over this dilute hydrochloric acid was poured. The reaction was violent and gave rise to a great ebullition of irritant gas, which affected workmen even at a distance of 100 metres from the tank.

Some similar cases have been reported in the United States by Carey, McCord, and Kilker.

According to Sekouilitch (1925), persons employed on wood work experience, due to the action of dust, frequent acute attacks of respiratory disease. The lesions appear gradually to pass into chronic forms and even into malignant tumours (cancer in particular) which are situated at the level of the junction of the lungs and stomach. The products of distilling wood, consisting of tannins and essences, set up chronic irritation, so that, as with pitch and tar, the derivatives of wood manifest a carcinogenic action, which must be borne in mind.

According to the statistics of the Health Insurance Office of Leipzig, wood workers present a comparative sickness rate as follows:

<table>
<thead>
<tr>
<th>Disease Category</th>

</table>

The death-rate, which for the whole group does not exceed that for all insured members, exhibits exceptions for the groups of coopers and of basket makers. For carpenters of the United States a death rate is given of 231 per 100,000 living. For 7,883 deaths, 10.1 per cent. were from tuberculosis, 7.1 from pneumonia, 2 from other respiratory diseases, 14.4 from circulatory diseases, and 2.7 from diseases of the digestive organs.

Among the diseases of the skin noted amongst carpenters should be mentioned those caused by the liquids used, e.g. solutions of potash or caustic soda, liquids for polishing, usually with a base of methyl alcohol or of denatured alcohol, and the different lacquers. Cases of urticaria, erythema or eczema caused by poisonous or exotic woods (see that article) are common and occur on the face, the neck, the hands, etc. Cases of bursitis of the wrist, elbow, and even of the knee among men who lay parquet flooring are numerous. After incision it is not uncommon to find that the cicatrix is painful and that it causes incapacity for work. Whitlows and phlegmons are frequent. Out of 5,341 cases observed at the Bureau for German Carpenters, 518, or 9.7 per cent., were cases of cellulitis.

The finger-nails are often coloured by the different polishing liquids or by the dyes or mordants used for the wood. The dust of wood or of substances used, and mineral particles may become deposited in the skin and thus form stigmata characteristic of these workers. Occupational callousities are situated on the pulp of the thumb and index finger of the right hand and often on the central part of the palm, where a bursitis may also be found. Among carpenters these marks are found on the thenar region.

Among cases of occupational infection, the case of a carpenter employed in repairing a manger infected by a diseased horse is interesting. It appears that the workman developed sporotrichosis.

Some cases of lead poisoning have
be noted among carpenters who use lead colours such as white lead and chromate of lead, or coatings with a base of prot oxide of lead in oil of turpentine and spirit in order to give wood a dull appearance.

Schuckardt and Wormhing found among workmen engaged in the manufacture of rulers, coated with chromate of lead, a large number of cases of poisoning with irritation of the throat; this occurrence has also been confirmed by the statistics of the Sickness Insurance Office of Leipzig.

There should not be omitted cases of irritation of the eyes (blepharitis and conjunctivitis) due to dust or to vapours from the liquids used and especially to methyl or denatured alcohol.

A case of catarrhal blepharo-conjunctivitis from sensitiveness to "green wood" has been reported by Lagrange and Pesme (1922). Traumatic lesions from fragments of wood that fly off from the machines are fairly common.

Among carpenters cases of crepitant teno-synovitis have also been noticed produced by planing; among the men employed in planing, calllosities are found on the thumb and index finger.

Wounds of the hands, fingers, and forearms are frequent, due to such wood-working machines as drills, planes, circular and band saws; they are quite characteristic and often lead to amputation. The Vienna Bureau noted among compensation cases 16.4 per cent. of wounds. Burns occur chiefly on the back of the hand.

Among effects on the locomotor system are reported cases of flat feet; deformity of the knee in carpenters, but less marked than among bakers; deviation of the spinal column, an extra height of the right shoulder which is characteristic of carpenters who plane by pushing with the right hand and pressing with the left. According to Sternberg the chest of carpenters has a special shape: it is flattened with scapula alata.

The joints are frequently affected and articular rheumatism is noted by different authors as quite a common cause of ill-health.

Comparatively common are troubles of the circulatory system and in particular of the vessels, e.g. varicose veins, especially of the left leg among carpenters. The endocarditis frequently found among wood workers is explained by the rheumatism and inflamed tonsils noticed among these workers.

Numerous cases of bronchitis are reported due to wood dusts which, according to certain authors, predispose to tuberculosis. The experts blame the introduction of such machines as circular saws and drills for causing increased amounts of dust. Out of 100 carpenters living, 13.37 were affected with tuberculosis, whilst among other wood workers there were only 10.06 and the total for all other occupied males was 3.07 (Koelsch).

Out of 5,341 cases of sickness registered by the Office of Carpenters at Vienna, which included 10,071 members, 1,056, or 28.1 per cent., were cases of tuberculosis or other respiratory diseases (Sternberg).

There may be mentioned here the troubles due to the condition of anaphylaxis (asthma caused by the inhalation of dust).

Gastric troubles have been attributed to the bad habit of drinking the liquids used for polishing (see article "Occupational Diseases: Digestive System").

Numerous cases of neurasthenia have also been noted among carpenters which may be attributed to overfatigue.

**HYGIENE**

The conditions of work and lodging during work in the forests are such that the employment of children and young persons should not be approved. The work is too hard for persons whose physical development, not being complete, would certainly be affected by the strain, causing acute hypertrophy of the heart as well as serious chronic sequelae. The feeding, which is monotonous and unsatisfactory during the stay in the forest, predisposes to diseases of the digestion and to diseases of the blood and nutrition. There are then reasons for prohibiting the employment of young persons at this work and for improving the living conditions of the workers as regards both accommodation and food.

Forest labour is dependent on rain, snow, and fine weather. Hence there are certain difficulties in applying definite rules regarding hours of work in this industry; on the other hand, attention can be devoted to seeing that the auxiliary machines are properly erected and protected and that the tools used are adequate. For housing and accommodation in general the same minimum hygienic conditions should be required as are laid down for builders and agricultural workers (see article "Social Welfare").

As accidents during work in the forest are very common, and as doctors are only to be found at some distance away, provision should be made at the places of work for suitable first-aid appliances in sufficient quantity (see article "First Aid").
A wood-working factory equipped with machinery, if suitably arranged, includes today, besides the machinery, a complete system of ducts intended for trapping the dust and shavings, produced in large quantities by tools revolving at great speed, and for removing these outside. One part of the installation is intended specially to trap the dust. The exhaust openings are placed as near as possible to the tool in use. But it is important to avoid as far as possible setting up a draught which might be somewhat bad for a workman obliged to work in one corner of the workshop without moving about. This disadvantage is avoided by not placing the openings of the exhaust apparatus too near the tools, but at different carefully-chosen points in the workshop, e.g. on the floor, in corners, half-way up or near the ceiling; the atmosphere is then, however, less effectually cleared of dust.

Dust is then, however, less effectually cleared of dust. The exhaust openings are placed as near as possible to the tool in use. But it is important to avoid as far as possible setting up a draught which might be somewhat bad for a workman obliged to work in one corner of the workshop without moving about. This disadvantage is avoided by not placing the openings of the exhaust apparatus too near the tools, but at different carefully-chosen points in the workshop, e.g. on the floor, in corners, half-way up or near the ceiling; the atmosphere is then, however, less effectually cleared of dust.

Different plant is provided for the automatic removal of shavings, sawdust and small debris, which fall during work. The openings of the suction apparatus are in this case placed near the tool.

All measures must be adopted to ensure adequate provision necessary for preventing fires and dust explosion (see article "Dust").

**Legislation**

The employment of children and young persons is regulated in different countries by laws concerning the work of children, especially when concerned with dangerous or heavy work, or that done by the aid of power-driven machinery. In Belgium children under sixteen years are excluded from the grinding of wood used for colouring (mills); in Canada (Quebec) they are excluded, as well as girls under eighteen years, from the mechanical sand-papering of wood. In Holland the employment of young persons is restricted by conditions laid down by the Act of 1899 when the work is done by means of machines and mechanical tools (section 25 (1)) and in certain processes such as drilling wood, and carving and engraving on wood, when the work causes dust, unless the means of avoiding risks to health laid down by legislation are adopted. Without entering into details, it will suffice to mention here and emphasise the importance of safety measures for the prevention of accidents either during work in the forest, or in the wood-working workshops, and saw mills.

Special legislation concerning wood working has been laid down in the following countries:

**Australia (West):** Regulations of 24 December 1926 on timber yards where wood is cut up.

**Denmark:** A very detailed Ministerial Decree dealing with wood works, dated 21 May 1908.

**Finland:** Resolution of 30 December 1924 concerning saw mills and timber yards.

**Germany:** Measures of hygiene and safety drawn up by the authorities of Berlin, 31 March 1914.

**Great Britain:** Order of 8 November 1918 on the provisions of ambulance and first-aid appliances in saw mills and factories making wooden articles, and Regulations of 1922 on machines for wood working.

**Canada:** The Provincial Bureau of Hygiene of Manitoba laid down in 1925 a series of regulations for the sanitary control of timber-yards (hewing, etc.)

**Great Britain:** The Statutory Order Rules of 8 November 1918, No. 1489, lay down measures concerning first aid in the wood industry.

**Latvia:** The Act relating to the floating of timber is dated 29 December 1926.

**Norway:** The Act relating to the insurance against accidents of industrial workers, etc. (Lov om ulykker i forbindelse med industriarbeidere, m. v. of 13 August 1915, with the additional Acts of 26 July 1918, 26 June 1920, and 17 July 1925), as well as that relating to insurance against sickness (Lov om sykeforskring) of 6 August 1915, modified by the Acts of 15 June 1917, 23 July 1918, 10 December 1920, 16 February 1923, 17 July 1925) extend to forest workers the advantages laid down for other workers; there is also the Act relating to the housing accommodation of men and horses during work in the forests and flotation (Lov om husvær for folks og hester under skogarbeide og flotting), dated 30 July 1915. In accordance with this Act, the local authorities have power to lay down regulations for the construction and management of suitable accommodation for men and horses.

As an example the arrangements approved by the canton of Røken are given below:

1. Any building used for the accommodation of workmen employed upon forestry or flotation work during the period from 1 October to 15 May shall be:
   (a) erected on a dry site where water is easily obtainable;
   (b) placed on stone foundations or furnished on the outside with a bank of turf or earth round the walls;
   (c) provided with solid walls with good joints and a good watertight roof, with good doors and well-fitting windows, with shelves, with beds placed at least 40 cm. from the floor, with a heating stove either self contained or connected with a chimney, with boxes containing first-aid appliances and a cupboard for keeping food; and
   (d) provided with adequate means of ventilation.

2. Any building or shed used as a stable during the transport of timber during...
the period from 1 October to 15 May shall be
(a) erected on a dry site;
(b) placed on stone foundations or furnished on the outside with a bank of turf or earth around the walls; and
(c) provided with solid walls with good joints and a good watertight roof, with good doors and well-fitting windows and stalls with a wooden floor; the stalls should have a minimum width of 1.95 m. and a length of 2.05 m. including the manger.

3. In accordance with the orders of the Health Council, any forest owner is required to proceed with the erection of the buildings referred to in sections 1 and 2 before commencing felling timber for sale or for industrial production, or before the expiration of a period fixed by the Health Council and dated from the commencement of felling.

4. A copy of these Regulations must be put up in a conspicuous place in each of the living quarters concerned under sections 1 and 2.

Russia: Ordinance No. 144/733 of the People's Commissariat of Labour, dated 12 April 1923, deals with conditions of work in the open air during the cold season; Regulations of 10 May 1922 are concerned with measures of safety in enterprises working wood by mechanical means.

Sweden: The Act relating to insurance against accidents during work (Lag om försäkring för olycksfald i arbete), dated 17 June 1916, with additional Acts, extends also to forest workers.

Switzerland: Instructions prepared by the federal inspectors of labour for workmen employed in the wood industry.

Uruguay: Decree of 26 February 1927 on the working of wood by machinery.

Accident insurance covers forest workers in some countries (British Columbia, Estonia, Finland, France, Germany, Italy) either by special legislation, or by regulations laid down for the industry.

In other countries, the workmen are insured against accidents as soon as they work on premises or in any place where mechanical power is employed, even if the number of the workmen employed is lower than that laid down as requiring an employer to take out an insurance policy (Argentina, Austria, Brazil, Chile, Czechoslovakia, Norway, Rumania, Spain, etc.).

Mercurialism among workmen employed in the kyanisation of wood is compulsorily notifiable as soon as there is inflammation of the joints and of the subcutaneous cellular tissue among carpenters in Holland and cases of diseases of the skin (eczema and dermatitis) among ebony workers. (See also articles "Dust", "Liquids", "Skin Diseases", etc.).

Tin

Tin (symbol Sn.; atomic weight 119) is a metalloid which is not found in nature in the free state. The mineral most in use for obtaining it is carsterite (SnO2), which is found especially in Great Britain, Saxony, Bohemia, Spain, Chile, Mexico, India and Malacca. In the deposits carsterite is present itself in three forms: in veins mixed with pyrites and mispickel (rock tin); mixed with sand (stream tin); and in fibrous concretions (wood tin).

Metallic tin, white and of a brilliancy recalling silver, possesses a characteristic taste and smell. It is the most fusible of all metals (melting between 228 and 232° C.). It boils at about 2170°, but before that it gives off reddish white fumes. Rather tenacious and very malleable it can be reduced to very fine leaves without hammering.

Tin changes very little in dry or humid air—hence its use in tinning (for this see below); when cast into moulds it becomes coated with a fine scale composed of the oxide and dioxide of tin—tin dross.

Tin is readily attacked by nitric and hydrochloric acid, but sulphuric acid has no obnoxious action. Boiled with potash, it is converted into potassium stannite.

INDUSTRIAL PROCESSES

The amount of mineral is first increased by sorting, crushing and wash-
The shaft furnace is generally constructed of granite; at its base a pipe communicates with a blower. The combustion of the coke is incomplete and it is the carbon monoxide which effects the reduction. The ashes are retained in the first outflow basin — the first crucible — and the tin is next run into a second crucible and finally into moulds. The ashes are recovered and melted in a smaller furnace with ashes from the furnace grate. The reducing action of the iron permits of further recovery of tin.

A reverberatory furnace is that most frequently used. It has a sloping floor — the molten tin can thus flow outside into a crucible. A little lime or fluor spar is added in order to assist the melting of the gangue and it is rabbled to remove the ashes.

**Refining**

The German method depends on the passage of the molten tin over a steel plate bearing red-hot charcoal; the less fusible metals remain with the charcoal and the tin flows into the moulds. In Great Britain the tin is fused, the lightest scale is removed and green boughs are plunged into the molten mass. The gases developed bring to the surface all the impurities which are removed by skimming. This process is called "poling".

**Recovery of the Tin from Cans, etc.**

The waste materials most used are old tin cans. Many processes exist for the recovery of tin from them, of which the commonest are:

1. Treatment with chlorine in the cold state; then only the tin is attacked and is converted into the liquid tetrachloride which is easily separated.

2. By means of a soda solution containing a little plumbite or sodium nitrate: a current of air is passed until all the tin is dissolved and then electrolysis is practised. Stannate of soda is formed which is converted into stannic acid by means of carbon dioxide. The stannic acid is then reduced by charcoal.

3. The scrap is immersed in a solution of copper sulphate. The copper is precipitated in the metallic state and the tin dissolved with a part of the iron.

In the United States the increasing price of tin makes recovery more and more important, especially since the
TIN

use of de-tinned scrap finds a readier market than does the tinned.

In the Goldschmidt process chlorine is introduced under pressure in the detinning chamber. In the Van Scutz process a dry mixture of chlorine and some other gas, e.g. dry air, is made to pass over the mass of scrap. This is the more rapid process. The process is simpler and maintenance very easy.

In the Aker process liquid chlorine continuously liberating chlorine gas is used as the detinning agent. Another process employs a mixture of stannic chloride and chlorine in a closed vat.

The chlorine processes would appear to have the advantage over electrolytical methods in allowing of the treatment of large quantities at one and the same time and they reduce handling of the scrap to a great extent.

**Compounds of Tin**

The chlorides are the most important stannous chloride (SnCl$_2$), anhydrous stannic chloride (SnCl$_4$), and hydrated stannic chloride (SnCl$_4$·5H$_2$O).

Stannous chloride (salt of tin, tin crystals, muriate of tin) is prepared by the action on granulated tin of concentrated hydrochloric acid, containing sometimes a little nitric acid, in stoneware or copper vessels. Heating is effected by a water bath; the vessels require to be covered and the gases drawn off. When the action is completed, decantation follows and the liquid is concentrated in leaden crystallising vats.

Stannous chloride can also be prepared by using gaseous hydrochloric acid. The manufacture of chloride of tin leads to the formation of a certain quantity of arsenic chloride.

Stannous chloride is a crystalline substance with an astringent taste. When heated it melts at 40°C., at which temperature it loses its water of crystallisation. It becomes yellow on contact with air through absorption of oxygen and water vapour. In solution it is an energetic producing agent. In dyeing it is used as a mordant to freshen colours, and in calico printing as a discharge.

Anhydrous stannic chloride (perchloride of tin, tin tetrachloride, smoking liquor of Lebavius) is prepared by treating tin when hot with chlorine in special retorts. Several other methods are in use for its preparation, among which there should be mentioned, as particularly dangerous, that of causing mercury dichloride in powder form to act on an amalgam of mercury and tin; anhydrous stannic chloride is a yellowish liquid boiling at 20°C. and solidifying at —30°C.

The hydrated stannic chloride (butter of tin) is prepared in several ways: (1) by dissolving tin dioxide in hydrochloric acid; (2) hydration of anhydrous chloride with water; (3) treatment by chlorine of a concentrated solution of a tin salt; (4) mixture of salt of tin and hydrochloric acid, and then addition gradually of nitric acid (escape of nitrous fumes).

Hydrated stannic acid is a very deliquescent white mass. It is very soluble in water. It is used in dyeing as a mordant, for charging silk, and in the manufacture of tinned articles. The tin compositions known under the names of "oxychloride of tin", etc., are mixtures of stannous and stannic chlorides and oxychloride of tin.

Tin sulphide or mosaic gold is used for imitation gilding of wood and in calico printing.

It is obtained by a wet and dry method. The latter, although not so simple, gives the better results. The operation is done over a sand bath (good localised ventilation is needed to remove the very poisonous fumes).

Tin shavings are heated with mercury over a sand bath; an amalgam is obtained which solidifies on cooling. A mixture of sulphur and sal ammoniac, prepared beforehand, is added to the pulverised amalgams. Heat is gently applied until no more fumes come off; then the temperature is raised to red heat, after which it is cooled.

Mosaic gold occurs in beautiful golden yellow crystals and those of the best quality are found in the upper part of the tubes.

A scale of tints varying from clear yellow to bright orange can be obtained by modifying the composition of the mixings or by boiling.

**Uses**

Metallic tin is used for making vessels and utensils of every description, beer pipes, etc. Reduced to foil it serves for the packing of merchandise (chocolate, cheese). Tin foil is made by hammering or rolling, or again by melting it in such a way that the molten metal is made to flow on to a revolving wooden cylinder covered with felt. Mention should be made of the fact that certain foil called tin foil, which serves to wrap up tobacco and tea, contains up to 90 per cent. of lead. This is not without danger to the consumer. Tin foil, however, is now largely replaced by aluminium foil. The tinning of glass — a dangerous process because of the use of mercury, is no longer practised; all looking-glasses are to-day made by silvering. Tin has replaced lead, as the material for the bed, in hand file making.

Tin forms many alloys, of which the commonest are "bronzes" (see articles "Bronzes" and "Copper"); English metal or white metal (Britannia metal) which contains tin, antimony and copper with traces of iron and lead; German tin (Kayserzinn), of analogous composition is sometimes given the
name of "Urania metal". Modern English tin contains no lead.

In order to avoid lead poisoning in France a maximum legal limit used to be laid down of 16.5 per cent. in the composition of tin solder; now 10 per cent. has been fixed (a figure recognised since 1907 in Great Britain).

Antimony and bismuth are sometimes added with the object of hardening the metal and rendering it whiter. Zinc serves also in reducing oxidation.

The tin plates for stamping music contain tin (27.3), lead (68.7), antimony (3.4) and copper (0.6).

The plates were formerly obtained by hammering; the measures and the cooking utensils by moulding, and bringing the different parts together with soft solder. The bronze moulds were first heated and smeared with red ochre and white of egg or powdered with pumice stone or sandarac. The moulded piece was finished by rubbing and hammering on the anvil. The articles were burnt with oil and rubbed with whitening. A lead tin alloy is also much in use for making small toys where sometimes the lead is present in proportions varying from 40 to 90 per cent.

The two most important uses of tin, however, are the tinning of iron plates or iron utensils and the preparation of solder.

Tinning.—In tinning the sheet iron is first pickled by dipping it into sulphuric acid, then into a weak solution of hydrochloric acid and chloride of zinc. Scouring is the next process, effected by rubbing with sand, then the article to be tinned is dipped into a bath of molten tin covered with tallow. If culinary utensils or lids are being made, they are rubbed, after tinning, with cloths dipped in sal ammoniac.

The tinning bath often contains a high proportion of lead, which may rise to 70 per cent. The workpeople then run the risk of poisoning, especially during the operation of wiping or dusting.

Tin is not only used for the manufacture of domestic articles, but especially for making boxes in industry and tins for holding jam. To answer its purpose the material must have such special qualities as resistance and malleability in order to withstand, without tearing or cracking, the operations of stamping and setting, which latter has almost universally taken the place of soldering.

The ingot is furnished in steel factories by the Martin furnace, on a basic hearth, yielding a metal free from phosphorus, homogeneous (by the process of tapping at the source) and possessing the indispensable quality of resistance.

The ingot, after being re-heated in a continuous furnace, is converted by rollers into large plates of a given weight and volume to the metre. The large plates are folded in sections, each yielding four, eight or sixteen black plates of the required size.

The tin plate vessel or "bidon" is brought to red heat in a roughing furnace into which from twenty to twenty-five flat slabs can be placed. They then pass to the rolling mill and are subsequently folded in a special apparatus and finally trimmed with shears. The sheets are separated, re-heated and the operation continues. The metal is folded a second, a third and sometimes a fourth time; by rolling after each operation there are obtained four, eight or sixteen sheets of double length.

It is the plates of least thickness which undergo doubling over the greatest number of times. The fine plates are finally trimmed to a right angle and separated by hand by women.

The product obtained is crude steel which has oxidised and in spite of the successive "heats" has been cold-hammered. The scale is removed by pickling in a bath of sulphuric acid, generally of 12° B. (and reaches 35° at the end of pickling) and at 90° C. to remove the rust without at the same time attacking the metal too much. The processes of dipping into and removal from the bath are done mechanically. Washing in water then follows. The washed plates are then piled in cast steel boxes and left for twenty-four hours in a continuous furnace at 1,000-1,050° C. in order to give the sheets great ductility (black annealing).

After separation the sheets are rolled in the cold state to give them a brilliant polish and remove all roughnesses so as to reduce to the smallest possible limit the quantity of tin necessary for tinning.

A second re-heating to 750° C., a white pickling with sulphuric acid at 6° B., and a washing in water follow.

The black plates used to be tinned by the grease process or in the bundle. The sheets on leaving the water bath had to be dried before passage through the molten tin, because, if they were not, the water would decompose and seriously affect the success of the operation. As drying the sheets by hand was too costly and lengthy, they were dipped into a bath of molten grease where the water did not decompose but evaporated. The sheets then passed
into the tinning crucible at the optimum temperature. This bath was covered with a layer of grease a few millimetres in thickness with the object of preventing oxidation in the metal bath. The next process (brushing) consisted of placing in a holder containing molten tin, at a lower temperature with a layer of grease on the surface. The plates, during this process, were freed from impurities, dross, and the excess of tin which collects on the surface. Once brushed, the sheets were taken to the further bath where they awaited their turn to be introduced into the subsequent bath for the most important process, "tinning".

Generally speaking even with quite smooth sheets the layer of tin adhering on leaving the crucible was always too great and it was necessary to remove it and recover the excess of tin. Each sheet used to pass between two or three pairs of rolls where it was strongly pressed. The operation took place in oil or grease at 350° C.; the tin entered in a molten state (its melting point is 232° C.); ran along the sheet and fell to the bottom of the bath.

This method is to-day replaced by chloride tinning or sheet tinning, which is cheaper. In this process zinc chloride plays the role of grease in an almost boiling state in order to dry the metal to be tinned. As a matter of fact the chloride resting on the surface of the molten tin (its density being below that of tin) dries the fine sheet before it meets the subjacent layer of molten tin as it is very hygroscopic and the water evaporates. In the adjoining bath palm oil takes the place of the melted grease above the fused tin. The sheet arrives in this bath and is directed by a guide between two pairs of cylinders which roll it and rid it of the excess of tin. Thus the five or six processes needed in the older method are now replaced by a single one.

In Great Britain the old method, in which the Abercarn crucible was most commonly used, has given place to a new process bearing the name of the first factory to use it, "Melin Griffith". This method enables the tinning of iron plates to be carried out automatically as the sheet, introduced into the machine at the moment of dipping in the acid bath, is not handled again by the workman until the stage of sorting and packing is reached; handling is only required in exceptional circumstances. Without entering unduly into details (these were described by Collis and Vernon in 1925) it will suffice to say that the new machine ensures for the workman better conditions than those attainable by previous methods; less radiation of heat, a lower temperature in the neighbourhood, more rapid current of air, and less escape of fume and dust. Although the work of charging the furnaces is more arduous, nevertheless less physical force is needed and work is less monotonous than with the Abercarn process.

The black plates thus obtained are greasy and it is necessary to free them of this before any other operation is done, especially so when they have to be pressed. For this purpose the sheets are passed through a mixture of plaster and sawdust; the cylinders receive and subject them to rollers covered with felt or rubber alternately with rollers covered with sheep skins. This brushing operation is repeated by passing the sheets through rollers of another kind arranged perpendicularly to that where they had first been placed. Sorting and packing follow. By washing the surface of sheet iron with a solution of hydrochloric and nitric acid the "watered metallic appearance" is obtained.

Many tin articles (capsules, tubes, etc.) are made by stamping leaves of tin, or more commonly by stamping sheets of lead sandwiched between tin sheeting.

Solder. — Solder is an alloy of lead and tin. In ordinary solder the two metals are in equal proportions. Hard solder contains two parts of lead to one of tin. The manufacture and use of solder presents some danger (see article "Soldering (Lead)"). "Putty powder" is a combination of oxide of tin and oxide of lead and is used in the manufacture of enamels and in polishing. It is prepared by heating an alloy of tin and lead. In cut glass windows a putty powder can be used which contains no lead (see article "Glass").

Sources of Risk

The work of extraction of tin does not present serious risk for the workmen employed. The presence of silica, however, in the veins of the mineral may favour the occurrence of respiratory diseases. Though the state of health of English miners is sufficiently serious, special causes have been at work in bringing this state of things about. Thus, many of the men emigrated to South Africa so that the personnel left to start work in the mines was physically below normal. Further, the workmen who returned from South Africa, where they had worked in the Rand mines, sometimes showed lesions of the respiratory organs, and they offered but slight resistance to causes of damage.
The metallurgy of tin does not create special dangers. It will suffice merely to mention the possible risk from carbon monoxide poisoning.

Tin cannot be regarded as an industrial poison because it is very difficult to find conditions under which any serious quantity of the metal can be absorbed into the system.

Lehmann's experiments have shown that 10 to 14 mg. of tin per kilogram of an animal body weight, taken over a period of from thirteen to twenty days can be tolerated. Salant (1914) has studied the absorption of tin by rats, administering to them 10 to 50 mg. of tartrate and chloride of tin for twenty-three days; then 20 mg. for three months. Salant did not find any obvious symptoms except a tendency to emaciation after very big doses (50 mg. per kilogram weight).

The stannic compounds exert only a slight action. They are used largely in the colour and varnishing industries. The chloride causes dermatitis in dyers and tinsmiths as a result of its caustic action. The tetra-chloride used in charging silk, has set up trouble as described by Jolles, Salzer, and recently (1927) by Pedley. According to the American Bureau of Mines the presence of 8.5 parts of tetra-chloride per million of air causes coughing; a content of 3 mg. per 1,000 is tolerated by a worker, whereas 10 to 15 mg. per kilogram weight causes coughing; a content of 0.085 mg. in the atmosphere, which is thick, window panes are covered with soot, etc., unless measures to improve hygienic conditions are adopted.

In the manufacture of tin plate the different sources of injury are heat, steam, dust, acid gases, fatty vapours, etc. These pollute the atmosphere, which is thick, window panes are covered with soot, etc., unless measures to improve hygienic conditions are adopted.

In this industry besides the risk of poisoning from the metallic vapours and from arsenuretted hydrogen gas the lesions due to handling the sheets must be borne in mind: injury to the hands and legs; risk of burns; the heavy work of carrying the sheets and handling the heavy strips.

The acid bath is kept in a vat lined with sheet lead and cases of lead poisoning have been reported among the cleaners, the lead having been dissolved in the acid (Maisoneneve); this source, however, has not been described by Layet.

The well recognised effects set up by the fumes given off in the course of galvanising the sheets were made the subject of an enquiry by a Committee in Great Britain in 1926. The enquiry covered the use of sulphuric acid which often replaces hydrochloric acid in the process of pickling; the use of mechanical means of lifting the sheets into the pickling baths and the use of hoods to remove the acid fumes, and the possibility of applying local exhaust ventilation. The Joint Commission appointed a sub-committee in 1926 to study the ventilation of galvanising workshops, but the sad plight of the industry at that time did not allow the enquiry to complete its labours. Nevertheless in many instances improvements have been effected. On the other hand, contact with the acids has been the cause of localised damage to the hands and arms, especially amongst those men employed in measuring the degree of acidity in the bath and testing all the time in order to ascertain whether the submerged articles have reached the desired condition.

Maintenance of a red heat in the furnaces is a cause of ocular troubles and particularly of cataract.

In the manufacture of capsules and tubes, etc., where the tinfoil is handled, cases of lead poisoning occur now and then. This, too, occurred fairly often among the workpeople engaged in the process known as "suction" in the tin ware industry. This operation consisted in drawing in the air with the mouth from the inside of hollow pieces so as to test their airtight condition.

**STATISTICS**

In Great Britain a high mortality from tuberculosis has been shown to exist among the tin miners. The figures for 1910-1912 give the following comparative mortality rates: from all causes 2,190 (as compared with 1,000 for the whole male population); pulmonary tuberculosis 851 (186); respiratory diseases 768 (174); accidents 68 (58); bronchitis 286 (57); pneumonia 81 (90).

Incidence of lead poisoning among tinders, makers of capsules, etc., is not high; it generally takes a mild form. For Great Britain the number of notified cases of plumbism in tinning is as follows: 1921: 6; 1922: 5; 1901, 10; 1902, 11; 1921, 1; 1922-1923, 4; 1924, 3; 1925, 4; 1926, 2; 1927, 3.

The figures of 1921-1923 for mortality (Registrar-General's Occupational Mortality Report) among the tin and copper miners of Cornwall is much above the average (as much as 41/2 times as high as the general rate). Despite reasons
in explanation of the gravity of these facts (as e.g. return of miners suffering from silicosis from the Transvaal, etc.) it has to be admitted that the excess mortality among miners is higher than that in any other class of work. This excess is very high in middle life (four times the average for the age-group 35-65), and, for the age-group 35-45, it reaches the enormous figure of 450 per cent. Tuberculosis is present 12.5 times more frequently than the average; respiratory diseases 6.3 times. The mortality is also high for diabetes, cerebral haemorrhage, chronic nephritis, myocardiitis, and even for cancer, which would not appear to have any connection with the work of tin mining. Readers are referred to the original report mentioned above (page LXVII) which contains very interesting details, too long however to be quoted in full here.

So far as tinsmith's work is concerned, the death rate from all causes only exceeds the average by 1.1 per cent, and does not offer any characteristic features. In France the cases of lead poisoning from tinning are not numerous and it is the same for the manufacture and manipulation of metal capsules for bottles.

The inspectors of factories in Germany, however, brought light in 1913-1914 in tin plate works and concluded that respiratory affections were fairly frequent among them.

Further, Udo J. Wile has described the special lesions found among animals working near the foundries in the copper and tin mines in Cornwall which are attributable to arsenic. In tinning of iron plates the workers may suffer from dermatoses as well as from injuries which in themselves lead to skin affections. Thus for example Fischl, in a capsule factory at Breslau, found eruptions on the lower third of the forearms, taking the form of papules, pustules, livid bluish areas, as well as on the external surface of the thigh, and on the back of the foot. The lesions itched much, but were not accompanied by constitutional effects. Fischl thought that the cause might have lain in the tin or lead or cleaning oil.

The lesion described has also been spoken of as "tin itch" among tinsmiths and among workmen coming into contact with capsules made of tin.

In addition to injuries to the hands and forearms mention should be made of the condition described by Mori of damage to the Achilles tendon which is characteristic of persons working on tinned strips. The lesion occurs to either the workman engaged in bending the strip (and precisely to the foot which has to exert pressure on the sheet) or to the workman beside him who is affected by the strip as it leaves the roller and is tossed on to the metal floor of the workroom. The strip glides along, jumps and generally strikes the workman on the Achilles tendon.

The skin of the picklers appears to be bleached and hardened by daily contact with acid, and shows cracks and numerous excoriations, especially at the articual folds. Sometimes the sensitiveness of the skin is diminished; the workpeople complain of numbness of the extremities.

Inside the mouth a chronic irritation of the gums bordering on the teeth is noted. The majority of old picklers are edentulous; the gums are pale and hardened; around the teeth and remaining stumps they take on a bright reddish colour with slight sponginess. The teeth and stumps are blackened and rough. Gradual change takes place in the enamel and tooth dentine which becomes smaller and smaller until it breaks at the base.

Possibly changes in the saliva and teeth brought about by the acids induce dyspepsia in time with gastralgia of which the picklers complain.

Slight irritation of the conjunctival mucous membranes of the nose and throat are also reported, but no spastic forms of bronchitis origin nor asthmatic attacks.

If the apparatus is not completely protected by a hood connected up to an efficient exhaust, the fumes, escaping freely into the atmosphere of the shed, set up coryza, dryness of the throat, oppression, sometimes marked, in the chest, loss of appetite, emaciation, etc. Collis and Hilditch in 1911 examined a thousand persons employed in tin plate works and concluded that respiratory affections were fairly frequent among them. But the data obtained as to tuberculosis were not sufficient to enable definite conclusions to be drawn.

Of the tinner examined by Walther 22.9 per cent. were found to have myopia. Leaving aside those of school origin he was able to say that the occupational origin was very frequent (15.6 per cent.)

Cataract was found by Healey (1921) among 200 steel workers aged thirty-five years and over, who were exposed
to the action of the heat rays. Among 350 workmen of thirty-five years and over he found opacities of the lens as follows: 35-40 years, 17.5; 41-45 years, 18; 51-55 years, 62; above 55 years, 65.

The cataract showed itself in two forms: a posterior cortical cataract similar to that occurring among glass-blowers and finishers, and in the form of a cortical opacity, in striae, wedge-shaped, with the base directed below.

The lesion is invariably found on the side exposed to radiant heat.

The English statistics tend to show that incidence of tumours is higher among tin and steel workers than the average. The presence of arsenic in the mineral might be thought of as explaining this frequency. Diseases of the nervous system and urinary tract are also higher than the average.

The incidence of lead poisoning among persons engaged in making capsules for bottles has been studied in Germany by Laurisch (1898) and Rasch (1900); in Italy by Carozzi (1909), etc.

Lastly, it should be recalled that Paschkis described in 1912 dermatoses due to the use of a bath of tin (chloride) and hydrochloric acid to charge silk. The lesion affected the fingers of the right hand and thumb of the left; it commenced as a round ulcer, fairly deep, with well-defined edges and of a brownish red colour. In 1927 Pedley had occasion to treat a workman sixty-six years of age who for thirty years had been in contact with tin tetrachloride for the purpose of dissolving it in hydrochloric acid. The patient complained of sore throat, a feeling of coldness in the chest (not in the extremities), morning sickness, pains in the shoulders and lower limbs, constipation, cough, etc. Pedley attributed the symptoms to neurasthenia. Nevertheless tin was found in the urine and faeces. The same symptoms were observed by Jolly (1901) and in a case studied by Salzer (1918). The first case was that of a woman who had worn socks dyed with a tin salt (she had paralysis, anaemia with albuminuria, cachexia). In the second case the patient was a man who wore false teeth — an upper and a lower set made of tin to the extent of two-thirds.

DETECTION

There rarely occurs in practice the necessity for detecting the presence of tin. For research methods in this connection the reader is referred to a text-book of toxicological chemistry.

HYGIENE

In tin mines the same measures should be adopted as are taken in mines in general. In Cornwall the following have been adopted: lowering the dust content in drilling by a water spray or other efficient method; prohibition of resumption of work under half an hour in a place where a mine has been exploded, in order to give time for the dust to settle and for ventilation of the spot; wearing of respirators, wet crushing and grinding of the ore or other efficient method, etc.

While in the metallurgy of tin or in the manufacture of the plates, tending the travelling belt usually adopted does not involve serious risk for the workmen, nevertheless the rolling and doubling, etc., of the black plates, work at the furnaces, the bending of the plates rough trimmed by hand, and separating them expose the workmen to high temperatures. Near the furnace and rolling mills the temperature reaches 400° C. and the fat which serves to grease the material is constantly converted into smoke and flame by the bearings.

In front of the furnaces a plenum system of ventilation pumps in pure air at a height of 2½ m. from the ground. Opposite the furnace man and the roller man vents controlled by dampers direct the air currents over the workpeople at a speed which can be calculated not to inconvenience them by chilling them too much and yet at the same time to give an adequate air supply.

Pickling, carried out at a temperature of 90° C., naturally occasions acid fumes (sulphuric acid). The automatic lifting enables the workpeople to remain at a convenient distance from the tanks, and consequently outside the range of obnoxious fumes. In order to remove the fumes from the workroom the tanks and apparatus are provided with hoods which hinder all re-entry of air likely to throw back the injurious fumes, which would enter the lower part of the hood and so get into the workroom.

In order to prevent all dissemination of the fumes of tin, palm-oil, hydrochloric acid, zinc chloride, etc. — fumes which are injurious as well as disagreeable — given off in the course of tinning and scouring, recourse must be had to different systems of localised ventilation. At the same time the work must not be interfered with while ensuring the protection of the workpeople from the fumes. On the other hand the palm oil vapour, especially in winter time, on coming into contact
with the side of the hood, liquifies and runs down to the edge of the hood.

The degreasing agents (plaster, sawdust) are heavy and tend to fall down, whilst the system of exhaust ventilation for the fumes tends to draw them towards the roof of the shed. The dust is thus subjected to a kind of mixing without being got rid of.

This is why in factories where this question has been carefully studied and where the methods employed for increasing the output have brought many inconveniences to light, it has been decided that tinning and degreasing should be kept separate from scouring.

The workroom for tinning and degreasing is divided into two parts, one of which is a large hood equipped with louvres in which the ascending force of the fumes at the immediate moment of their production is utilised. By the side of the ordinary means of air entry there is an additional one which can be regulated according to the wish of the tinner. The arrival of the black plates at the tinning crucible is effected by a mechanical travelling endless belt which is attended to, just as is a printing machine, by one workman, who is not inconvenienced by the smoke or fume of palm oil as he is at least 2 metres away from their source. Similarly an identical arrangement carries the sheets to the place where they are scoured. Here the dust given off is of little importance as the dust raised is made to fall to the ground. Maintenance of a slight negative pressure increases this tendency, bringing the plaster and sawdust into a channel and so preventing them getting into the workroom.

LEGISLATION

Women and young persons under eighteen years of age are prohibited in France from work in sheet iron and varnished metals where toxic substances are used.

A special Code of Regulations controls work in metalliferous mines in Great Britain (see Mines Regulations, 1911). Welfare Orders referring to tin plate works came into force in 1907 (No. 1035), and in 1909 (No. 750) Regulations for tinning of metal hollow-ware, iron drums and harness furniture have been enacted.

In France a Decree of 1 October 1913 prohibits the operation of testing airtightness by suction with the mouth (pompage) in the tinware industry.

Lead poisoning from tinning is scheduled for compensation in France, Great Britain and Russia, as is also the case with mercury tin amalgam in France and poisoning by tin chloride in Switzerland.

For compensation for cataract see article "Occupational Diseases: Eyes".

Titanium

Titanium (symbol, Ti) is a metal (metalloid) which is not as rare as has been believed up to the present. Its chemical properties are closely allied to those of silicon. It is found as a dioxide in certain minerals, known as rutile, brookite and octahedrite; the first is the only important one from a practical point of view. In the form of titanate, titanium is found chiefly in perovskite, ferrocalcic titanate (CaFeTiO₃), and in titanite silico-titanate of calcium (CaTiSiO₄). It is also found in zirconates and vanadates, in numerous salts of lime, of iron and of manganese, and in oxides of rare metals. The most abundant mineral source is titanate of iron, or ilmenite; with 25 to 55 per cent. of TiO₂.

Titanium was obtained in the free state by Berzelius. To-day it is obtained from its oxide by heating it with very finely powdered aluminium. It appears as a grey metallic powder or
as a mass resembling steel, being just as hard and as difficult to melt, but it can be worked at a red heat.

In industry it is added to steel up to 10-15 per cent. in order to make the steel more resistant (ferro-titanium); to carbon and tungsten for the manufacture of electrodes, electric lighters and the filaments of incandescent lamps. It is used as a catalyst in the synthesis of ammonia, and for absorbing the last traces of water in vacuum bulbs used for electric lamps and X-ray tubes, as titanium readily absorbs oxygen and nitrogen.

Among the most important compounds are: chloride of titanium, which has a pungent smell and fumes on exposure to the air, giving off hydrochloric acid and titanic acid; it is one of the most powerful-reducing agents, and is used as a mordant in dyeing and for dyeing skins; tetrachloride, which is used in the preparation of the trichloride and other salts of titanium; iridium, iridium is a suitable rate, and, during the war, of smoke screens; the tannate, which is used as a mordant, and, especially, the double oxalate of titanium and potassium; ferro-cyanide, a green pigment destined to replace arsenical pigments; sulphocyanide, a strong reducing agent, used also in dyeing; and, finally, natural oxides, rutile and ilmenite, used in ceramic work for glazes. Among the most important compounds in use is white or oxide of titanium (TiO₂), which is used as a mordant in dyeing, as a pigment or body in the India-rubber industry and as the pigment of artificial plastic materials, oilecloth and linoleum, and in the preparation of rice powders and beauty creams.

It is chiefly in the paint industry that it has acquired an ever-increasing industrial importance. In 1906, the waste from the treatment of titaniferous bauxite was used for the first time for the preparation of paints and mastic, and, at the same time, in Norway efforts to treat ilmenite to produce iron led to a process for manufacturing a white pigment from titanate of iron or ilmenite. Numerous investigations led to industrial trials in America and Norway, and to several processes, most of which have now been given up. It was in this way that the chloride process did not become industrialised, although it may one day be used for the extraction of pure titanic acid from some ores of titanium. There are seven processes of preparation (Cartorot and Devaux, Princetown and Monk-Irvin). Among the processes adopted, one of the most extensively used is that based on the treatment of ilmenite with sulphuric acid; ilmenite is attacked when it is heated in large cast-iron receptacles at about 120° C. with concentrated sulphuric acid. The product of the reaction is dissolved in water, then decanted to recover the mineral not attacked; and the ferric salts present in the solution, which might interfere with hydrolysis, are reduced by nascent hydrogen. The resulting sulphate of titanium is a somewhat complex product and contains also sulphate of titanyl.

One of the most important phases in the manufacture is certainly the operation of heating the titanic acid solution with sulphuric acid in the presence of water. After clarification, in order to remove small quantities of colloidal substances present, the sulphate is allowed to crystallise between cooled rotary crystallisers. The oxide of titanium is then centrifuged, concentrated in a vacuum, heated and precipitated by hydrolysis by diluting at a suitable rate. Next, the oxide of titanium, which still contains sulphuric acid, is filtered on acid-resisting filters. It is washed and neutralised with a volatile alkali. Next, it is treated with given quantities of colloidal solutions of oxide of titanium, digested separately with hydrochloric acid. A colloidal gel of oxide of titanium is obtained which is filtered, dried and calcined in a rotatory furnace, at 900° to 1,050° C., so as to make at least a fixed fraction of the oxide of titanium pass into a microcrystalline state. It is this final operation which decides the quality of the product. The new bodies formed take on more and more a colloidal character.

Titanic acid in the form obtained by hydrolysing the purified solution of titanyl sulphate is a white powder, possessing a new structure. The oxide, on being taken from the furnace, is disintegrated in a crushing machine, which pulverises it into extremely fine particles. After a final washing the pigment is freed from moisture, then thoroughly dried, and passed into an air-separating apparatus in order to isolate a light powder, with great homogeneity of particles, possessing a specific gravity of 3.7, compared with white lead 6.4, zinc oxide 5.5 and lithopone 4.15, and having an index of refraction lying between 2.30 and 2.60, one of the highest of the various white pigments. In some factories "composite pigments" are prepared, in which titanic acid is the element giving to the material quality and colour, as well as that body which is normally provided by sulphate of baryta; in other factories very pure titanic acid
is prepared, which is used in different ways in the industry for paints made with oil, alcohol or with mixed solvents and cellulose varnishes.

To-day oxide of titanium plays a part of first importance among the white pigments which may be used in substitution for such toxic pigments as white lead and lead sulphate. While some experts maintain that pigments of titanium are more difficult to make into a paste than those of zinc, and do not react with drying oils, industrial practice, on the contrary, shows that the problem of how to use pigments of titanium is being solved in a very satisfactory way.

Oxide of titanium is of all the pigments the one which gives particles of the smallest size (1 μ for titanium against 5 to 10 μ for white of zinc and 50 to 80 μ for white lead); further, oxide of titanium is the lightest of the white pigments used in the painting industry. Hence, its fineness and lightness ensure stability to its suspensions.

As regards covering power, without entering into details, which are to be found in the works of Olsen (1921) and Noel-Heaton (1922), quoted by Vila, mention is here confined to remarking that the values obtained in the last of these returns under "weight of white lead" and "weight of pigment" show that white lead always has a covering power inferior to that of zinc oxide, considering the weight deposited, and, at most, equal to zinc oxide when the volumes of these powders are taken into consideration. The same covering power of lithopones slightly exceeds that of the oxides of zinc of an equal quantity. The covering power of whites of titanium made up with 25 per cent. of TiO₂ is only slightly superior to that of lithopone; but the pure pigments alone have a covering power decidedly higher.

Although pigments of titanium have a weak affinity for oil, it is nevertheless possible, according to American and Norwegian investigations, to obtain more stable coatings when the pigments made from titanium are mixed with other substances. The substances, introduced to give body to the materials, with the object of lowering the price, are now becoming means for improving the product, if introduced in the right proportions and under favourable conditions.

The paint industry has at the present time succeeded in overcoming the difficulties which prevented titanium from being effectively crushed, difficulties which were certainly greater than those met with in the case of zinc oxide and lithopone. By means of perfected apparatus, titanium can very easily be formed into a paste with 15 per cent. of oil.

As regards solidity and protective properties, it should be said that at the present time there can be found on the market paints made with a basis of titanium which, for solidity and protective power, are at least equal to products made with a basis of other pigments.

The value of a paint depends on several factors, which are not, however, of equal importance when estimating the value of paints made with a basis of different pigments. Thus, for example, the active reaction of the basic pigments with the acid bodies which are formed during the oxidation of the drying oils — a reaction which renders the coatings obtained with these pigments more resistant — cannot be claimed, or only in modified terms, for pigments of titanium, even when they contain appreciable quantities of one or the other of the known pigments. Technique answers this objection by oxidising with heat the drying oils as a preliminary, so as to make them lose a large part of the acid products which tend to form in the cold state. The problem of a good paint with a basis of titanium is somewhat complicated. But by the help of a better combination of titanium either with the active pigments or with the body, by the most careful selection and treatment of the binding substance and the diluents, and, further, by means of a formula for the composition of the paint, corresponding to practical requirements, the industry has obtained products giving every satisfaction.

It cannot be hoped that the use of titanium white will be developed by modifying the titanium oxide industry, but rather by an improvement in the paint industry in general. By enlightening as to the substances available for use and as to the special characteristics of these products, the industry may be persuaded to make intelligent use of such substances, as is already the case in the linoleum industry and that of artificial india-rubber.

**Pathology**

Oxide of titanium is devoid of toxicity in consequence of its chemical inertia. Some experiments made by Schoofs in 1927 on guinea-pigs showed that food mixed with titanium white does not cause any disturbance. Kerkhof did not find, post-mortem, any trace of
titanium other than in the alimentary canal.

Lehmann and Herget (1927) also showed experimentally that oxide of titanium is not absorbed by the body and that it does not exercise any toxic effect. After having administered to animals, for periods reaching sixteen months, varying doses of oxide of titanium, either alone or in the presence of mineral and organic matter, these experts did not find any trace on chemical examination of the principal organs, with the exception of the digestive tract, which contained a quantity corresponding to the dose administered. During life, the animals did not present any special disturbance and autopsies on the killed animals showed the organs to be histologically healthy.

In 1928 Vernetti-Blina, by exposing dogs to the effect of oxide of titanium introduced by the respiratory or digestive route, or subcutaneously, was able to show, more than once, a complete absence of toxicity for titanium white. The same expert confirmed his observations on workmen employed in closed workplaces on operations which gave off titanicate oxide dust. Clinical examination of these men, and even radiological examination, showed that any appreciable lesion was absent.

**Tobacco**

Tobacco is considered to be one of the most insidious poisons against which humanity has to protect itself. Tobacco was discovered in America in the Island of San Salvador, by the men who went out with Columbus, and was introduced into Europe by the Spaniard Friar Thvet in 1517; its diffusion is due to the naturalist Hernandez, of Toledo. It is an interesting fact that some seeds were sent from Portugal to France by the Ambassador Jean Nicot de Villemain, to cure Catherine de Medici, who had long suffered from neuralgia.

The medicinal properties of tobacco had been recognised in the country where it originally grew, and this was an important factor in favour of the new product. But whereas in France the use of tobacco spread under the name of "Queen's herb", elsewhere its introduction was fiercely opposed; its use was strictly forbidden under pain of very severe penalties. However, by degrees all classes, including persons in the highest social position, were won over to favour the adoption of tobacco. Then persecution on the subject ceased. Richelieu was the first to impose a duty on tobacco, thus converting a vice into a source of revenue to the State. At time went on increasingly well-organised monopolies ended in becoming virtual State industries in some countries. At first tobacco was used as snuff; the habit of smoking it was not adopted until later on, when the soldiers of the French Revolution and those of the Empire set the fashion.

The recent war completed the establishment of this dangerous habit, particularly among women and quite young persons.

**TECHNICAL FACTS**

Tobacco is a herbaceous annual, sometimes a bi-annual, plant, of the solanaceous family, which includes fifty species and sub-species. It received the name of Nicotania Tabacum in memory of Jean Nicot. It is produced chiefly in the United States and in British India; but the favourite kind on the market is that which is grown in Cuba. In Continental Europe Oriental tobacco is the most popular.

The tobacco plants are grown from seeds, sown in hotbeds, in nursery gardens, in garden frames or greenhouses. The seedlings are pricked out and transplanted in cultivated fields. In March, and at the beginning of July, the grower starts to pull off any withered and dirty leaves near the ground, and also any branches of flowers; then he gathers the other usable leaves as they gradually turn yellow. The leaves are put to dry in the sun for several hours, and then are threaded on a stick one by one, and carried to the drying rooms. The leaves are cured either in the sun or in the shade, or with artificial heat, according to the quality of the tobacco. There is no universal method. The cured leaves are sorted, tied up in bundles or "hands", and, in January, arranged in heaps, the object being to induce a first fermentation.
The leaves are sent to the factories wrapped in cloths. A first selection is then made, so as to separate the leaves for various types of tobacco. The leaves are then shaken, and beaten, so as to get rid of all dust and grit, and arranged in layers, each layer being sprinkled with a solution of 5-10 per cent. of sodium chloride. At this stage sometimes a second fermentation is allowed to take place; it is obtained by means of washings with weak solutions of salts, alkalis or acids. Improvement of the flavour and the aroma is obtained by "steeping", i.e. immersion of the leaves in a special solution, each factory having its own particular recipe. The leaves are drained or pressed, and are then left in the mass, sometimes for a long period, sometimes for a short period. There are special machines for removing the stems from the leaves, and, if necessary, for cutting them into strips. Next, the leaves are torrefied; then they are dried and rapidly cooled in a current of air. Finally comes the preparation of the cigars, cigarettes and snuff—all of which is to-day done almost entirely by machinery.

The cultivation of tobacco, especially in countries which are chiefly given up to small holdings (metayage), is left to the women and children, as it only entails light work which is fairly remunerative, and because in this way all members of the farmer's family can be employed.

An enquiry into the conditions of labour in the tobacco industry in Java was made in 1928 by the Volksraad of the Dutch Indies. According to this enquiry, tobacco is cultivated on land belonging to the villages and rented for one year to the manufacturers. The village land is divided into five sections, of which one-fifth is reserved for the village communal requirements; two-fifths are let to the tobacco manufacturers and two-fifths to the coolies. In the fields the cultivation of tobacco by the manufacturers, and of rice by the coolies, is on an alternative system, so that a field planted with tobacco one year may be cultivated the following year by a coolie on his own account. As a rule the coolies and their families supply the labour for the tobacco plantations. Whilst cultivating their rice fields, they increase their income by working at the same time for the tobacco manufacturers. In this way the coolie can claim half the rice crop which he has grown in the fields let out, after the tobacco has been harvested; one-half is his in return for his labour, and he can buy the other half at reduced prices.

In fixing the hours of labour, the manager of the plantation takes into account the fact that the coolie must also have time to work on his rice plot.

There are a good many stages in the work that has to be done in the fields up to the time when the tobacco is harvested, and it goes on for several months. The coolie, helped by his whole family, children included, works in the drying rooms, which are built of bamboo, and are situated quite near where the coolies live. Sorting operations take place in large sheds, which are considered to be enclosed premises, and thus, according to Order 25, children under twelve are excluded from work in them. The different operations which take place in these sheds are carried out by men or by women, according to the nature of the work.

**TOXIC ACTION**

There are two classes of tobacco: mild tobacco, containing 1 to 2 per cent. nicotine, and strong tobacco, with 6 to 10 per cent. Fresh or dried tobacco is more toxic than the manufactured product.

Tobacco contains several poisonous substances: nicotine, nicotianine, nicotinie, nicotene, nicotelline; and traces of malic, citric, oxalic and nitric acids. In tobacco smoke there are to be found pyridine, picoline and collidine, as well as gases of hydrocarbons, carbon monoxide and carbon dioxide, ammoniacal salts, especially cyanide of ammonia, and cyanogen.

Of all the poisons mentioned above, the most poisonous, and, from the point of view of occupational hygiene, the most interesting, is nicotine \((\text{C}_{10}\text{H}_{14}\text{N}_2)\).

Nicotine is a strong bivalent base, united to malic and citric acids. It occurs as an oily liquid, boiling at 247° C., with a strong smell; it is soluble in water, alcohol and ether, and turns brown when exposed to the air. It may be obtained from an ordinary extract of tobacco, and also synthetically, starting from \(\beta\)-amino-pyridine, salified with mucic acid.
Nicotine has been known in its impure state for a great many years, for in a book dating from 1686 Brogiani, of Florence, mentions an oil from tobacco capable of killing animals in a few minutes; Lemery, in 1696, speaks of a poisonious oil which is obtained in the course of the dry distillation of tobacco, and Vauquelin, in 1809, draws attention to the presence of nicotine in tobacco leaves. It was isolated in the pure state in 1828 by Posselt and Reinmann.

Although pure nicotine is very toxic, this fact has been exaggerated; 5-10 cg. will kill a large dog quickly; a dose of 20-21 mg. per kilogram kills a rabbit (Grasset and Parenty, quoted by Kohn-Abreast).

Tobacco causes both acute poisoning and chronic poisoning. The channels by which it may enter the system are the digestive tract, the respiratory passages and the skin, but it is only the latter which are of interest from the occupational point of view. The channels of elimination of the poison are the urine, saliva, sweat, and possibly the milk.

Occupational poisoning may appear in the acute form, or the chronic. However, tobacco poisoning is never found in people who are employed in the cultivation of tobacco, not only because their work is not continuous and lasts a short time, takes place out of doors and alternates with other forms of agricultural activity, but chiefly because, in the green leaves, only superficially dried, the nicotine is united with the organic acids, and because in the dried leaves it is only liberated slowly and in small quantities in ammonia, water and carbon dioxide (Allevi). It is only during fermentation when the leaves are being prepared for cigars that nicotine is liberated.

This absence of risk from poisoning is not only characteristic of strictly agricultural work, but also of labour of preindustrial nature, which deals with the preservation and utilisation of the tobacco before it is sent to the factories, i.e. sorting, putting in boxes and packing.

After an enquiry in 1915 on the manipulation of Oriental tobacco as it is carried on in the province of Lecce (Italy), Carozzi came to the conclusion that the fact that the various operations are carried out on withered leaves which have not as yet been subjected to fermentation, capable of transforming the organic substances (acids or bases) present in the leaves, explains the innocuousness of this work, although in the course of the various manipulations a small quantity of nicotine is liberated, estimated actually at 0.2-0.3 per cent. But as this always remains in the leaves united with organic acids, it cannot be liberated or pass into the surrounding air as a harmful agent.

When the tobacco reaches the factory it becomes a source of danger, chiefly in the processes of sorting and fermenting the leaves, and in the manufacture of cigars. The workers are exposed in the first case to the inhalation of tobacco dust; in the second case to the inhalation of injurious fumes; and in the third to the contact with the wet tobacco leaf.

Ramazzini was the first to recognise the injurious nature of work on tobacco. But whereas many experts have confirmed the opinion of the Italian scientist, others have contradicted it, and have even put forward the opinion that work on tobacco can prevent and cure infectious diseases, among others tuberculosis.

No one disputes the local action of tobacco dust and juice, especially during the first months of work. This action is observed on the skin and on the exposed mucous membranes. It has even been stated that tobacco dust and juice finds its way, or is conveyed by the unwashed hands, to the genital regions, especially in the case of women, and causes conditions of irritation, which often extend to the vagina.

The general symptoms caused by tobacco may be produced by the dust inhaled or swallowed, by the fumes which are liberated during certain operations, especially fermentation, and by carrying food to the mouth with hands that have not been carefully washed and are soiled with tobacco dust or juice. Hencke found in the tobacco dust of certain factories 0.56 per cent. of nicotine.

Chronic poisoning in the case of workmen who handle tobacco has long been a question of debate.

In France, Pointe in 1828 drew attention to cases of purpura among the men who worked in factories at Lyons; in 1842 Viscount Siméon published a summary of reports from doctors who were attached to the French tobacco factories, according to which the workers appear to have exhibited a power of resistance to infectious diseases superior to that of the population in general: at Morlaix this was proved in the case of an epidemic of dysentery, and at Tonneins of sweating sickness, which raged among the rest of the population.
But Ygonin in 1867 and Poisson in 1881 expressed doubts in regard to these statements.

There are available reports of numerous enquiries on the influence of tobacco on the development and evolution of tuberculosis among the workers in the factories. There is no doubt that tobacco dust can cause irritation of a mechanical and chemical nature of the upper respiratory tracts. But whereas in the early days the conclusions arrived at pointed to an injurious effect on the health, more recent enquiries have resulted in contrary conclusions.

In 1885, for the first time, the Baden Office of Statistics felt they were justified in accepting the view that there was a connection of cause and effect between pulmonary tuberculosis and work on tobacco in the manufacture of cigars. In 1890, Worishofer drew attention to the extremely high death rate from tuberculosis among workers on tobacco; this mortality, however, was attributed by Thiele and Walther to other causes of a social nature, although the industry in question might influence the development of the disease among juveniles, especially where there were any persons suffering from open tuberculosis in the workshop.

A Swedish enquiry of 1921 dealing with nearly all the factory workers in this industry (84 to 98 per cent.) and including a systematic examination of the workers, showed that the number of cases of tuberculosis was no higher than that for the rest of the population. Similar reports have been issued in Austria by Jehle, in Spain by Oliva, in the United States, in Finland, in Italy by Celli, and in Great Britain; Brunbaum concluded his enquiry in Baden in 1926 by saying that this industry is free from danger to health for the workers, and that their state of health is the result of the social conditions of a poor population receiving low wages, with sub-normal constitution. The same opinion has been expressed by Muller, Berghaus and Borschatschewsky. The latter studied 1,658 workers in Odessa factories for five years, and in 1930 found symptoms of tuberculosis in 691 cases. But he is of the opinion that these cases were not due to the occupation, which does not appear to exert any predisposing influence towards tuberculous infection. It is true that results vary according to districts, and that in certain factories a higher incidence from tuberculosis has actually been found than in the occupational categories notoriously affected by this disease.

But this statement is only of relative value, for other factors besides the work would seem to play their part.

Further, this opinion has been modified in the course of recent years, through the use of more modern methods of diagnosis. Examination, even with X-rays, is said not to have shown the existence of pulmonary tuberculosis, although sometimes revealing a condition of tobacco poisoning.

Holtzmann in 1930 studied this industry in Baden, and came to the conclusion that bad food, poor housing and particularly the lack of segregation of the sick and healthy, the poor constitution of some of the workers engaged, especially some of the women, and also early sexual relations, are more important factors than that of tobacco.

Gross in 1931 has stated that in Dresden the rate of sickness among tobacco workers is not much higher than the rate of sickness for the general body of workers inscribed at the Dresden Insurance Office: tuberculosis, manifest or suspected, stands at 2.9 per cent. against 2.6 per cent. among the other workers; influenza at 16.3 per cent. against 17 per cent.; respiratory diseases at 12.9 per cent. against 12.6 per cent.; gastro-intestinal, cardiac and cutaneous diseases, as well as injuries, occur more frequently among the general body of insured workers than among tobacco workers. On the other hand, tobacco workers suffer more often from genito-urinary diseases, exhaustion, and nervous diseases, and Gross considers that this particular frequency can be accounted for by the large number of women among the personnel of the factory, which amounted at Dresden to 372 women for every 100 men.

In the opinion of Gross, nicotinism does not constitute an occupational illness among tobacco workers; he denies the existence of any pneumoniais, and does not consider that work on tobacco can render pulmonary tuberculosis worse. The respiratory troubles observed consisted in simple catarrhal irritations of the upper respiratory passages, and were chiefly found among the beginners.

In Italy, from 1922 to 1928, the mortality from pulmonary tuberculosis among the factory workers was 0.116 per cent.; thus it is lower than that in the large industrial centres (Fraccarela). Out of an annual average of 21,381 persons examined, 18,303 of whom were women, there were 249 deaths from tuberculosis.
In the opinion of Jötten and Kortmann, tobacco dust is the least harmful of the various kinds of dust with which the same workers came into contact. After several months of inhalation, the animals only manifested a very mild tendency to pneumoconiosis, and the elastic tissue had not been affected. This dust did not influence the development and evolution of the tubercle bacillus; and this infection did not become serious, even in the case of animals which had been poisoned previously. In fact one may say this dust does not play an important part in the production of any pneumoconiosis.

Another point about which there is much difference of opinion concerns the harmful effect of tobacco on pregnancy, and also on the child when it is born.

Whereas Delaunay, Decaisne, Quinquaud, Layet, etc., admitted that this influence was harmful, Ygonin, Lebail, Poisson and others have denied it, but have at the same time recognised that the sexual organs in a woman are stimulated to over-activity by tobacco.

As a matter of fact, several authorities have observed among women addicted to smoking a high incidence of disorders of menstruation, especially menorrhagia and a greater frequency of post-partum haemorrhage (enquiry by Giessen, 1906).

Nicotine has been found in the amniotic fluid by Ruef and Stolz; and in the milk by Kostial, although De Blasi and Simonini did not succeed in detecting it; for this reason it is thought that the action of the alcaloid may be harmful to the embryo or foetus as well as to the new-born child during nursing.

Guzzi and Resinelli La Torre among the gynaecologists, and Guido Pieraccini, Gayard and others blamed work on tobacco for an increased number of miscarriages among women who worked in the factories. On the other hand, Vaccari, Aymérich, Montuoro and Rossi do not admit this action of tobacco on pregnancy, and Monti held the opinion that there was a diminution in fertility.

As far back as 1897 an enquiry by Etienne among seventeen families in which there had been 93 cases of pregnancy pointed to the conclusion that tobacco had no harmful effect on pregnancy. The same enquiry brought out that, whereas the infantile mortality was more than double that of the general population, this could be reduced by providing facilities for the mothers who had returned to work to nurse their children, and also by prohibiting return to the factory for a minimum of four to six weeks after the birth of a living child. An enquiry by Courtois-Suffit in 1908 dealing with 17,000 French women workers confirmed the opinion that tobacco seems to have no influence on the births, and that miscarriages among these particular women were not more frequent than among the rest of the population. Among their children disease was not more frequent nor the death rate higher, so long as they were properly looked after, than in any other class. The children who were breast-fed by careful mothers developed normally, and exhibited no particular sign of ill-health for which the quantity or quality of the milk might be held accountable.

In Italy, Peri, Montuoro and Celli in 1906 came to the conclusion that the number of miscarriages and the infantile mortality were not so high as were found in other factories that were under observation for the purpose of comparison. From 1922 to 1928, in Italian factories employing 149,668 workers (128,163 women), with an annual average of 21,381 (18,303 women), there were registered 16,346 confinements, giving an annual average of 2,332, and 941 miscarriages, with an average of 3.75 per cent. of confinements.

Mention should be made of the effect of fumes liberated chiefly in the course of drying and fermenting the tobacco. The composition of these fumes has not yet been well determined; but special notice should be taken of their effect when they have been accumulating for several hours in close workshops, particularly during the summer heat. The fermentation generally goes on for some time, on an average for two months, and, although it is unusual for the air of the workshop to be contaminated to the point of becoming harmful to the health of the workers, it is quite a different matter when fermentation is accelerated, a process accompanied by a considerable liberation of gas and fumes. Here the rate of illness among workers manipulating the tobacco, which is undergoing artificial fermentation, is found to be higher than that observed among workers in contact with the "slow" fermentation.

Seiff in 1931 affirmed that the quantity of nicotine which is liberated from the apparatus used for moistening the tobacco, and from the bales of tobacco which are taken out of it, is considerable, as is shown by the table below:
in order to ascertain the degree of harm-
women declared they preferred work-
serious.
ness
cephalalgia, palpitations, intense sick-
diminution in visual acuity.
ning in the shade in the sheds rather

The other harmful products — carbon monoxide, carbon dioxide, ammonia and furfurol — do not seem to be taken into account. Out of 12 work-
men employed on the apparatus for accelerated fermentation, Seif found, during the season 1930-1931, that 9 men, aged from twenty-two to forty,
three years, were taken ill several times, and 4 of these were obliged to be absent from work during periods varying from eighteen to forty-three days. The sick men complained of cephalalgia, palpitations, intense sick-
ness and nausea, sometimes with diminution in visual acuity. Several of the men vomited during work, more particularly in the evening. A diag-
nosis was made of nicotine poisoning, with intestinal disorders, more or less serious. Five cases of gastric catarrh among the workmen were also attribu-
ted to nicotine.
The enquiry at Java mentioned above pointed out that in the sorting sheds the fermentation of numerous heaps of tobacco at a temperature of 50° C. and higher is bound to vitiate the atmos-
phere. It is difficult to remedy this trouble, as a certain degree of humi-
dity must be maintained constantly in the sheds, and so there can only be a moderate amount of ventilation. The investigators engaged on the enquiry observed, during the month of April, temperatures of 27.7° to 30° C. in the morning, and 31.1° to 33.3° C. in the afternoon. Yet the workers did not complain of the heat; in fact the women declared they preferred working in the shade in the sheds rather than in the sun.
The investigators recommend that a technical enquiry be carried out in order to ascertain the degree of harm-
fulness of the nicotine contained in the atmosphere of the sheds. They also intimated that it would be useful if a medical investigation were under-
taken into the length of time worked by the boys who help to heap up the tobacco, and of the effect on the women and girls who work in the sheds of their bent posture. In several sheds the investigators found children of four and even younger, who had come with their mothers, and were trying to unfold tobacco leaves; they therefore state that they consider the presence of any child under twelve years of age should be prohibited if it is medically demonstrated that there is danger therefrom for the child. In such cases, there should be on the premises near the shed where the sorting is done, a place reserved for children, who should be placed under the care of a person paid by the firm.

The acute form of poisoning occurs particularly among those persons who for the first time take up work on tobacco. It occurs in a transitory form which, however, depends on the capacity of the individual to become accustomed to the injurious influence of the surroundings.

According to some rather old observa-
tions made by Kostial, 72 out of 100 newly engaged cigar makers, girls between twelve and sixteen years of age, became ill during the first six months. The disorders under observation were diagnosed as follows: cerebral congestion, nervousness, precordial pains, palpitation, anaemia, gastritis, enteritis, conjunctivitis, lassitude, feverishness, insomnia, cold sweats and anorexia. But Ygonin considered these disorders to be of unusual occurrence.

Other experts have reported headache, giddiness, a sensation of throat con-
striction, nausea, vomiting, conjunctival irritation and watering of the eyes. Legge has reported a fatal case — that of a workman employed in "steeping" the tobacco; he apparently developed an acute attack of nicotine poisoning. Cases of acute poisoning have also been described among vine growers who had used nicotine for disinfecting the plants.

Lockhart, of Nottingham, is quoted by Bridge as describing in 1890 a case of acute poisoning in a woman who, whilst carrying a wooden jug of concen-
trated nicotine, upset a little on her sleeve (about 00 grm.). Although she immediately turned up the sleeve and washed the skin with warm water, yet thirty minutes later she suddenly collapsed. Emergency measures with artificial respiration were employed. She was incapacitated for several days.

The nurse who looked after her and had touched the dress stained with
nicotine was also affected, though slightly. Quite possibly absorption of the alcoloid through the skin was helped by cleansing the skin with warm water. Overton in 1930 examined five women employed in packing fumigation paper saturated in nicotine. The women wore masks, but two complained, before using the protecting apparatus, of troubles due to dust from the paper. Overton stated that both women were suffering from pellagra.

There is general agreement in the opinions held with respect to acute poisoning; but there is great divergence of opinion among experts in respect to chronic poisoning.

Very divergent results from enquiries carried out in the factories of several countries are on record. According to Allevi, these negative results do not exclude the possibility of a chronic occupational tobacco poisoning. They only prove the non-existence of such a toxic condition among the factory workers examined, which is quite a different thing. In order to exclude the possibility of occupational poisoning, it would be necessary to cancel all the observations and research carried out up to our times which point to the contrary. Since this is not possible, it becomes essential to find some explanation which helps to reconcile apparently irreconcilable facts, in other words to make seemingly contradictory results agree.

While refraining from the acceptance of certain opinions that are somewhat exaggerated, Allevi does admit that there is such a thing as chronic poisoning by tobacco. The negative results emphasise the fact that tobacco poisoning, like many other occupational diseases, is tending to disappear, thanks to continuous advance in industrial technique and hygiene. As a matter of fact, the favourable results of the greater part of the enquiries come from countries where tobacco is a monopoly, whereas less favourable come from those countries where the industry is free, and carried on either at home or in small factories, e.g. in Great Britain, where, according to Giglioli in 1906, the sanitary conditions were good in the large factories, whereas in the small factories many of the women complained of persistent headache, nausea, general debility, and menstruation troubles; while the number of miscarriages reached 60 per cent., which is very high.

A rapid summary of the special pathology of tobacco workers gives the following facts:

Among native workers employed on the tobacco plantations, e.g. in Sumatra, ulcers on the legs have been observed, and also a fairly high incidence of cases of ankylostomiasis. The coolies of Northern Borneo know very well that in the course of preparing the soil for the planting they are exposed to a risk of contracting dermatitis, caused by contact with the Anacardiacae and in particular with the Rhus and the Rhus.

In the factories the workers suffer from dermatitis due to contact with the leaves, the dust or the juice from the tobacco. The lesion is situated generally on the back of the hands, but may affect the face, the back and other parts of the body, and, in particular, the genital organs, where the dust and juice may be conveyed by unwashed hands (Davis, Karrman). Sensitisation tests with nicotine have proved that an allergic condition can undoubtedly be established.

Besides these cases of dermatitis, other forms have been noted which are persistent and recurrent (Roth, Stephani), especially among cigar-makers (United States, 1916), caused by the glue used for sticking the cigar covering, or by olive oil used for the manufacture of roll or plug tobacco (Collis). In these last cases, numbering 27, the lesion was situated especially on the back of the left hand. The persons affected are those employed in the selection of the finest leaves (picking) or in stemming, for removal of the nerver of the leaves, or in taking to pieces the tobacco milis, called "maces" after the fermentation, or in grinding or sifting snuff. Overton in 1929 often came across cases of dermatitis among workers employed in stemming, and stated that the use of tools, which diminished manual labour, seems to reduce the frequency of these affections.

Damage to the nails of one or two fingers has also been observed on one or both hands. Listengarten in 1930 wrote that the free edge of the nail becomes thin; the nail comes off and a very painful hyperkeratosis follows, caused by the dust. The worker is obliged to stay away from work. The nail grows again, but as a rule the resumption of work, at the end of a fortnight, causes the nail to come off again. According to this authority, the lesion is due to a chemical rather than a mechanical agency.

Cases of gingivitis, acute and chronic, and of stomatitis have been reported among tobacco workers by Fischer. Of 158 persons who were examined only
35 had a normal buccal mucous membrane.

Catarh of the respiratory tract, inactive tuberculosis, but no cases of pneumoconiosis, were described by Kruger, Rostoski and Saupe in 1928; cases of bronchitis were reported by Allevi, Rosenfeld and Pirnet; cases of pulmonary congestion by Lavagna; and also cases of asthma.

At the autopsy on two women workers, Zenker observed brownish patches on the pulmonary parenchyma and on the hilum glands as well as very marked atrophy of the lungs. He attributed these lesions to the action of tobacco, and described them under the name of "tobaccosis".

Whilst Landis, Funk, Smyth and Miller do not admit injuries of the respiratory apparatus caused by tobacco, basing their opinion on the results of an enquiry made in Philadelphia factories, Landis in 1920 acknowledged that there is a certain amount of tobacco dust in the air of the workshops, but states that the clinical and radioscopic examinations of the people employed are such that all question of pulmonary lesion may be excluded.

In 1921 Palitzsch resumed the study of pneumoconiosis caused by tobacco, and feels justified in concluding, according to his clinical and radioscopic observations, that this "tobaccosis" resembles very closely anthracosis, in the peculiarity of having the lesions at the back of the eye caused by tobacco; Dowling in 1892 reported a case of bronchitis, some years after the individual had worked at a tobacco factory, and described them under the name of "tobaccosis".Whilst Landis, Funk, Smyth and Miller do not admit injuries of the respiratory apparatus caused by tobacco, basing their opinion on the results of an enquiry made in Philadelphia factories, Landis in 1920 acknowledged that there is a certain amount of tobacco dust in the air of the workshops, but states that the clinical and radioscopic examinations of the people employed are such that all question of pulmonary lesion may be excluded.

Disorders of the digestive organs are reported by Kruger, Rostoski, Saupe, Allevi and Rosenfeld, and appear to be rather frequent. Experimental facts (Adler, Josué, Boveri, etc.) and statistics prove the incidence of such arterial lesions as endarteritis.

The toxic elements of tobacco, and in particular nicotine, seem to settle on the nervous tissue (Guillain and Gy), which would explain the disorders mentioned, and certain local manifestations, such as optic neuritis, as well as cases described under the name of "hysteria" due to tobacco (Gilbert). Peri reported that nervous disorders were frequent among women who worked in an Italian factory, especially during the catamenial periods; and Neiding has noted the same among women workers at Odessa. This authority also considers that nicotine has an injurious effect on the internal secretory glands, and in particular on the thyroid gland.

Most of these experts hold that in the case of these women workers a greater number of disorders of the sexual system is observed than among the general population. In an Austrian report of 1893, Hirsch, Stephani and others affirm that tobacco causes marked sexual excitation. But diseases of the genital apparatus are fairly frequent among the women workers of the factories, and it is chiefly to the repercussion in which these lesions involve the organism, rather than to tobacco itself, that Carozzi attributes the clinical picture known under the name of "chronic tobacco poisoning" among cigarette makers who visit the Industrial Clinic at Milan.

Tobacco dust causes marked irritation of the eyelids and conjunctiva, and causes, especially among beginners, lachrymation and a sensation of burning in the eyes. In the Celli report, cases of conjunctivitis and keratitis stood at figures of 1.58 per 100 sick persons and 0.96 per 100 workers respectively.

Legge has also reported two cases of amblyopia, and several cases of occupational origin are mentioned in medical literature.

Galezowski and Ely in 1897 reported lesions at the back of the eye caused by tobacco; Dowling in 1892 reported a case of amblyopia in a woman who had worked for five or six years and did not smoke; this expert collected facts about 25 cases, observed among 203 workers, of whom 23 were men and moderate smokers, and 2 women who did not smoke at all; De Schweinitz in 1896 observed a case affecting a woman who did not smoke and had worked on tobacco for several years. In Cincinnati factories, Dowling observed disorders of the eyesight, with reduction in visual acuity and confusion of colours in the central vision, attaining a frequency of 5 per cent. But he considered that these disorders were not of occupational origin, as women who did not smoke were not affected.

**Hygiene**

The workshops should satisfy all the standards required by hygiene, with strict cleanliness and the removal of dust as far as possible. The industrial technique should be based on the adoption of mechanical methods to an ever increasing extent; and machines should be supplied with apparatus for
carrying away dust and disposing of it. Thus in the Italian factories from 70-80 per cent. of tobacco dust is successfully removed.

Good ventilation should be ensured and also adequate heating of the workshops.

Every possible measure should be adopted which limits as far as possible contact with tobacco in the form of dust, juice or liquid fumes from the maceration. These measures are more particularly essential in certain departments, e.g. drying, stemming, maturation of the cigars, and the manufacture of snuff.

Further, the fermentation premises should be separated from those where other operations are carried on; and women and young persons should be excluded. Steps should also be taken to ensure the complete isolation of workshops where the leaves are dried and the maturation of cigars is carried on.

Fig. 155. — Type of crèche provided in an Italian tobacco factory.

Measures of personal hygiene, such as lavatories and douche-baths, and working overalls and lead coverings for the women should be provided. Where possible well-managed canteens should be erected for workers who cannot go home for meals.

Strict medical examination should be instituted when signing on, and renewed periodically. As the labour is generally supplied by women, it is advisable to institute a welfare organisation to watch carefully over the health of the women, especially if they are pregnant or have families. It is advisable for pregnant women to quit work during the last months of their pregnancy, and not to return under four or six weeks after the confinement. Facilities should be provided for nursing infants by establishing or developing crèches and special rooms for nursing the babies; installations of this type have for some time past proved their great usefulness in several countries, e.g. in France and Italy (see fig. 155).

LEGISLATION

The employment of women is forbidden in drying shops in Switzerland, and in the Argentine in workshops where the bales of tobacco are opened and where dust is liberated. The employment of boys under fifteen is forbidden in the United States (Delaware) on stemming and sorting; in Poland in tobacco factories under sixteen years; in the United States, on sorting, manufacture and packing and sometimes on stemming (Alabama, California, Kentucky, New Jersey, Massachusetts, Ohio and Pennsylvania); in warehouses, manufacture of cigars and in workshops where tobacco is prepared (Arizona, Nevada and Wisconsin); in France in workshops where the "maces" are taken to pieces; the employment of children under fifteen in Italy on opening of bales, sorting leaves that have not been moistened, and on fermentation; transport of fermented products, drying in closed workshops, crushing, sifting, manufacture of extracts and cutting; under sixteen in Greece and in Spain.

Women under eighteen are not allowed to work in tobacco factories in Greece; the employment of women under twenty-one is forbidden in Spain and Italy on those operations enumerated for boys in the countries in question. Special legislation for tobacco factories exists in Germany (17 February 1917; the Regulations of 17 November 1913 deal with domestic work on tobacco; in Prussia, a Ministerial Decree of 19 February 1929 provides protection for persons employed on certain operations in the manufacture of cigars); in Denmark (Decree of 1 June 1904, amended 31 October 1906); in Estonia (Decree of 1925); in Egypt (14 Au-
Almost insoluble in water, it mixes with alcohol, ether and sulphide of carbon. It dissolves sulphur, phosphorus, iodine and, especially, in very large quantity, fats and resins. When set on fire, it burns with a flame which produces much soot.

Toluene constitutes 10-25 per cent. of crude benzenes. It is formed by the dry distillation of balsam of Tolu, of various resins and by the distillation of tar. It is extracted also by distillation from mineral oils, from oils of coal tar and lignite when subjected to a high temperature. When solvent naphtha is submitted to the process of "cracking", or partial breaking down, it liberates large quantities of toluene in the presence of Blau gas. It is obtained industrially in large quantities as a by-product from coal tar, in cokers and gas works (see article "Gas Works").

Crude toluene is purified from the carbohydrates of the fatty series, such as olefinic and paraffinic hydrocarbons, which always accompany it, by washing it with hot sulphuric acid, to which has been added a little nitric acid. It can also be purified by heating with metallic sodium.

Commercial toluene distils to a 99 per cent. purity below 112° C. It is chiefly used as a solvent mixed with benzene. It is used in the manufacture of pharmaceutical products, perfumes, intermediary products of colouring materials, and in the manufacture of its derivatives and other products, such as benzaaldehyde, benzoic acid and saccharine.

Large quantities of toluene are nitrated and used chiefly in the form of trinitrotoluene (see that article).

Among the derivatives of toluene the following should be mentioned in particular:

**Nitrotoluene**: ortho-, meta- and para-nitrotoluene (C₆H₄(CH₃)NO₂) and the dinitrotoluenes (C₆H₄(CH₃)₂(NO₂)). As regards these derivatives, see the article "Nitrobenzene".

**Halogen derivatives**: The following are the most important: benzyl chloride (C₆H₅CH₂Cl), benzyldene chloride (C₆H₅CHCl₂) and the chlorides of benzene or phenylchloroform; and benzene trichloride. They are fluids with a strong aromatic odour; they cause in experiments on animals violent manifestations of irritation after exposure lasting for several hours.

**Amine derivatives**: The most important are represented by the ortho-, meta- and para-toluidines, homologues of aniline, which are obtained
by reduction of the corresponding nitrated derivatives.

As in the nitration of toluene, three similar isomeres are obtained; by their reduction a mixture of the three aminated derivatives is obtained, which can be split up by allowing it to fall into a solution of oxalic acid, in the presence of hydrochloric acid, kept at boiling point. The oxalate of para-toluidine then separates, and the liquid filtrate contains the soluble chlorohydrates of the two other toluidines.

The ortho-isomere, \((\text{C}_6\text{H}_5\text{CH}_2\text{NH}_2\text{Cl})\), is fluid: the para-solid, in the form of scales; they volatilise with steam. Their toxic effect is analogous to, and, according to some authorities, even stronger than, that of aniline. The clinical picture resembles that of anilism; however, cyanosis is less frequent, while from the beginning severe headaches are quite common.

A feeling of heat situated on the face is a characteristic and early symptom. Several authorities consider that while, generally speaking, the toxic effect of toluidine is similar to that of aniline, the latter is liquid and the former solid (Hamilton). The three isomeres destroy the red blood corpuscles and lower the temperature. The meta-isomere is not used in industry; the para-isomer is more toxic than the ortho-, although the latter is liquid and the former solid (Hamilton). The reason why the risk is more serious than with aniline lies in the fact that, when centrifuging the two toluidines, workmen are exposed to both the action of fumes and to contact with the products. Several serious cases are recorded in literature, by Friedlaender in 1900, and Stark in 1892, with coma, delirium and prostration, from simple contact of the skin with toluidines.

Persons who are employed in the manufacture of aniline colours and explosives, due to inhalation of toluidine fumes, are particularly exposed to the risk of poisoning.

**Chloro-toluidine** \((\text{C}_6\text{H}_5\text{CH}_2\text{NH}_2\text{Cl})\), which is obtained by reduction of the corresponding chloro-nitrotoluene, is liquid and volatilises very rapidly at the ordinary temperature \((18-22^\circ\text{C})\).

It is used in the preparation of some of the aniline colours. Having regard to the extreme facility with which it volatilises at ordinary temperatures, risk of poisoning by its inhalation is unexpectedly small. As a matter of fact, inhalation of fumes of chloro-toluidine, continued experimentally for from ten to twenty-one days, has not caused any definite signs of poisoning in animals. On the other hand, its application to the skin gives rise to a pronounced haemolytic reaction.

No case of industrial origin is known (Hessbruggen, 1928); but some authorities suspect this product to have been the cause of cancer of the bladder among workmen who had handled it.

In Great Britain, in 1930, 10 cases of poisoning by inhalation of the 5 ortho-chloro-toluidine were reported. From the commencement of work the workmen were affected with slight headache, somnolence, and irritation of the nasal and conjunctival mucous membranes. Later, strangury was reported, followed by haematuria.

The rarity of this poisoning being accepted, an investigation undertaken by the Industrial Hygiene Service of the International Labour Office has made it possible to present the following facts. No case has been observed up to the present in Germany, and the question has been submitted to a conference of factory medical officers in the chemical industry. In Switzerland, one case was reported in 1928, in a workman who had received a jet of chloro-toluidine on the lips; he suffered from haematuria, albuminuria, strangury and necrosing cystitis. Apparent recovery had occurred at the end of a month; but six months later there was a return of the cystitis; and work could not be resumed until two months later. In the United States, no case of poisoning has been observed in a factory which prepares the product in question on a large scale, up to several thousand pounds a month. The manager of this factory thinks that this can be attributed to the fact that 5 ortho-chloro-toluidine is used in the form of the sulphate or chloride, the toxicity being thus reduced.

The para-isomere is the commonest of the toluyldiamines; it is obtained by reducing the corresponding dinitrotoluene with iron, together with hydrochloric acid (see article "Paraphenylendiamine"), and is chiefly used in the manufacture of such colouring materials as Safranine T. It is often mixed with paraphenylendiamine. Poisoning may occur from the inhalation of fumes or dust. It is a blood poison with haemolytic action; it forms methaemoglobin, and is also a poison to the hepatic cell. It is said to be less toxic than toluidine.

Next should be mentioned aminoazetolubine, a derivative of ortho-toluidine, used in the preparation of alizarine.
Two cases of poisoning are known, which were characterised by cyanosis, headaches, a slight rise of temperature, pulse rate, and albuminuria. These were cases in which aminoazo-benzene, or scarlet red, had been applied locally on broken skin.

The toxic action of toluene is analogous to that of benzene, although experiments on animals have proved that it is a little more toxic; according to Lehmann commercial toluene is two-fifths more toxic. Narcosis comes on sooner than with benzene (Lehmann), whilst the other symptoms appear more slowly. Kober and Pugliesi, on the other hand, are of the opinion that the toxicity of toluene is less than that of benzene, although it shows a stronger irritant action on the mucous membranes. It has less tendency to produce convulsions than has benzene. Recovery from the effects of toluene is slower than in the case of poisoning by benzene.

Rambousek, using a solution of 10-12 mg. per litre, found that rats at the end of two hours lay on their side, and died if the strength of toluene was carried to 30-35 mg. per litre. In the case of a pure product, 30 mg. per litre causes profound narcosis; with 40-45 mg. at the end of fifteen minutes the animals stagger and become paralytic. Batchelor, in 1927, found that 6 mg. per litre causes in man irritation of the mucous membranes, slight nervous disorders and somnolence.

It is only at high concentrations of toluene and xylene that there occurs a moderate diminution in the number of red blood corpuscles, and of haemoglobin, with, generally, strong leucytosis. Hektoen, on the other hand, has not obtained with toluene the changes in leucocytes which are caused by benzene: neither immediate changes in the number, nor in the formula, nor in the phagocytic activity of the leucocytes. Nor did he find any change in the sedimentation or in the resistance of the red blood corpuscles. In conclusion, the action of toluene and xylene on the blood may perhaps be regarded as less serious than that of benzene.

In chronic experimental poisoning by toluene the symptoms are also less characteristic than in poisoning by benzene (Hektoen, Brown). With animals, repeated injections of toluene have caused hyperplasia of the myelocytes of the bone marrow and phagocytosis of the leucocytes by the giant cells, without any concomitant increase in the blood cells or changes in the liver or spleen (Brown).

In Great Britain, 2 cases of poisoning were reported in 1919; but it should be said that many of the cases are included under the heading "poisoning by aniline". As a matter of fact, from 1925 — the date at which notification of cases of poisoning by nitro- and amino-derivatives became compulsory — to 1930, 193 cases had come to notice; of these, 66 were due to dinitrobenzene, dinitrotoluene and trinitrotoluene; 11 to toluidine; and 10, in 1930, to chloro-ortho-toluidine.

An investigation in 1929 by Overton in factories making artificial leather has shown once again that, generally speaking, this material is not a single product, but a mixture of several organic substances, for example, benzene, 84 per cent.; toluene, 13 per cent.; and xylene, 3 per cent.; as well as traces in varying quantity of acetone, and methyl alcohol, etc. Commercial toluene is most often composed of benzene, 15 per cent.; xylene, 5 per cent.; and toluene, 80 per cent.; but its constitution varies according to its use. According to Overton, this mixture causes among workers affections which resemble very closely those due to benzene.

Cases of poisoning by toluidine, in addition to those reported in Great Britain, have been observed in Germany, as well as others due to chloro-toluidine, and in one case to its chlorohydrate. The symptoms are similar to those of anilism: cyanosis, headache, haematuria, icterus, leucocytosis, lymphopenia, cramps and coma (Friedlaender, Stark).

Cases of sub-acute poisoning, among workers preparing a flypaper paste, due to toluidine have been reported by Rosenthal-Deussen in 1930. In addition to the symptoms enumerated above, the patients presented characteristic haematological lesions, without apparent change in the haemoglobin or the red blood cells; but, on the other hand, there was a marked diminution in neutrophiles, with deviation to the left, and a great increase in the eosinophiles.

In Germany, cases of chronic poisoning have been reported, following upon the handling of toluene either as a solvent or for cleaning purposes. One case of poisoning was caused by the sulphonchloride of toluene.

In Austria, Adler-Herzmark and Selinger in 1931 examined the workers in various Viennese factories wherein are handled products containing benzene, toluene and xylene. In a group of 48 workers, 10 of whom were women, employed in painting
large articles with a spray, it was found that the blood formula was changed in 35, 4 of whom were women, aged twenty-five years or less. In addition, the workers complained of cephalalgia, vertigo, nausea, cough and irritation of the pharynx. The objective symptoms noticed were: pallor, 9 times; pharyngitis, 24; trembling, 11; exaggeration of reflexes, 16; and goitre, 5.

In a group of 56 workers, 36 of whom were women, employed in painting small articles with a spray, alterations in the blood formula were found in 42, 27 of whom were women. The workers complained of the same affections as those of the first group. A worker employed at a factory for pharmaceutical products in dissolving certain substances in pure benzene showed only a slight trembling, whilst one of his comrades complained of burning in the eyes, cough and vertigo, and exhibited conjunctivitis, pharyngitis, pallor and exaggerated reflexes. In both cases there was alteration in the blood.

In a last group, comprising 33 workers, 6 of whom were women, the blood formula was changed in 27 workers, 5 of whom were women. Nearly half of those examined did not make subjective complaints. Among the others, there were present cephalalgias, vertigo, gastric disorders, and a state of ebriety and confusion.

As regards cases of poisoning by toluol, benzol and xylol among workers employed in heliography work, see article "Printing Trades".

Since the case reported in 1911— which was due to the inhalation of the fumes of meta-toluyldiamine, and was characterised by violent headaches, vomiting and jaundice, with death from cardiac failure, while at the autopsy acute yellow atrophy of the liver was found — the toxic effect of this substance has been made the object of researches by Arrak, who drew attention in 1927 to polyglobulins; by Shyogo Hosoya, who in 1927-1928 studied jaundice due to toluylendiamine; by Stadelmann, Dragendorff and Pick in 1909; and by Kaneyoshi Miha in 1925.

As regards measures of hygiene and treatment, see articles "Benzene Derivatives", "Nitro and Amino Derivatives", etc.

Dr. R. Fischer (Berlin).

Tortoiseshell (Turtleshell)

Under this name is known industrially the horny plate constituting the shell of certain kinds of sea tortoises of the genus Chelonia.

Commercially several kinds of tortoiseshell are designated according to their thickness, colour and transparency, varying according to the kind of animal and the part of the shell (upper or lower). The light shells, the thickest and the most transparent are those most sought after.

Tortoiseshell consists of a horny substance appearing under the microscope in the form of oblong regular translucent or opaque cells with a yellow ground more or less stained and veined reddish brown, at times an almost uniform brown colour.

Tortoiseshell is used in the manufacture of small objects such as fans, knife handles, handles for lorgnettes and eye glasses, small stationery goods, combs, brush backs, snuff boxes and cigar and cigarette cases.

Tortoiseshell is worked like horn (see that article). It is softened by a hot process, pressed, agglomerated, moulded, sawn, cut into sheets for manufacture of fancy goods, cut out and polished. The bits of waste left over can be soldered by means of pressure at a high temperature and furnish a composite tortoiseshell lacking the colour and transparency of natural tortoiseshell. There should also be mentioned imitation tortoiseshell made from celluloid, gelatine mixtures, bone meal, galalith, bakelite and other similar products, or again from horns steeped in vinegar and then placed in alum, and dyed.

The manufacture of snuff boxes and cigar and cigarette cases involves, among others, the operations of dressing and mounting. The side pieces are cut out and placed on a frame or a wooden mould. After hinges have been added, the operations of fitting and putting on the lid are proceeded with; finally, the article is engraved, decorated and polished.

The sources of risk are similar to those due to horn (see that article), especially during polishing (dust), together with the effects of products applied during the various operations. There is no risk from infectious diseases.

For artificial tortoiseshell the danger is connected with the various products utilised (see corresponding articles).
For hygienic precautions to be taken, see article "Horn".

***

Transport Industry

(a) Railways, Tramways, etc.

French: Chemins de fer, tramways, etc. — German: Eisenbahnen, Straßenbahnen, usw. — Italian: Ferrovie, tranvie, etc. — Spanish: Ferrocarriles, tranvías, etc.

Means of transport by road and rail have rapidly extended since the second half of last century. Motor transport now tends to exceed in development all other means.

The entire number of persons occupied is continually increasing, especially as numerous undertakings effecting accessory work continue to increase the personnel exclusively engaged in transport.

Railways

The staff of railway systems is everywhere very numerous: Germany (1930), 700,000; Great Britain (1930), 700,000; Italy (1929), 150,043; United States (1930), nearly 1,700,000. The term "railway staff" includes groups of individuals exercising widely different operations, so that the factors effecting injury to the persons involved are very numerous. The 150,043 Italian employees include, among others:

1 The expression Stations: Personnel de fatigue (French) or Stazioni: Personale di fatica (Italian) has been rendered in English by the words "station employees" throughout the text. It covers all manual workers engaged in the station and excludes clerical staff.

For obvious reasons reference will not be made in this article to the clerical staff or workers in the railway workshops.

As to the remainder of the staff, those employed on the permanent way must be included, the work done being comparable to that of navvies and the workers being continuously exposed to atmospheric influences and to the varying conditions under which the work has to be done (muscular effort).

Risk incurred by station-masters, agents, etc., whose business it is to look after the trains, is represented by standing about in the open air (atmospheric conditions), brusque changes in the temperature (frequent going in and out of offices), etc. The same causes also affect pointsmen, shunters, etc.

The last two categories have often to do night work. But in general the work of the pointsmen and shunters is not very different from that of the line superintendents.

The signal-box staff at important stations is subjected to much nervous strain due to the intensity and duration of the work, as well as to the intense muscular effort (manipulating the signals).

Specific railway work is that confided to the locomotive men and guards. The factors which it is necessary to take into account are the following: irregularity of hours of work, long journeys constantly recurring, irregular meals—generally far from home, and sometimes cold—sleep taken on the journey, rarely at home. In the case of the engine-drivers there must be added the brusque changes of temperature (great heat radiated from the furnace and external cold), shocks and vibration, draughts, noises, etc., etc. Great differences of temperature exist in the cabin itself (nearly 40°C, for example, between the floor and the level of the head), according to place and time (Variscey, 1957). While going through tunnels there is the possibility of poisoning by carbon monoxide and by other products such as sulphur dioxide from coal with a high sulphur content. There must also be taken into account the prolonged nervous tension for the engine-driver when the going is difficult, and the intense muscular effort of the fireman (in stoking the coal).

The task of carriage cleaner does not seem to be particularly unhealthy. Van Themsche did not find a higher amount of respiratory illness than that to be met with in any dusty trade, nor was there a higher rate of illness attributable to using solutions and disinfectants. But it is advisable that only persons with absolutely sound lungs should be admitted to this occupation.

The influence of these various elements on the state of health of the workers can only be elucidated by an examination of the morbidity data, the diminution in capacity for work, and the mortality data, as furnished by the railway companies. In this study there has been taken especially into account the statistics of the Italian railways as recorded since 1880 by one of the largest companies (that of the Adriatic) and continued since the unification of the principal railways of the State.
For the period 1886-1892 on the Adriatic Railway the general morbidity figure was 110 for 100 persons; the number of days lost 10.9 for each case of sickness, and 11.6 per person.

It should not be forgotten that in the statistics of the Italian and French (P.L.M.) railways cases of sickness are computed from the first day of absence, and that, on the other hand, statistics of industrial morbidity relate in general to cases having a duration of incapacity exceeding a week (waiting period). Thus all the slight cases are eliminated, which undoubtedly constitute the majority (nearly 73 per cent.) on Italian railways according to an approximate calculation made by Filippini. In column 3 of Table I, morbidity is calculated only for cases lasting over a week.

Even when submitted to this elimination the morbidity figures for the railway employees are still generally so much higher than those of other classes of workers as not to be of use for comparison. These differences must depend on various causes, among others on the manner in which the statistics are prepared. Moreover, the epidemics which attack the rest of the population also affect railway staffs (e.g. pandemia of influenza in 1919). Other elements contribute to alter the morbidity curve; for example, the con-

cessation made in 1909 to Italian railway-men to pay full wages from the first day of illness (instead of two-thirds as previously) caused a sudden rise in the cases of sickness without obvious morbidity cause. Likewise, American statistics show that the frequency of cases of long duration (80 days and over) is greater for those workers who receive sickness pay for 52 weeks than among those who receive it only for 13 or 26 weeks (the average duration of cases of sickness in such statistics is from 30 to 58 days).

The occupation may cause morbidity affections obliging the workers to give up their work before the time gener-

years of age. These are subjects unsuited to the work and unfit, who, having survived the medical examination, succumb at the first contact with the work and are eliminated. After the period of stabilisation — the working prime so to speak (thirty to forty years) — round about forty-five years the effect of the medical re-examination of the special senses becomes manifest, causing a notable elimination, increased by various effects of wear and tear on the system due to age. The premature elimination reaches its maximum from fifty to fifty-five years.

A similar phenomenon is seen among railwaymen belonging to railways which arrange their statistics by age-groups. Thus, for example, on the Swiss Federal Railways, the morbidity, which amounts to 74.2 per cent. under 50 years, descends to 69.5 for age-group 30-34, to 65.9 for 35-39, to 63.3 for 40-44, to 64.1 for 45-49, to 66.8 for 50-54, and to 78.2 for 55-59.

In Germany the morbidity and mortality figures are above the average of those for the rest of the population. That is especially the case for the train staff. They hold first place as regards invalidity, followed by the station employees and the workers on the permanent way (Bogdan).

Besides accidents the causes of incapacity are especially rheumatism, gout and heart diseases. Pulmonary phthisis plays a minor role, especially amongst the clerical staff (Bogdan).

If the morbidity figures for each class are examined the following values are found in Italy for example per 100 persons during the period 1923-1929:

- Workers in workshops: 114.50
- Station shunters: 111.70
- Train staff: 108.10
- Locomotive men: 101.60
- Workers on the permanent way: 94.83
- Stations (employees): 66.76
- Clerical staff: 43.66

The retirements per 1,000 persons during the period 1925-1928 gives the following figures:

In Australia the morbidity and mortality of the employees on the railways and tramways of New South Wales (1924) and railways of the State of Victoria (1922-1923 and 1924) have been studied in detail by Robertson and Taylor.

During the period stated the number of days of sickness was 38,371 for New South Wales and 27,384 (annual average) for Victoria. The latter figure includes absences due to sickness and accidents, while the figure for New South Wales includes neither sickness for less than three days nor accidents.

The average number of days of sickness per individual and per year was 3.24 (New South Wales) and 3.85 (Victoria).

Taking account of all causes, including accidents, the number of illnesses was 239.7 per 1,000 (New South Wales) and 419.5 (Victoria); it falls to 215.1 and 207.3 respectively when external causes and absences of less than three days are excluded.

The following table contains a comparative statement of cases of sickness analysed according to cause:

**Table IV. — New South Wales and Victoria**

Examining the diverse cases of sickness, according to the age of the persons attacked, no conclusions can be drawn as to their particular frequency for a particular period. According to the various months of the year a notable frequency of rheumatism, gout, respiratory disease (winter months) and digestive troubles have been noted during the first three months of the year.

In Switzerland the morbidity of the Federal Railways staff between seventeen and twenty-five years is characterised as follows: the curve for infectious diseases heads the list in each year and for each class. In practice it is chiefly a question of influenza; the other diseases, including tuberculosis, occupy a quite secondary place. In order of importance there follow respiratory diseases. Influenza, it should be noted, has undergone, since 1918, a biennial exacerbation. In 1918 the proportion reached 54.28 per cent. (workshops) and 51.2 (traction). Further, during periods of influenza, the curve of the other maladies has fallen in general. This has been attributed partly to the fact that during the epidemic all affections have been ascribed to influenza. Generally speaking, the morbidity of workshop operatives is greater than that of the train staff. Cases of disease and accidents (1924 and 1925) of the employees and workmen of the Swiss Federal Railways averaged:

In the U.S.S.R., an enquiry (1926) on the morbidity on the Murman Railways covered 24,212 employees (21,139 men and 3,073 women) classifying the workers in the following 7 categories: locomotive men; train staff; permanent-way workers; station staff; ticket office staff, statistics department and counting-house clerks. Diseases of the digestive tract take first place, followed by dermatosis. The locomotive men showed the largest number of diseases; and the workers on the trains a high proportion of venereal diseases, eye affections and tuberculosis; the workers on the permanent way suffered especially from skin diseases, rheumatic affections and bronchitis. Adolescents (fifteen to nineteen years) constitute the age-group most affected by disease.

**Mortality.** — In Italy, the mortality rate passed from 6.30 per 1,000 (1886-1892) to 7.16 (1906-1912) and 2.28 (1921-1928). Only in 1918 did it reach 13 per 1,000 (influenza pandemic). Not only did the other classes of workers show a much higher mortality figure, but even the male population in general from twenty to sixty years (corresponding to the age of the railway workers) showed a figure of 6.9 per 1,000 in 1926, a year of low mortality.

The death rate per cent, in descending order during the period 1921-1928 works out as follows: general diseases: station staff (shunters, pointsmen, etc.) 2.3; train staff, 2.28; locomotive men, 2.16; permanent-way workers, 2.08; clerical staff, 2.04; station staff (clerks), 1.96; workers in the workshops, 1.96. If accidents are taken into consideration, the order is as follows: locomotive men, 0.81; permanent-way workers, 0.78; station staff (shunters, pointsmen, etc.), 0.69; train staff, 0.64; in the workshops, 0.56; station staff (clerks), 0.08; office staff, 0.07.

Such a privileged condition in comparison with other classes of workers is due partly to selection of the work-
ers before admission; it proves also in every way that work on railways does not entail important risks for life and safety.

The principal causes of death are in descending order: respiratory diseases, the consequences of accidents and circulatory diseases.

Of 635 cases of death in Germany reported in 1913-1917 among engine-drivers, accidents accounted for 137, pneumonia for 65, heart disease for 68, diseases of the intestines for 66, tuberculosis for 67, influenza for 44, and cancer for 42.

In Australia the statistics already quoted by D. G. Robertson and G. H. Taylor give the following indications:

In the United States the mortality of engine-drivers has undergone, according to the published statistics of the Metropolitan Life Insurance Company, considerable diminution (from 1912 to 1922), especially between the ages of thirty-one and fifty-five years. Over fifty-five years the indications are not convincing as the number of persons exposed to risk is so reduced. The most considerable diminution was observed in regard to fatal accidents, which, from 318 per 10,000 (1912), fell to 167 (1922), thanks to the improvement in safety precautions for the persons employed. It explains also, in great part, the considerable diminution in mortality for the age group 31-55 years. Similarly, the death rate from typhoid fever fell from 29 per 10,000 (1912) to 2 (1922), and that of tuberculosis from 55 to 40. Increases in mortality are attributable to diseases characteristic of middle and advanced life (heart affections, which caused a death rate of 74 per cent, greater in 1922 than in 1912; cerebral haemorrhage and apoplexy, 11.4 in 1922 more than in 1912; causes which, on the other hand, have shown a marked diminution in the general male population).

In France the average for the decennial period 1913-1922 was, for the Paris-Lyons-Mediterranean Railway, 0.98, with a maximum of 14 per 1,000 in 1912 (influenza pandemic).

According to English statistics for the years 1921-1923, railway officials show a comparative mortality figure of 679 — with a lower mortality than the average over twenty years of age, except for diabetes and appendicitis.

Other railway workers also show a low death rate with the exception of porters. For signalmen the figure is even lower than that of railway officials; for the pointsmen the high death rate is mainly due to accidents.

The causes showing excessive death rates are: for engine-drivers, diabetes and peptic ulcer; for guards, influenza, diabetes and cerebral haemorrhage; for pointsmen, syphilis, cancer of the stomach, cerebral haemorrhage, valvular disease of the heart, bronchitis and peptic ulcer; for porters and lampmen, tuberculosis and respiratory diseases. Some available comparative mortality figures are as follows:

Total males occupied and retired (20-65 years) 9,704,660
Number of registered deaths (20-65 years) 966,384
Railways employees (20-65 years) 275,258
Number of registered deaths (20-65 years) 5,716
Persons employed in road transport (20-65 years) 459,415
Number of registered deaths 12,383

In taking 1,000 as the figure for deaths from all causes for all occupied and retired males between twenty and sixty-five years of age, the mortality rate of railwaymen from different causes works out as follows:
In Switzerland the mortality rate for the period 1917-1928 varied from 4.1 to 4.7 per 1,000, attaining in 1918 only the figure 14.4 (influenza pandemic).

**Pathology**

Analysis of the morbidity, mortality and incapacity for work curves, prepared from the figures just quoted, shows that they are not parallel. Certain categories occupying the first place as regards morbidity rank only second in regard to mortality and pension. In general, engine-drivers and guards on trains show a high morbidity rate. That of the workshop staff is still higher, tending to show that specific railway work exposes to less risk than that of workmen in general. This morbidity, however, has no effect on the general health of the shop workers who come last in regard to incapacity (Italy, Switzerland).

On the other hand, the station employees, then those on the trains, and lastly the locomotive men appear to be those most liable to contract illnesses exerting an effect on their general health. The workers employed on the permanent way also show a low morbidity.

In Italy, diseases of the digestive tract stand highest up to the end of 1918 (influenza pandemic) and after that they are exceeded by rheumatic affections. Digestive trouble is found amongst the train staff (530 per 1,000) and locomotive men (503): the general incidence is 325 per 1,000. In Germany and Switzerland also the same classes furnish a high rate for these maladies. But they have not grave consequences as causes of retirement (0.10 per 1,000), nor do they seriously affect the death rate. This high incidence is explained by irregularity in hours of work, necessity for meals to be taken away from home, by the frequent recourse to cold drinks when perspiring, alcoholic habits, brusque vibration, etc.

Under the term *rheumatism* are included influenza, acute articular *rheumatism* and rheumatic fevers, etc. The various proportions in which these three forms occur are respectively 140, 7.56 and 117 for the year 1928; and 257, 5.8 and 145 for the year 1919 (Italy).

Together with diseases of the digestive tract, rheumatic affections represent the half and even two-thirds of all cases of sickness. The causes are obvious in the case of engine-drivers; for the other categories (except shop workers and clerical staff) they are insufficient protection against changes in the weather; for the numerous agents at stations, work executed alternately on the platforms and in offices with brusque changes in temperature. Rheumatic affections which like digestive maladies, are the most frequent diseases also in the rest of the population, are found most frequently amongst engine-drivers (457 per 1,000) and those in charge of the trains (430), the general average being 303.

Respiratory diseases in Italy show a figure of 107 per 1,000; the maximum occurs among train staff (166) and

</table>

This high morbidity rate cannot be explained by greater accident incidence, the accident rate being 20 per cent, as compared with 10 per cent. as the average for all workers.
Diseases was 129 per 1,000 (average for the period 36-40 years may be regarded as critical periods for circulatory maladies. It is to be remarked that the diseases which provoke the greatest amount of incapacity do not come on suddenly, but develop in the course of several years, giving an appearance of being due to age (Anastasieff).

Lastly, varicose veins should receive mention. Some writers consider them to be most frequent amongst mechanics. In seeking a cause for this it is necessary to take into account the constitutional factor in the case and the same applies to haemorrhoids, which some writers hold to be more frequent among the train staff.

In the U.S.S.R., circulatory diseases would appear to be rare during the first year of work, but after that they are met with pretty frequently. After a duration of work of from one to five years more than a fifth of the subjects examined showed varicose veins; for later periods (five to twenty years) this symptom increases in frequency and severity and becomes the rule at the end of twenty-five years of employment (Anastasieff).

Blood. — Bobroff (1928) in the course of an enquiry covering over 260 engine-drivers and 187 firemen collected data enabling him to say that polycythemia is less marked amongst engine-drivers than amongst firemen, who show a higher incidence for leucocytosis. Among engine-drivers he also found slight pathological modifications of the red blood corpuscles, a tendency to leucopenia (leucocytosis among the firemen), a modification in the differential count (lymphocytosis, eosinophilia, monocytosis), and change of the neutrophiles to the right (to the left in firemen). The nature of this work, according to Bobroff, acts indirectly on the blood, causing alteration in the different organs, which in their turn, act on the constitution of the blood.

Diseases of the nervous system do not show special characteristics and it cannot be said that their number is considerable when it is remembered that under this head a number of widely varied diseases is included.

In Italy, a matter of fact, circulatory diseases show figures above the average (16 per 1,000) precisely in the classes showing also a low morbidity for rheumatoid complaints: station-masters, agents, etc., (22), clerical staff (21), while they predominate as a cause for retirement (general average 0.26) among workers on the permanent way (0.37), the train staff (0.33), and among the causes of death (general average 0.22), among the workshop hands (0.26) and station-masters, agents, etc. (0.34). Arteriosclerosis as a cause of retirement among the workers on the permanent way (0.88) and station employees (0.41) is very much higher than the average (0.34).

In Switzerland, the number of persons retiring on account of circulatory diseases is very high (almost double other causes) and higher still is the place those diseases occupy in mortality figures.

In the U.S.S.R., arteriosclerosis and dilatation of the right side of the heart were said to be very noticeable at the end of the year's work and were met with in 50 per cent of those examined at the end of sixteen to twenty years' service.

Duration of employment of eleven to fifteen years coupled with the age-period 36-40 years may be regarded...
(0.58), station employees (0.52) and those on the trains (0.45).

In Switzerland, the highest morbidity figures are those for the locomotive men (40 per 1,000), and workshop hands (37), the lowest being workers on the permanent way.

In the United States, in 1909, Edsall pointed to the frequency of right sciatica amongst locomotive men, due to the fact that they are in the habit of sitting on the edge of the bench, so much so that, in consequence of the constant vibration, the weight of the body rests mainly on the right thigh. A modification in the construction obliging the men to sit square immediately reduced the number of the cases.

A case of paralysis of the cervical plexus, manifested by double paresis of the pectoral, deltoid, coracobrachialis and biceps muscles on both sides with muscular atrophy, was reported by Curschmann (1927) in a workman employed in carrying rails on his shoulders.

Anastasieff, who has examined the statistics of various Russian sickness funds since 1925, as well as the medical examination files for locomotive men, considers that the most important pathological element arises from nervous diseases, the frequency of which increases with duration of employment.

As regards mental diseases, the average is exceeded in Italy by the clerical staff and train staff, the lowest being found amongst workers on the permanent way. The figures do not reveal the fact that nervous or mental diseases are particularly associated with any one branch of the railway service; their rarity indicates that any occupational pathogenetic element must be excluded, as, moreover, does their prevalence from the point of view of retirement among the clerical staff.

Nor is there evidence (at any rate for Italian railways) to prove that accidents or collisions result from a consequence of mental disease of the staff. An elementary measure of safety, however, must be frequent medical examination of the staff entrusted with the safety of trains (Filippini).

Diseases of the eyes have no particular feature because they are mainly the result of accidents (most often penetration by foreign bodies). It has been stated that locomotive men suffer from failing eyesight as a result of fatigue; but experience has shown that even after twelve hours' continuous work, at night and in tunnels, there is neither diminution nor failure of acuity of sight nor loss of colour sense.

Among persons employed on the American telegraph trains, McCord has reported cases of nystagmus.

Ear disorders are more frequent among locomotive men than amongst clerical workers, but they are still higher in the workshops where the risks involved are not similar. Generally the cases consist of chronic catarrhal otitis media, associated with stenosis of the Eustachian tube and naso-pharyngeal affections. The locomotive men also show a certain frequency of damage to the internal ear from vibration.

As for nutritional diseases it should be recalled that on certain American railways (Chicago North Western) a high proportion of excessively heavy persons has been observed — an observation not confirmed elsewhere. Recent examination of old employees, engine-drivers and guards has shown that 90 per cent. of the engine-drivers are too heavy and 60 per cent. weigh more than 100 kg. Almost all eat three times as much as they require (Dowdall).

Some writers (Navarre) have attributed the greater frequency of diabetes among the locomotive men to the action of train vibration. In Italy retirement for diabetes (57 cases between 1919 and 1928) was more numerous among the clerical staff (0.69 per 1,000) than among the locomotive men and train staff (0.64 and 0.61 respectively); it was least among the workers on the permanent way (0.09).

It is open to doubt whether Navarre's cases were not simple transitory glycosuria, which is not infrequently seen at a certain period of age, when the functions of the liver are no longer active. In addition to a high percentage of diabetes and hypertension among the engine-drivers on the Chicago North Western Railroad, Dowdall found 1.13 per cent. with glycosuria. As he fails to distinguish between the different categories of workers no conclusion can be drawn.

Cases of pulmonary tuberculosis in Italy oscillate between 2.5 and 3.3 per 1,000, with an average duration of 65-68 days per case. The cases represent only 2-3 per cent. of all maladies. Analysed as to the class of worker, tuberculosis affects especially the clerical staff (4.4 per 1,000), station employees (pointsmen, lampmen, etc.) (2.76) and station-masters, agents, etc. (2.52), workers on the permanent way (2.51), workers in the shops (2.09), train staff (1.91), and locomotive men (1.44).

The morbidity from tuberculosis is caused not only by variations in the
general morbidity from this disease, but also, among other causes, by the different criteria adopted in the selection of the staff (less rigorous examination during the war).

At any rate, the frequency of pulmonary tuberculosis among railwaymen can hardly be higher than that met with amongst the general population. As a matter of fact, the mortality was (1921-1928) 0.33 per 1,000, and, even presuming that the cases of retirement for this cause (0.58 per 1,000) ended fatally, which would be an exaggeration, there would be a mortality of 0.91 per 1,000 which is much below the 1.415 for the male Italian population from twenty to sixty years of age (1926).

The average of 0.91 is exceeded by train staffs (1.17), and station employees and clerical staff in stations (1.07). Show the figures 0.91, while lower figures are furnished by locomotive men (0.90), station-masters, agents, etc. (0.60) and workers on the permanent way (0.33).

In the United States in one section of a railway company the annual incidence of tuberculosis was 1 case in 800 employees (Philippi, 1929); in France (Paris-Lyons-Mediterranean Railway) the mortality from tuberculosis was 10.07 per 1,000, and in Switzerland the total retirement and mortality was 1.416 per 1,000.

Attempt has been made to explain the high percentage of cancer among railway workers by the fact that they come into contact with coal. But in Italy the morbidity from cancer (0.54 per 1,000 from 1914 to 1926) is noticeably higher amongst workshop staffs (0.65), train staffs (0.62), station-masters, agents, etc. (0.63), clerical staffs (0.62), and station employees (0.55), and is, on the contrary, lower among workers on the permanent way (0.53) and lowest of all amongst locomotive men (0.47), which comprises the workers most exposed to contact with coal.

According to English statistics, the section most affected is that of railway navvies or workers on the permanent way, and the most frequent situation is in the stomach. The least affected are locomotive men and cleaners, in whom the situation is predominantly gastro-intestinal.

In consequence of continual contact with the public and continual movement from place to place, railway servants are rather liable to contract infectious diseases.

In Australia these are by far the predominating maladies, especially if rheumatic affections and influenza are included, although these are generally considered apart. Typhus fever is found most frequently among train staffs (3.17 per 1,000 in Italy) subjected to frequent travel, though the latter are not subject to the same movement from place to place.

In malarial areas, this disease may represent an important cause of sickness for the railway staff. In Italy it represented, in 1889, 37 per cent. of all sicknesses, but now it has been reduced to 1.08.

Malaria is very severe among railwaymen in certain countries (Bulgaria, India). In India, recent study (1928) has been directed to determining precisely the measures to be taken against malaria when constructing railway lines.

Mention ought to be made also of diseases transmissible from animals to man which may be caught by railway employees who have to attend to trucks carrying animals or their products: cattle plague, anthrax, foot-and-mouth disease, etc.

Among the intoxications, the commonest is alcoholism, more frequent among station employees than among locomotive men or train staffs. It is also of common occurrence amongst workers on the permanent way. The frequency varies according to the countries: fairly low in Italy, where alcoholism figures at 0.16 retirements per 1,000 persons; cases of acute alcoholism which might entail destitution are exceptional. Alcoholism is fairly frequent among the railway staffs of central and northern Europe. In Switzerland, for example, since 1924, 1.76 retirements per 1,000 persons were due to this cause.

Excessive smoking is rare. This, it may be recalled, may cause transitory amblyopia.
Carbon monoxide is a real professional form of poisoning which may happen during passage through tunnels. In the past veritable catastrophes have happened through this cause, because the locomotive men and train staff became affected and the train was left to itself. This intoxication has, moreover, occasionally affected workers in the permanent way, especially those working in long tunnels. Among them effects of varying gravity have been reported from the lighter effects (headache, loss of consciousness) to a fatal issue. Allevi (1914) has reported cases of leucocytosis among the train staff after passage through a tunnel. This form of poisoning is said to have disappeared now by the introduction of better ventilation, and especially from the use of electric traction.

Medical literature contains also reference to a case of a fireman poisoned by sulphurous acid fumes liberated from patent fuel briquettes, which often contain sulphur.

Other occupational diseases may be observed among different classes of railway workers: dermatoses from impregnating and maintenance of the sleepers. Tar oil or creosote (in England, a case of skin cancer has also been reported) used for impregnation causes cutaneous lesions on the shoulder at the point where the sleepers are carried — skin of the collar bone and on the side of the back (Tichonmoff). The workers who lay them are exposed to the action of other deleterious products, which are given off when the doors of the impregnating chamber are opened: arseniugetted hydrogen gas and hydrochloric acid used to dissolve zinc, containing sometimes traces of arsenic. Skin eruptions have been reported among those loading pitch.

In France, Hudelet, Rabut, Cailliau and Mornet reported (1927) a case of melanodermy with, in six months, successive growths in the face upper limbs and abdomen, in a navvy working on the line, due possibly to the creosote in which the sleepers are steeped.

Lead poisoning among railway carriage painters in Italy has disappeared since the use of white lead was suppressed (1905) in that country.

Mention should finally be made of infection from acarasis, or grain disease, set up by Pediculodes verticorosus, of which cases have been observed among station employees and train staffs.

Van Themsche and Wautriche made a study of work in tending the furnaces in the engine cab. The work is hard, fatiguing and arduous, carried on in a hot and dry atmosphere. The principal danger present in this kind of work (operations of poking, levelling the crosspieces, the rivets of the seams, replacing the grills of the hearth, cleaning out the hearth, construction and repair of the vaults made of refractory bricks) arises from the excessive strain on the heart muscle as much as from remaining constantly in a hot and dry atmosphere. A second danger comes from the brusque change from an overheated atmosphere to a normal temperature. During the work, the worker is obliged to undergo an excessive thoraco-abdominal strain.

Accidents do not differ generally from those encountered in other engineering industries, except that they are in general more serious (Bogdan). They occur with varying frequency amongst the different classes of railway servants.

In Italy accidents represent one-fifth of the common maladies (106 to 250 per 1,000 insured persons) with a mortality rate of 0.35 to 0.62 per 100 accidents; in France (P.L.M. Railway) about one-tenth of the common maladies; in Switzerland in a proportion of 150 to 200 per 1,000.

These figures, as a whole, may not seem high in view of the industrial character of work on the railway, but it so happens that accidents constitute the most characteristic cause of illness among railwaymen.

Their frequency varies with the nature of the services, being highest in the shops, where accidents reach a proportion double that of the average.

In France (P.L.M. Railway) their maximum is highest for the locomotive staff and railway shop workers (the two departments being linked together) and lowest for the workers on the permanent way. The lesions for the most part are contusions and wounds; fractures and dislocations are rather rare. Oliver pointed out as early as 1902 that in Great Britain the three operations presenting special dangers were laying and repairing the permanent way, point work and shunting goods trains.

In Italy, permanent invalidity from accident, sufficient to lead to retirement of the victim, is found in almost equal proportions amongst locomotive men (0.90 per 1,000), workshop staff (0.88) and amongst station employees (0.84). Accidents causing mutilations are more frequent among snunters in stations and pointsmen, followed by brakesmen and workers on the permanent way. Mutilation of the lower...
limbs is much the most frequent. The death rate from accidents is highest among locomotive men, workers on the line and shunters in stations; it is lower for the men in the workshops.

In Switzerland mortality is greatest among the workers on the permanent way (0.9), after which come the station employees (0.7), then the locomotive men (0.7).

A type of characteristic accident is that due to crushing from the buffers during coupling of the carriages. According to an enquiry made by the International Labour Office, there were 2 killed and 50 injured per 1,000 persons employed as station staff each year.

In Italy, of 100 accidents due to imprudence or lack of attention to rules, those due to coupling number at least 5. The proportion then is not high; at any rate the obvious reasons for protecting the exposed person, as well as reasons of interest leading to the adoption of protective measures, are sufficient to prevent such accidents attaining high proportions.

The choice of coupling apparatus is not technically easy. Automatic coupling has been obligatory in the United States since 1893 (where, however, it does not ensure the automatic coupling of brakes and heating arrangements) and it has reduced accidents so caused by 83 per cent.

Japan is at the moment passing from one system to the other.

In 1930 a committee was formed by the International Labour Office to study this question.

Another type of accident which affects railwaymen to-day is that due to electricity. On Italian railways where traction is effected by steam, firemen whose shovels come into contact with the wire conducting the current are specially liable to such accidents. In Switzerland 27 deaths (either instantaneous or after some days) occurred between 1919 and 1926, and two cases of permanent incapacity.

When railway lines are under construction the sources of danger to navvies are accidents, malaria (in malarious districts), ankylostomiasis (tunnelling), and in tropical countries diverse maladies (dysentery, beri-beri) which affect imported rather than native labour. Generally speaking, it may be said that railwaymen have no specific diseases, not even when they are engaged on strictly railway work. Though certain diseases show a very high incidence, they do not exercise an injurious influence on the general health, and do not set up early invalidity or death.

As occupational diseases may be considered poisoning by carbon monoxide, kyphosis amongst coppersmiths and some other maladies to be found amongst certain categories and further, naturally, accidents.

**HYGIENE**

In view of the diverse character of the population concerned in railway work and their differing functions, necessity compels special hygienic measures for each group.
While general rules of hygiene (as regards cubic space, lighting, ventilation, washing accommodation, etc.) are of value for all railway staffs, they cannot for obvious reasons be applied in their entirety or even partially to such specialised classes of railway workers as locomotive men, train staff and station employees.

Night work, a rhythm of irregular work, exposure to weather changes, are unavoidable, and the hygienist can merely attenuate this state of things. As far as possible, hours of such length as will satisfy the industrial organisation and the just demands of hygiene should be advised. The chart on page 11 gives the hours for guards and stokers, the train staffs, for an Italian district, fixes 94 work days (585 hours 55 minutes on the trains, 126 hours 27 minutes of accessory work and 7 hours 47 minutes of journeys while not on duty; an average day of 7 hours 40 minutes, of which 6 hours 15 minutes is spent on the train), with 21 days' leave and 55 days in reserve (within call in case of necessity).

Analogous hour sheets have been laid down for the locomotive men. Sometimes, but rarely, when it is a question of long-distance trains, the train staff does 11 to 12 hours' work, followed by an adequate period of rest.

Sleeping accommodation should be provided for the workers obliged to sleep away from home. Modern types of installation have separate bedrooms, common-rooms, dining-rooms, baths, etc.

Efforts should be made to avoid, as far as possible, the necessity for the workers remaining in the brakesman's box on goods trains. The technical details for preventing exposure of the engine-drivers and stokers to draughts while watching the line should be studied and, for this purpose, lateral windows should be provided. Smirnov is of opinion that the hot air of the cabin should be removed by displacement (by opening the side windows) and that the incoming fresh air should be regulated by utilising the pressure of the outside air resulting from the speed of travelling, so that the layer of cold air forms a screen between the furnace and the working post. Automatic feeding of the hearths and the use of pulverised fuel should be encouraged.

Electric traction has many advantages: protection against inclement weather, suppression of draughts and variations in temperature. It obviates the radiant heat from the hearth, the laborious work of piling on the coal, the annoyance and danger from smoke. As a matter of fact, the Swiss statistics show a notable diminution in the morbidity figures of engine-staffs since the introduction of electric traction.

Analogous advantages have been obtained from the use of Diesel or electro-Diesel engines.

Waterproof clothing and shelters should be provided for those exposed to weather conditions, and hot drinks in cold weather, etc. Advantage would accrue if meals were provided for the staff on their journeys so as to compensate for the irregularity of their meals, and the food should be varied (Bogdan). In Germany the staff are provided with means for preparing and heating their food. Provision is likewise made for distribution of refreshments, coffee and non-alcoholic drinks. The buffet attendants are required to supply the railway staff with food and drink at a reasonable price.

Certain companies conduct an active propaganda for the limitation of alcohol. The Union of Railway Teetotalers, including all lines except those of Italy, Spain and Portugal, has not a large number of members, but the managements of the railways inflict heavy penalties on those guilty of alcoholic excess, and it is certainly a useful measure to prohibit, as some companies do (Bogdan), the sale of alcohol to railway servants during working hours.

Electric traction naturally does away with the risk of carbon monoxide poisoning in tunnels. With steam traction the tunnels must be well ventilated. In Italy the “Saccardo” apparatus has been used for a number of years and has given good results. When the danger of poisoning is great, suitable breathing apparatus should be provided.

As far as possible, mechanical means should take the place of hand labour: motor-driven trucks for the transport of luggage and goods, automatically discharging wagons (for coal and gravel), automatic methods of charging coal into the tenders and hearths of locomotives. Much of the work on the line can also be done by mechanical means.

It is superfluous to insist on the obvious necessity for prevention of accidents, seeing that they constitute the highest cause of morbidity among railwaymen. At the same time difficulties in regard to prophylaxis are greater for them than for the railway shopworkers, because in order to avert them appeal has to be made to individual attention. It is precisely for
this reason that selection of workers, especially on the basis of a psycho-
technical examination, might be pro-
ductive of favourable results.

An adequate organisation of first-aid equipment diminishes the consequences of accident: first-aid boxes at all the stations, permanent attendance of a trained nurse, permanent medical attendance at large stations. It would be useful also to have medical attendance on long-distance trains, and on electric trains mechanical means for effecting artificial respiration should be provided.

In railway construction, dwellings for the labourers should be built along the line, with requisite sanitary installations (washing accommodation, baths, shower baths, facilities for drying working clothes, etc.), means of medical-surgical treatment; and means for waging the campaign against malaria where this is required (see article "Malaria").

When making tunnels, abundant ventilation should be insisted on; attention should be bestowed on: the elimination of gases evolved in the course of blasting (many of the explosives used are very powerful), in the great tunnel through the Apennines, on the Bologna-Florence line, about 12,000 kg. of dynamite was used monthly and at the opening every month 2 million cub. metres of air were introduced, 450,000 of which was used for advancing, the prevention of ankylostomiasis (methodical examination of the stools of all the workers employed, movable latrines attached to the train carrying the workmen, etc.).

The welfare schemes, both hygienic and social, undertaken by the railway companies are numerous. For instance the sanitary service, the object of which is not only the discovery of illness, but also its cure. In Italy, this service, inaugurated in 1878, has organised health supervision of the personnel and has enlarged its scope further and further, limiting its health crusade to districts either malarious or difficult of access. This function has now been assumed by the National Association of Railway Servants, which also provides assistance to the families of its members. In Belgium, the medical services of the National Railway Society take on the functions of an insurance society (accidents to travellers, to persons injured not coming under Workmen’s Compensation Acts, accidents to persons not belonging to the service) or of an ordinary insurance office against accidents and diseases due to work; or of a large federation of mutual aid societies, or lastly as a service of industrial hygiene. In France the P.L.M. Railway possesses several medical centres with all the necessary means for diagnosis and treatment. The Paris-Orleans Railway has hospitals for dealing with social diseases (tuberculosis, syphilis, diseases of infants). The Midi Railway erected, in 1925, dispensaries at Bordeaux and Toulon for railwaymen and their families.

These services are situated naturally near the trunk railway lines in the different countries and they even have laboratories for research into questions bearing on the railways themselves (such as water, foods, etc.).

It suffices to mention also the accident, invalidity and old-age insurance schemes in force in many countries.

A very important initial step has been taken in the creation of housing facilities for railwaymen’s families, or for single men, which are let at moderate prices or sold on the instalment plan.

Lastly, besides the hospitals, sanatoria, dental clinics, etc., which certain railway companies (Japan, United States, etc.) have built exclusively for their employees, other companies have organised seaside or mountain homes for railwaymen’s children, or model villages for the railway staff, canteens for dispensing food of every kind at moderate prices, as well as institutes for recreation (conference halls, libraries, theatres, music, sports, etc.). (See also article “Social Welfare").

Tramways

The work of tramway driving entails remaining for long hours in an upright or rather hunched-up position, the legs spread apart on an oscillating floor, with ceaseless concentration of attention, executing all the time the same movements, and always holding the hands in the same position. In winter, too, it should be added, there is exposure to cold, aggravated by the necessity for maintaining an immobile position.

For the conductor a possible cause of risk comes from his continual contact with the public (from whom he may contract infection especially of the respiratory tract).

An enquiry in Russia in 1927 has shown that the work is constantly carried on under the influence of repeated shocks, which become more severe the worse the state of the vehicle. Another cause of fatigue is due to the fact that
the conductor must often descend to replace the trolley (Tatar).

For the road men (looking after the track), risk lies in exposure to the elements.

According to statistics published in Milan the morbidity rate for the tram- way staff per 100 workers was 81 to 100 for the office staff, 78 to 79 for the inspectors, 88 to 100 for the travelling personnel (drivers and conductors), 100 for the line-men, and 106 to 117 for the workmen.

The percentage of accidents was very high among the workmen (16-50), less high among the travelling personnel (9.5-13.3) and still lower among the men working on the line (8.4-8.8).

A statistical enquiry made in 1928 by the Moscow Government Social Insurance Committee dealt with the staff of the Moscow tramways, covering nearly 11,000 persons, of whom one-half were drivers and the other half conductors. The co-efficient of sickness (days of absence for incapacity per insured) increased from 14 in 1924 to 16 in 1925 and to 18 in 1926. During the same years, whilst the sickness percentage was 100 for the men, among the women the figures were 128, 150 and 137. A third of the sickness absence was caused by infectious diseases (influenza, phthisis), which totalled up to 25 per cent. more among the women than among the men; 17 per cent. of the general total was due to diseases of the digestive organs (mainly among the conductors); 8 to 10 to nervous diseases (mainly among the drivers).

According to English statistics of industrial mortality in the Registrar-General’s Report for 1921-1923, the comparative mortality figure for tramway drivers is similar to that of motor-drivers (875), but with a lower accident rate.

Tramway and omnibus drivers have a figure just below the average (990) and the principal causes of deaths are phthisis, cancer and appendicitis.

The incidence — very high according to some authorities — of varicose veins, hernia, flat feet, is said to be due to work in a standing position and is more marked among the conductors than the drivers. Filippini is of opinion that in the production of these lesions the constitutional element plays a role greater than the industrial, especially as one finds individuals with more than forty years’ service free from any symptoms.

Earlier observations made by Schwarze (1904-1906) reveal the relative frequency of hernia, which this writer explains by the bad attitude assumed by drivers in using the brakes, and among conductors by their habit of leaning backwards too much when replacing the trolley on the platform and the muscular effort entailed in getting off and on.

This author also reports an excessive frequency of conjunctivitis due to dust, draughts and eye strain.

Rather frequent also are said to be forms of a somewhat vague type of neurosis, with headache, vertigo, asthenopia, tremor, weakness of the legs, pains in the back, etc. The neurasthenia is of cerebral type with which are associated various troubles circulatory in origin (soft pulse, changes in blood pressure) and affecting the sexual organs.

Among the Berlin tramway drivers who continually strike a signalling bell, Schwarze has similarly reported neuritis of the right leg, as well as progressive atrophy of the shoulder and right arm muscles, of which the sole cause, in his opinion, is the continuous effort exercised for years in braking. Modern brakes acting by compressed air have however caused this form of injury to disappear.

Burns from the electric current (replacing burnt fuses, etc.) and shocks are rare (Schwarze).

Among women menstrual troubles and poverty of blood are frequent.

The observations of Raneletti and Fraschetti (1920) on women employed as drivers (49) or as conductors (304) show the injurious effect of this work on the female organism.

Measures of hygiene require first and foremost good construction of the vehicles and lines, so as to diminish shock and vibration, placing at the disposal of the driver a movable seat and one that can be lifted, which in some types of vehicle takes the form of a revolving armchair.

From a prophylactic point of view, trusses and elastic stockings are to be recommended for those predisposed to tissue weakness.

In order to avoid continual contact with the public, a kind of vehicle is being more extensively adopted in which the conductor is placed in a kind of niche and the public is obliged to pass before it to pay before leaving.

A French Bill (1930) requires the provision in public vehicles of seats for the employees.

Suitable hours of work should be made the object of further study and
likewise the provision of suitable seasonable clothing, provision of warm quarters, canteens (hot soups, tea, coffee). In certain towns in Switzerland (Geneva, for example) a tramcar which has been converted into a canteen runs along the line and stops at fixed places and hours at the disposal of the staff.

Underground Electric Trains

In many large cities electric railways have been organised, occupying a mid-way position between that of tramways and omnibuses and that of ordinary railway lines.

The conditions under which the drivers work are fairly similar to those of tramway drivers, except that, all the lines being free of all obstacles, attention is limited to observation of the signals.

The train staff assures the opening and shutting of the doors and the halts at stations. It is an operation demanding certain effort because it has to be done rapidly, but for some years now closure of the doors by hand has been replaced by automatic systems acting by electricity or compressed air.

These two classes, as likewise the station attendants, are subject to general conditions of life in artificial light, in a more or less confined atmosphere especially at the rush hours. As in the case of tram conductors, so here there enters a certain pathogenetic element in continuous contact with the public.

But the question that has pre-occupied hygienists most is that of the atmosphere of the tunnels and subways, although generally this has been considered mainly from the point of view of its content in bacteria.

A study (1920) of the Metropolitan Railway in London did not show, in the main, a greater richness in bacteria than that of the outside air (Graham Forbes).

According to Sutherland (quoted by Kober), the proportion of carbonic acid gas in the stations and carriages of the electric railways varied from 4 to 20 parts in volume when the air outside showed 2.8. A similar enquiry made relative to the air in the Metropolitan Railway in Paris (1928) covering chemical analysis, with inoculation of guinea-pigs in cages kept underground, did not reveal the air to have any injurious effect. On the other hand, examination of the staff did not show that those working underground presented any signs of tuberculosis.

Thus the enquiry was not pursued further.

Quite convincing is an old study made by Soper (1906-1907; quoted by Kober), giving the following results (per cent.) of analyses of air in the New York Metropolitan:

<table>

The average quantity of dust was 61.6 mg. and the maximum weight 20 mg. per 1,000 cub. metres of air. The excess of dust in comparison with the outside air was therefore 47 per cent. By suspending magnets in tunnels, Soper caught more particles of iron (from friction on the rails, slippers of the brakes, etc.) than he would have done in identical conditions in an iron foundry or in grinding and polishing shops.

Very few data can be found in medical literature relative to the pathology of the staff of underground railways.

Medical examination of the staff enabled Soper to report a very high incidence of dry pleurisy unattended by pain or physical discomfort (53 per cent. as against 14.5 among persons not working on underground railways), of congestion and inflammation of the upper respiratory tract which he attributed to draughty conditions and changes of temperature as well as to the nature of the dusts. But the reports are not of recent date. It is therefore highly desirable to have more numerous and precise data relative to the pathology of these workers.

Motorists and Chauffeurs

The principal factors causing harm to motorists are vibration, draughts, exhaust gases and prolonged nervous tension, not to mention the risk of accidents.

Available statistical data on morbidity among motor-drivers are recent, but are confined almost exclusively to bus-drivers. As regards mortality in England (1921) the Registrar-General gives a comparative mortality figure for motorists of 862—a lower figure than the average (1,000) for all occupied and retired males between twenty and seventy years of age.

As regards pathology many diverse symptoms may be shown, indicative of fatigue which may be due to very many causes—various noises in the car, lack of comfort, state of the road,
defective signal arrangements, dazzling sun, bright light signals, etc. In order of frequency the symptoms are frequent and un conquerable yawning, feeling of heaviness in the head, sleepiness even in holding the wheel, difficulty in falling asleep on going to bed, readiness to waken and nocturnal insomnia, anxiety and heart spasms, pathological absent-mindedness. These signs are aggravated in those who indulge in alcohol, even in moderate quantity. In a cold and humid atmosphere headache is said to be frequent and to cease generally soon after the subject finds himself in a warm place. Persons predisposed can protect themselves by adequate clothing and head gear (Boschi). English physicians have called attention to cases of fatigue from long motor-car journeys. On stepping out from his car the driver presents the spectacle of a symptomatic complex reminding one, at first sight, of an intoxicated person: tremor of the hands, difficulty in maintaining equilibrium, stiff movements, etc.

Petrazzani was the first (1907) to describe psychical troubles in a driver who had taken part in several races: mistiness before the eyes, confusion, inability to see the road properly, weakness of sight, nausea. The symptoms disappeared when a stop was called.

More recently (1926) G. Modena has again called attention to psychical troubles affecting drivers.

Cases of neuritis and perineuritis of the brachial plexus have been attributed to draughts striking the back and nape of the neck of the driver. A neuritis of the brachial plexus was described (1957) by H. S. Gaskell under the name of "motor arm" and was attributed also to the effect of a draught of cold air. In an open car the current of air strikes the wind-screen, rebounds in a semi-circle and strikes the back of the neck and back of the driver at the level of emergence of the 4th to 8th pair of cervical nerves. The trouble set up may take the form of pain and a "pins and needles" sensation in the brachial plexus and muscles of the forearm, or by pains localised in the splenius and trapezius muscles entailing rigidity and stiff neck. Many cases of typical radial neuritis have been reported in drivers of saloon cars where the drivers are in the habit of keeping the window on the windward side lowered. The pain in the arm is great, and the hand is sometimes doubled up. Pain increases on movement and with changes in the weather.

Motor-cyclists are less frequently affected (Gaskell) as they are generally better protected by their clothes; moreover the current of air catches them in front. A case of pain in the left leg was observed (resulting from the position of the leg) and also dragging of the right leg, which rubbed against the control levers; the compression on the peroneal muscle and the repetition of these little traumatisms induced trouble in the nerve and muscles.

Driver's talon douloureux (painful heel) may be seen after a drive necessitating frequent use of the pedals. The pain, which is said to appear generally on the following day, has its seat in the sole, especially at the points where the plantar fascia is attached, due to the facts that the heel rests merely its posterior surface on the ground and that it is in the position of dorso flexion of the foot to bring the pedals into action. These two factors, aided by the shaking, pull and strain the fascia. Serous bursae are also reported over the tendon Achilles (Bertwistle).

Calabrese (1934) has noted several cases of disease of the digestive system amongst motor-bus drivers and conductors.

Motoring exerts a pernicious influence on latent forms of cholecystitis, as well as on heart trouble and derangements of the appendix.

Persons with a vago-tonic tendency suffer from discomfort resembling seasickness when motoring.

In the case of slight lesions of the pelvic organs (appendages of the uterus, prostate, rectum), moderate and intermittent motor exercise may exert a favourable influence; in the case of advanced disease of this type, however, it is liable to aggravate the condition.

Motoring exercises a specially harmful action on gynaecological affections, and likewise on the health of women approaching the menopause.

As regards the urinaiy apparatus the automobile causes in particular a diminution in diuresis, which, in normal persons, is compensated for by polyuria after rest in a horizontal position. It occurs, on the other hand, more easily and is more obstinate in persons with slight renal insufficiency, but may have serious consequences for those in whom polyuria constitutes a compensatory mechanism.

Sometimes pain in the nape of the neck occurs with affection of the sight, brain fog, or general giddiness, which would point in a certain degree of renal insufficiency.

The strong air pressure on the eyeballs causes an infection of the con-
Transport Industry

Junctival vessels; a feeling of heaviness, running of the eyes, sometimes sufficiently abundant as to trouble vision; definite conjunctivitis with spasm and blinking of the pupils, and blepharitis.

The too rapid succession of luminous sensations suppresses or diminishes the retinal faculty of distinguishing properly the appearance of objects and fundamental colours; with this there may be dizziness.

Hearing also suffers. The drivers of large lorries are deafened by the continuous roar of their engines and their acuity of hearing is gradually diminished. It is for this reason that a periodic examination of these drivers has been suggested (Jacques).

Poisoning. — The exhaust gases always contain a certain quantity of carbon monoxide (1 litre of petrol equals about 530 litres), which increases if combustion is incomplete (when the motor is working badly or allowed to run free), in which case it may constitute 14 per cent. of the total exhaust gases. These also contain traces of methane, ethylene and acetylene hydrocarbons, as well as acrolein (in starting the engine).

The danger from carbon monoxide is especially marked in garages (see that article) and during the winter. The exhaust gases, further, may penetrate into closed cars (faulty floors) and thus cause poisoning.

In this respect systems of heating cars by apparatus through which the exhaust gases circulate are very dangerous.

Poisoning has been caused by petrol (washing the machine) and by benzol (mixed with petrol).

The troubles reported are various: headache, vomiting, loss of appetite, pallor, loss of mental control.

Mention should also be made of the risk of poisoning from the anti-knock substances added to the petrol and, in particular, lead tetra-ethyl (see that article) inside closed garages since the lead, which represents 64 per cent. of the weight and is found in the exhaust gases, may cause serious poisoning.

Petrol is now sometimes replaced by prop gas, obtained by the combustion of wood and charcoal which contains 25 to 27 per cent. carbon monoxide and 4-8 hydrogen. Heim, Agasse-Lafont and Feil have drawn attention to a new cause of industrial carbon monoxide poisoning which may happen when the gasogen is charged by the upper door, or when it is being cleaned from the lower opening, or when there are cracks and the gas escapes. Similarly, mention should be made of attempts to use compressed lighting gas as motive power.

The use of methyl alcohol as an anti-freezing mixture in the radiator would seem to represent a new danger for health. But an enquiry by the Bureau of Mines in the United States (1930) showed that there is no danger, that the data relative to poisoning by way of the skin are few and even these are not conclusive. All the same it is believed that continued exposure to high concentrations of the alcohol can set up severe troubles. The solutions of methyl alcohol used as an anti-freezing mixture should be coloured in order to avoid any accident.

Besides accidents due to collisions or overturning, the characteristic accident of motorists is fracture of the radius, described by Pouteau, Colle and Dupuytren, as a fracture "en dos de fourchette", caused by brisk return of the handle at the moment of starting. It is generally caused by marked extension of the hand along the forearm, but may also be due to tearing of pressure and flexion, as well as to any other mechanism. It is usually situated at the point at which the two upper thirds join the lower third. Research has been carried out in Germany more particularly with a view to discovering devices capable of preventing backfiring of the handle.

In Great Britain (1930) severe accidents have been reported on starting up. A youth, who for ten minutes had made vain efforts in turning the handle before making the engine start, complained the same evening of discomfort in his right leg, then loss of heat sensation and of pain radiating towards the thigh and right side of the abdominal wall as far as to 3 cm. above Poupart's ligament. Probably he had ruptured a small intramedullary blood vessel in the effort he had made. Another man, at the moment of starting, had the sensation of splitting pain and shock in the chest, followed by fainting. Here probably an aortic valve had been ruptured.

Alcoholism should also be borne in mind as a principal cause, especially at night, in numerous accidents. It is a nervous troubles, or simply fatigue after a long journey, may show a peculiar train of symptoms (stiffness, muscular slowness, staggering and motor inco-ordination), which may easily be mistaken for drunkenness. Nowadays methods allow of determining the amount of alcohol in the blood and urine in the living or in the organs in the dead body: methods of Nicloux,
Martini, Astruc and Radet, and Southgate.

Obviously, other habit drugs (cocaine, morphia, ether) detract from the skill of a good driver.

According to a study by Viteles and Gardner (1929), women taxi-drivers are more likely to have accidents than men, although it is not possible to say whether it is a question of relative inexperience or of a greater susceptibility to traffic accidents.

HYGIENE

Extremely long hours at the wheel should be avoided; the necessary measures should be adopted of avoiding causes of injury (discomfort from draughts, etc.; provision of closed cars and automatic starters; wearing of protective goggles and other means to prevent dazzle).

Care should be taken to see that the floor of the car is always in sound condition. (See article "Garages" for precautionary measures.)

The British Transport Bill (1930) proposes five and a half hours without a break on public transport services and heavy motor vehicles, with the object of preventing accidents from fatigue of overworked drivers. Exception is made in the case of fire and ambulance cars.

Medical examination should be made to eliminate persons with renal, liver and heart affections. Similarly there should be gynaecological examination of women seeking to take up public service, and work should not be permitted for them immediately after childbirth or miscarriage.

Carter and Coachmen

With the development of motor transport, horse transport tends to diminish more and more and to be of less importance. The data about the latter activity are, however, very scarce.

According to English statistics the comparative mortality figure for drivers of horse vehicles, principally employed in carrying merchandise, was 1,578, which is very high and well above the average for transport workers on the road. The principal causes in this excess mortality are cancer, respiratory diseases and accidents; but they are in large part to be more correctly attributed to social rather than occupational circumstances.

American statistics (1909), relating to 3,850 deaths, may be thus distributed in percentages: phthisis 25.9; pneumonia 12.5; bronchitis 1.5; other respiratory diseases 2.4; which would give a total of 42.4, although the percentage expected would be 26.5. Mortality from diseases of the heart and arteries was also in excess.

Hoffman considers that exposure to dust of roads and towns, inclemencies of weather, the arduous nature of the work, especially that of draymen and teamsters, are, in addition to alcohol, predisposing factors.

Maunlre reported (1930) Dupuytren's contraction among drivers, which he regards as an occupational malady.

Frequently in winter this class of worker suffers from frostbite of the hands and tips of the ear, and they are also exposed to certain infectious diseases (glanders, etc.) as well as to bites and kicks from horses, etc.

Kober suggests, among preventive measures, diminution in dust, to be obtained by proper road construction, and good methods of cleaning the streets in cities, etc.

Selection of Transport Workers

In the transport industry the selection of workers clearly corresponds with the collective safety of travellers and the public. For this reason probably railways were the first among the great industries to select the most suitable individuals for their own staff. Long ago a catastrophe at sea, due to inexact distinction of coloured lights, revealed the seriousness of this danger and the need was clear for having careful examination made as to colour blindness and acuity of vision.

Railways

Nowadays nearly all the large companies examine candidates prior to engagement on very much the same lines. The examination comprises the general state of health, but its strictness varies according to the countries and even according to the railway company in question.

With some the candidate has to answer a questionnaire dealing with illnesses and defects, and the medical examination includes examination of the urine, relation of height and weight according to the Quetelet table (France, P.L.M. Railway), etc. With others again, where no precise instructions deal with maladies and organic defects which might involve exclusion, a sound constitution, normal nervous system and physical and psychological aptitudes necessary for carrying out the special duties sought after, are insisted on (Italy: a height of at least
1.50 to 1.55 metres, according to the category, with a maximum of 1.70 metres for shunters and a minimum of 1.60 metres for brakesmen. In countries where the causes of exclusion are definitely stated (Austria, France, United States, Switzerland, etc.) rejection is made in the case of weak individuals, or those with heart disease, lung diseases, chronic intestinal disorders, kidney diseases, transmissible skin and genito-urinary diseases, advanced goitre, epilepsy, nervous diseases, bad skeletal deformities, changes in the blood vessels, etc. (Austria). For station and train work persons with chronic hoarseness and speech defects are rejected (Austria).

Too much attention cannot be bestowed on determining the existence of latent or recognised syphilis in the applicant because of the ocular and nervous complications which may develop.

Examination of the special senses (sight and hearing) is very important. The requirements as to sight vary a great deal: 6/6 or 5/5 for the locomotive staff (Austria); 14/10, without glasses, for both eyes, with at least 5/10 for one, for the categories of workers on whom the safety of the travelling public depends (France, P.L.M. Railway); 10/10 without glasses for each eye (France: State Railway); 0.7 at least for one eye and 0.5 for the other; use of glasses forbidden (France: Nord Railway); 12/10 for both eyes, with visual acuity of one eye not below normal (France: Paris-Orléans and Midi Railways). In Italy, acuity of vision for those concerned with safety must be 10/10 (optotypes of Monoyer) for each eye. For other categories, the requirements are less stringent and glasses are permitted. Correction by glasses is not essential for drivers, guards and workers on the permanent way. For others a maximum of 14/10 or 10/10, even after correction with glasses (respectively dioptries —4 or —5 or +5 or —10 is allowed). In Switzerland, visual acuity is measured by Snellen’s tables on a decimal system; A = 1.0 for every member of the locomotive and train staff is required.

In the United States, locomotive men, guards and pointsmen must have 20/20 for each eye without glasses; on subsequent re-examination 20/20 for one eye and 20/30 for the other, always without glasses; shunters, station employees and station-masters, etc., 20/20 for one eye and at least 20/40 for the other without glasses.

Ginestous considers that central visual acuity ought to be equal in each eye, examined separately, at 10/10 and that no optical correction should be accepted. In addition to the clinical determination and the central visual acuity, account should be taken of the quickness of vision (perception speed) and of the variations of acuity according to lighting changes, which bring out definitely the subject’s adaptive qualities to light.

The various companies require a normal field of vision.

The examination of the peripheral field in order to ascertain if the vision has preserved its normal extent in the peripheral field (investigation as to concentric narrowing, hemianopic scotoma), binocular vision (not often required), permit of verification of the soundness of the oculomotor apparatus.

All the companies require complete freedom from colour blindness both quantitative and qualitative. Only the methods of determining this differ (see the special publication of the I.L.O. 1 and report of Bourdier and Shaaff (1920)).

The Thirteenth International Congress of Ophthalmology (Amsterdam 1929), after having discussed the question of visual aptitude among aviators, motor-drivers, railwaymen and seamen, expressed the view that this question ought to be extended so as to include also the conditions of aptitude in respect of hearing and of the nervous system.

As regards hearing the whispered voice should be heard at 5 metres by each ear (Austria), or, for those on whom safety depends, at a distance of at least 1 metre (France: P.L.M. Railway), or for the same classes at 8 metres (Italy), at 6 metres on admission and at 8 metres on re-examination (speaking voice; United States, etc. For the other classes, generally 4 or 8 metres is required. In the case of noisy occupations (coppersmiths, iron beaters, etc.) perception of the spoken voice at 2 metres for each ear is enough.

Railway workers are subjected usually to periodic re-examination, the frequency of which varies according to class and according to age. These re-examinations relate to the general condition and special senses, having for their object the detection especially of signs suggesting alcoholism, syphilis, tuberculosis, epilepsy, diabetes, nervous disorders, kidney disease, derangement of sight, etc. For...

---

the classes concerned with the public safety this re-examination is made every five years up to forty-five years of age, every three years from forty-five to sixty years, and every two years above that age (Austria). Persons showing haemeralopia are seen each year, and those showing signs of cataract every six months. Similar requirements are made in Germany. In France, revision by the P.L.M. Railway is carried out every seven years up to forty years of age and every five years above that age. The Midi Railway re-examines every five years up to forty years of age and every three years thereafter.

In Italy, re-examination is made of all railwaymen as soon as they reach forty-five years of age; in the United States every five years up to forty years and every two years afterwards. At this visit the blood pressure is measured; every person showing 150-200 mm. is placed under observation and those above 200 mm. are rejected.

The attention of engineers and heads of services should be drawn to the necessity for detecting signs of mental affections, such as change in character, intelligence, queer behaviour, which may be premonitory signs demanding an immediate examination.

Obligatory re-examinations are required also when change in the qualifications occurs (Austria, France, Italy, United States); when workers suffer from serious injuries or diseases of the head, eyes, ears, or when they become addicted to alcohol (Italy); after infectious, nervous or kidney diseases; after diabetes, excessive nicotine addiction, alcoholism (Austria); after accidents (Austria, France, United States); when there is doubt as to the physical or psychical state of the men (Italy, France, Midi Railway); when nervous manifestations occur or fears arise as to vision (France, Midi Railway), etc.

Certain railway companies also require psycho-technical examination (Germany, Belgium, Italy, Switzerland, Poland, U.S.S.R., etc.); these are made at special centres.

TRAMWAYS AND PUBLIC TRANSPORT SERVICES

For similar reasons most of the tramway and public transport services arrange for a medical and psycho-technical examination of applicants before engaging them. Generally speaking, these examinations cover the same ground as those for railwaymen: sound physical condition with intact functioning of the special senses, especially in the case of drivers and conductors. A central laboratory for the study of industrial diseases opened in Moscow in 1926 comprises the following sections; physiology, psychology, hygiene, anthropology, functional diagnosis, polyclinic, hospital treatment. The objects of this institute are: study of the physiological characteristics of the transport industry and its industrial risks, determination of the professional aptitude requisite for the different categories of workers; and utilisation of labour in accordance with individual aptitude.

Munsterberg, before the war, drew up a programme for psychotechnical selection, and, subsequently, Lahy (Paris), Stern (Hamburg), Tramm (Berlin), Houdmont (Brussels) and others at Rome, Milan, etc., have laid down methodical tests. Without desiring to enter into details in regard to the tests in use or proposed, the principal basis for the selection of drivers may be enumerated thus: study of the occupational reaction time; examination or chosen reactions; different reactions according to different forms of stimulation; measurement of the time taken to do certain things; control of precision with which those things are done.

Use is also made of classifying and consultant tests (Lahy). The former are so called because their standardisation is carried out with a precision sufficient for the values given to each subject to be compared with the results furnished by a large number of subjects, the occupational value of which is known. These tests are those of motor sensibility, of attention disturbed by visual and auditory stimuli combined, of the regularity of the reaction time, and its homogeneity.

The consultant tests do not present a sufficient standardisation, but the information they furnish can be utilised in the case where they show a clear inferiority among the subjects. They are tests for appreciating speed, rapidity of the reaction time, motor fatigue with measurement of the strength of tenacity, rapidity with which images are grasped, emotivity.

These tests are completed by tests carried out on the platform (tramway or motor-bus) when the occupational movements of the driver are studied whilst a film representing an everyday scene is unrolled before him, that is, the route along which the candidate will have to drive his vehicle.

Medical and psycho-technical examination is obligatory before admission. As in the case of railways, the
companies have also instituted periodic re-examination — compulsory, in certain cases, after accidents.

The practical value of the psychotechnical examination will be sufficiently illustrated on recalling that at Paris, during the first year of service, 100 drivers thus selected were involved or in accidents at a rate of 18.5 per cent. less than the number of non-selected drivers. At Barcelona 3 accidents to every 35 drivers who had not passed the tests occurred as against 1 to 45 drivers who had.

MOTORISTS AND CHAUFFEURS

The increase in motor transport and the impressive increase in the number of accidents requires that more and more attention be bestowed on the physical and psychical state of drivers. Many times medical examination has revealed defects of such a nature as to make it dangerous for themselves and others; defect in the special senses, loss of arm or leg, various organic diseases, psychopathies, etc. In a period of eighteen months Toulouse, Dupouy and Schiff (1925) examined 36 chauffeurs, of whom 24 were taxi-drivers, from the point of view of mental capacity, and found the following defects: psychasthenia, obsessions and impulses not amounting to insanity: 12; toxicomanias: 2; epilepsy: 2; chronic alcoholism: 5; alcoholsim with dementia syndrome: 2; various dementias: 3; general paralysis: 10. Analogous observations showing the existence among motorists of definite causes of incapacity to drive are numerous. In remarkably agreement among medical men has been arrived at as to certain physical and psychical aptitudes and inaptitudes. Heart diseases are a cause of rejection, especially when there are anginal attacks, myocarditis, lesions of the aorta or of the aortic valves; high blood pressure; diabetes (acidosis); certain nervous conditions (epileptiform seizures, psychical disturbances in arterio-sclerotic persons, giddiness, tremor, motor inco-ordination; Etienne 1929).

Rejection is called for also in the case of over-excitables, anxious persons suffering from phobias or obsessions who might be smitten with psychical inhibition under circumstances involving unexpected dangers; addicts of all kinds especially alcoholics (Aubry); persons with defective limbs (loss of arms or leg, more or less complete functional inability to use them, limitation of movements, paralyses).

Integrity of the special senses (sight and hearing) has similarly great importance. Good visual acuity (0.3 for the one eye and 0.05 for the other; 200 m. maximum sight over the road; Jeandelize). Rejection of the one-eyed (public transport) whom certain experts on the question of safety are inclined to admit. As a matter of fact, experience has shown that there are one-eyed persons who drive very well, just as there are good drivers suffering from the loss of an arm or leg. Persons with one eye are rejected in Germany for the occupation of drivers of public vehicles but they are allowed to act as private chauffeurs.

The visual field, ocular motility and sense of light should be normal. It would likewise be advisable to reject those suffering from homeralopia.

Diplopia, opacities in the centre of the cornea, detached retina; anything which retracts the field of vision should be regarded as a cause for rejection.

Acuity of hearing with both ears is necessary for the perception of noises and their localisation. Deafness in one ear is nearly as dangerous as deafness in both, because it hinders the determination of where the sound is coming from (Jeandelize). Candidates who suffer from buzzing in the ears, persistent noises (subjective abnormal noises or paracusis) should be rejected as this creates confusion with useful noises. Persons should also be rejected who suffer from failure to maintain equilibrium, vertigo. Motor-car driving is never advisable during attacks of rhyno-pharyngitis with intermittent deafness.

So far as aptitudes of a psychical nature are concerned, the general mental state should be sound and, everyone suffering from mental affections characterised by hallucinations, mania, impulsiveness, obsession, paranoia, or general paralysis should be rejected. Qualities, such as power of attention, sensorial perception, motor reactions, exact appreciation of speed, of distance and of time, should be quite sound.

Among the studies on psychometric and autographic examination of motorists, those of Patrizi and his pupils are very important.

LEGISLATION

Several countries require medical examination before applicants are given driving licences. According to an enquiry conducted by the International Professional Association of Medical Men in 1928; in this examination is compulsory in Austria, Bulgaria, Danzig, Denmark, Estonia, Finland, Germany, Hungary, Italy, Latvia,
Luxemburg, Norway, Netherlands, Poland, Spain, Sweden and Yugoslavia. In France, Great Britain and in certain cantons of Switzerland it is only obligatory for drivers of public vehicles.

In Belgium the regulations specify that the drivers must possess the physical qualities required, and the Belgian Academy of Medicine has laid down the tests with which drivers of public vehicles should comply.

It is not possible to enter into the details of the different regulations in force. Some countries apply these in general terms (Danzig, Estonia, France, Hungary, Latvia, the Netherlands, Yugoslavia), while others define them more precisely and even specify the causes of rejection. These relate to the general state of health (Austria, Denmark, Estonia, Norway; or special senses (sight): Austria, Bulgaria, Denmark, Estonia, Germany, Italy, Luxemburg, Norway, Sweden (hearing); Bulgaria, Denmark, Estonia, Germany, Italy, Luxemburg, Norway, Sweden for which minimum have been fixed, as in the case of railway employees.

The requirements as to sight and hearing are less severe for drivers of private than for public vehicles (Germany, Italy, for example). The medical certificate may last for all time, or must be renewed every three years (Poland), every five years (Denmark, Finland, Latvia), every five years for sight (Norway), when an accident happens (Latvia), when temporary withdrawal of the licence is made.

Compensation for occupational diseases is only granted under Russian law, which awards compensation for Dupuytren's contraction among mechanics.

Certain countries, however, or certain State railways (Italy, for example) award compensation for certain specified diseases (chronic poisoning from toxic gases; chronic respiratory diseases from inhalation of irritant gases or dusts; deafness due to noise; chronic recurring dermatitis; eczema from exotic woods and among workers occupied in impregnating sleepers; retinal atrophies — death; workers engaged for ex-due to prolonged action of corrosive substances; retinal asthenopia and other ocular lesions among soldiers, casters and electricians; mobigraphia, industrial cramp, Dupuytren's contraction, caisson disease) occurring among railwaymen and workmen employed in railway workshops. The organisation of health work as it exists in connection with the railways in most countries renders impossible comparison with similar organisation as adopted in industry.

BIBLIOGRAPHY

The bibliography on this subject being very wide, the reader is referred to the quarterly publication of the International Labour Office: Bibliography of Industrial Hygiene.

Prof. A. Filippini

(k) Porters and Workers Engaged in All Forms of Transport and Propulsion other than Mechanical

French: Transport par l'homme : portage.
German: Träger.
Italian: Lavoratori addetti ai trasporti.
Spanish: Portadores.

GENERAL

This section deals with employment in which transport is an end in itself, and workers devote all their energy to that particular activity, substituting their muscular strength for that of animals or inanimate motors, even for considerable distances.

Among these workers there are some who do porters' work all their lives; others who are employed temporarily or only on certain occasions, e.g. young boys who commence work as carriers of various things for some years before being accepted as apprentices, or skilled workers who may be compelled to act as porters during periods of unemployment, or to work in making roads or fortifications, or in improving rural districts. The number of these workers is still considerable; but it varies greatly according to the country, and sometimes according to districts. The absence or impassableness of roads, a scarcity of animals or of vehicles, and of adequate equipment for them, a superabundance of manual labour, ignorance or incapacity for following other trades — all these factors affect the development of transport by man. In some regions these conditions are in-keeping with a low standard of civilisation, which may approach that of slavery.

In former ages the number of men employed as porters was much greater than at present Herodotus, for example, records that the building of the great pyramid of Cheops lasted thirty years and necessitated the employment of 370,000 slaves, half of whom died at the work, although they were changed every three months. Even to-day, in the interior of Africa, natives have to undertake forced labour which, for the most part, consists in carrying on the back, and has caused a cruel decimation of the population of certain districts (Goudal).

The question of forced labour, which was discussed at the International Labour Conference of 1929, is thus identified very largely with the question of transport.

A particular aspect of the risks for transport workers (see article "Dock Labourers") is also the question of
accidents among labourers employed in loading and unloading ships.

In many parts of Asia, and even on the coast, carrying chairs are used, not only in the towns, but also for quite long journeys. In other countries, such as China and Tonkin, there are still in public use in towns rickshaws drawn by men, an occupation which is fatiguing, dangerous and disagreeable; it is not only a source of injury to health, but is an offence against the dignity of man.

Whilst it is to be deplored that the number of human beasts of burden ( caballus) as Plautus, quoted by Ramazzini, calls them, is still considerable, it must be realised that in civilised countries, wherever there is economic progress, there are still, and there will always be, many conditions which demand human labour for such transport work as loading and unloading animals or vehicles, putting goods or furniture into warehouses or dwellings, the harvesting of food crops, laying out certain kinds of ground, building work on mountains and handling small ships; here human labour alone is able to adapt itself to the most varied conditions of weather and situation better than animals or mechanical means can do. But the diffusion and perfection of modern mechanical devices will tend to make man’s share in such toil increasingly rare.

Methods of transport by human labour are dependent on the direction through which the goods have to be moved, whether it be horizontal, vertical or oblique, on their shape, size, weight, their degree of cohesion, their resistance and hardness; also on the nature of the journey, whether by land or water, which in the former case will present varied resistances according to the state of the surface and according to the incline, and in the latter according to the presence of more or less strong currents. These methods of transport are also considerably affected by the help furnished by certain tools and appliances, such as levers, capstans, windlasses, pulleys and small trucks, as well as by local custom, or by some necessity for fitting in with special conditions. As regards this point, it is interesting to consider the various methods used, among different peoples, by mothers for carrying their children: — on the arms drawn up towards the chest in Europe, on the hip in Annam; or seated on the muscles of the buttock among Hottentots; or suspended on the back by means of a large band or a small bag, the ends of which cross in front of the chest, in China and Japan.

Every change in the position of the load, in the manner of fixing it and carrying it, exercises a different effect on the body and modifies perceptibly the conditions of the physiopathological problem.

The method of transport engaged in by man can be reduced to the three following types: (a) carrying the load on the person; (b) drawing or pushing the load; (c) raising or lowering the load.

These three methods can be subdivided into numerous other secondary methods.

Carrying on the Person

(1) The load may be placed on the top of the head (sinciput), with or without help from the arms; this method is chiefly used for carrying stones, bundles of wood, or receptacles containing water or provisions.

(2) The load may be placed on the upper part of the back or on the neck with or without help from the arms, as when carrying very large or very heavy objects, and with a band which encircles the forehead, especially on long journeys.

(3) The load may be placed on a shoulder, with or without the support from the arms, as when carrying kegs, sacks or planks, or on the two shoulders, as for wooden ladders, stretchers or carrying-chairs. A variation in the last method consists in hanging the objects to the two ends of a stout stick held horizontally on a shoulder, as when carrying with a yoke, or with a balancing pole, or on the two ends of a strap.

(4) The load may be placed on the shoulders with bands or straps, hanging from the trunk, either in front, like a French postman’s box, or the boxes of itinerant vendors, or on the side, like a scholar’s satchel or the soldier’s haversack, or at the back, like the pack of the soldier, the rucksack of the Alpine climber, or the basket of the mountaineer. The basket is often furnished with a frontal band, in addition to straps supported by a shoulder girdle, and rests on the lumbar region of the back.

(5) The load may be placed on the two forearms, or on one, with or without the aid of the hands. The principal varieties of this method of carry-
may be supported on the abdomen, as when carrying bundles, faggots, or parcels held under the arm. iliac crest, as when carrying bundles, firewood, bricks or trays; arms folded in a lateral curve to the trunk, with or without support from the hands on the back, i.e., with the arms extended or folded, but held at the side of the body, as for sacks, small trucks, or boxes; or with the arms extended or folded, but held at the side of the body, as for stones, kegs and heavy or bulky parcels; or on the coils, as for sacks and furniture, or persons sitting astride.

Loads Drawn or Pushed

On land the loads may be pushed with the arms extended in front, as for casks, small trucks, or boxes; or with the arms extended or folded, but held at the side of the body, as when moving various wheel vehicles furnished with shafts; or drawn or hauled by holding the shafts or ropes with both hands, or attaching ropes to the body in different ways; or using vehicles moved by the feet, such as peda l-bicycles or tricycles.

On water the unloading of boats, the pulling of fishing boats ashore or the nets to land in line fishing, presents operations similar to drawing and pulling on land, and the body takes up the usual positions.

During the act of rowing, the position of the body varies according to whether the act is effected by indirect impulsion, or from the bow of the boat, with one or two oars, in a sitting or standing position, with a fixed or sliding seat. A particular kind of rowing is used by the Venetian gondoliers, who stand on the poop and use a single oar.

When it is a case of pushing boats and rafts along on shallow rivers or lagoons, the boatman plants the lower end of the oar obliquely on the bottom of the lagoon, holds the other in the external subclavicular hollow; and then, using all his weight, pushes the boat backwards with his feet.

Raising or Lowering of Loads

The raising and lowering of loads includes hand transport from a lower level to a higher, or vice versa; it comprises loading and unloading loads, on the man's own person or on another person, on an animal or on a vehicle; the lifting of materials for building walls, or the stacking of goods. The positions of the body vary according to the weight of the load; the height and position of the levels from which a load is lifted and to which it is moved; and the vertical or oblique traction of a load by means either of a free cord or one passed over a pulley or a windlass.

The classification of the methods of transport just described is simply schematic, for these methods depend on individual habits, local customs, and special circumstances of the work. It may even be stated that for the same work the variations are more numerous than the movements and the attitudes adopted. Yet a precise analysis will disclose numerous analogies, not only between the different methods of carrying, but also between these and other muscular work which has not transport as its object.

It is, therefore, advisable to analyse the various kinds of transport and to take into account the attitudes of the body in all their phases, if the object is to make a conscientious physiological study. Attention will here be confined to illustrating the principal methods already classified, since the facts which concern them are easily applicable to methods which are derived from them or are similar.

Physiology

The problem for the physiologist consists in calculating the necessary effort — the energy-cost of the work — and in studying methods of participation by the different parts of the locomotor system and the internal organs.

For calculating the effort, it is necessary to consider both the exertion required to maintain the equilibrium of the body, i.e., static work, and also that necessary for moving the loads, i.e., dynamic or effective work.

Effort of Equilibrium

This effort is very pronounced in all methods of carrying of loads on the back. On the other hand, it is almost nil when drawing or pushing loads, or when lifting or lowering with machinery, because then the body finds a fixed point in the resistance of the load.

The amount of the effort depends partly on the weight of the load, but chiefly, on the method of carrying it. Even when no load is carried, a man in the upright position cannot preserve the equilibrium of the body and
avoid oscillations without carrying out static effort, due to muscular contractions with their consequences of bad circulation and fatigue, which is greater than the dynamic effort of slow walking. This latter requires in a man weighing 67 kg. 2,377 calories a day, or nearly 253 calories, or 12 per cent. more than those used up by a man in absolute repose (Zuntz). The upright position, at ease, on the contrary, requires 2,441 calories, or 15 per cent. more; and the rigid position or position of attention of the soldier, 2,548, or 20 per cent. more (Katzenstein). The centre of gravity of the human body when upright is at 57/100ths of its height above the ground, a point which lies between the promontory of the sacrum (Weber) and the upper border of the third sacral vertebra (Braune and Fischer). In the symmetrical vertical position, heels together, known as the "position at ease" of Braune and Fischer, not only is the effort less, but the equilibrium is yet more stable than in the rigid upright position, because in the first position the line of gravity passes 4 cm. in front of the line which unites the centres of the femoral heads, and touches the ground almost at the centre of the base of support of the body, that is to say, almost at equal distance from the two lines which unite respectively the heels and the toes, whilst in the second position the line approaches nearer the heels. The separation of the feet, one from the other, improves equilibrium, in consequence of the enlargement of the base of support. But, for a man standing still, the most comfortable and economical position is the lateralised position, resting on one hip, that is to say, resting on one leg whilst the other is ready to correct any small oscillations of the former.

Locomotion continually causes displacement of the centre of gravity as well as the base of support. Yet the energy-cost of maintaining equilibrium is less than that required to maintain the body still in the upright position, and this is so particularly in walking with short and slow steps. The same advantage is found in walking when a weight is carried which necessitates inclining the body forward. Ramazini has observed that a load is carried more easily on the shoulder with the body bent: "that is why porters and those who are carrying loads lean forward and push out the middle part of their body behind, so that the centre of gravity is found in the axis of their direction."

In order to estimate the effort of equilibrium, and also to take into account other factors, it is necessary to remember the following general law: "For equal loads, the muscular effort is greater in proportion to the degree to which the point of support for this effort is eccentric."

1. Carrying loads on the top of the head should theoretically be the best, for the axis of gravity of the load coincides with that of the body. However, it is often neither the most convenient, nor the most economic for heavy weights, because the load is badly supported by the cranial vault and the centre of gravity is raised, but particularly because all the muscles of the neck and part of those of the trunk are strongly contracted, while the arms have to be raised very high to support the load. This method is fairly efficient in the case of light loads, carried for a short time. Women, however, almost always prefer it as being more aesthetic than the others. As a matter of fact, when walking, the forced immobility of the head, neck and upper part of the trunk is compensated by an undulatory movement of the hips which is not ungraceful.

2. Carrying on the area which includes the upper part of the neck, the nape and shoulders is more comfortable and more economical, especially in the case of a heavy or bulky load. The area on which the load is placed is a large, firm surface, made up by flat bones, strong masses of muscle and pads of fat; so it is well adapted for carrying heavy bodies. This method has the advantage of lowering the centre of gravity, and of distributing the load better on the powerful dorso-lumbar muscles, the resistance of which is greater than that of the muscles of the neck. Further, when the raised arms are used to keep the load in position, less effort is required than that necessary for keeping the load on the head. Finally, if the arms are curved, with the hands resting on the flanks, the deltoid area contributes to enlarge the surface of the shoulders, so that the work of the dorsal and lumbar muscles is lightened. However, the axis of gravity in this method of transport on the shoulders can hardly ever coincide with that of the body. But the displacement and the consequent effort to maintain equilibrium remains quite slight if the load is distributed equally around the axis of gravity, transversely on the two shoulders, or in the sagittal direction,
with part before and part behind, or obliquely.

According to Speck, the consumption of energy for transporting a load of 25 kg., placed symmetrically with the line of gravity, is not markedly different from that required to keep the body upright at ease. On the contrary, the same weight, carried on a single shoulder requires a consumption of energy of 7 to 30 calories per kilogram per minute greater than the consumption required by ordinary walking. For the most economic transport possible of a load, it is necessary, according to Bedale and Vernon, that the human body should be displaced as little as possible from the vertical position, while the load should be equally distributed around the line of gravity of the body.

An example of transport of baggage in wallets is a double sack such as friars and peasants carry on the neck; or again two buckets may be fixed at the ends of a pole kept in equilibrium on the shoulder in the sagittal, transverse or oblique direction; and two valises joined together by a leathern strap imitating the valises, and two valises joined together by a strap or a band, is frequently used when the weight is not excessive or partially free, in the end it is more fatiguing (than carrying on the shoulder by holding them on the back, or when it has to be carried a long time.

A method which consists in carrying the load hanging against the trunk, either in front or at the side, but attached to the shoulders by a strap or a hand, is frequently used when the weight is not excessive or when it has to be carried a long time.

A method which consists in supporting the loads on the pelvic girdle, and has been proposed for soldiers because it has the advantage of decidedly lowering the centre of gravity, of having a rigid base on the iliac bones and of not straining the muscles or articular ligaments, on the other hand renders the movements of the legs and arms more difficult and leads to loss of the advantages accruing from diminution of the oscillations from the line of gravity on the march, and from cessation of the efforts of the trunk muscles. It is only an auxiliary means for lessening the weight on the shoulders and on the back, and is especially suited for carrying articles which are not bulky, such as cartridges.

(4) At least as fatiguing as the preceding is carrying on the forearms, that is to say, between the trunk and the curved arms, with the exception that in this last case there is the pos-
sibility of resting the load on the iliac crest. The effort is still greater when the arms must be stretched in front and the load is supported not on the forearms, but on the hands, as waiters do when carrying plates.

(5) Carrying by hand with the arms hanging the length of the flanks, or slightly bent, requires a consumption of energy of 30 calories per kg. per minute higher than is necessary for carrying on the shoulders a load arranged symmetrically to the line of gravity (Speck). Miss Bedale has also found this method less economic than carrying with the yoke.

The beneficial result of the considerable lowering of the centre of gravity of the body is annulled, for, whilst walking, the body oscillates continually from one side to the other. The load then interferes with the movements of the leg and compels the carrier to make a supplementary effort to replace the body at each step in the line of gravity and to hold the arms out away from the body. If the load is held by only one arm, the effort of equilibrium is the maximum of that required by all the other methods of transport; it compels the porter to hold the opposite arm raised horizontally to make a counterweight.

The carrying of articles with the arms hanging down is, for short distances, the method of transport which is preferable to all others, because it is more dignified than carrying on the shoulders, and affords the convenience of enabling the carrier to put the load down and take it up easily.

The carrying of loads held by the hands, but resting on the abdomen, does not call for an effort of equilibrium greater in general than that necessitated by carrying on the shoulders, and affords the convenience of enabling the carrier to put the load down and take it up easily.

(6) The lifting or lowering of a load by the arms without the use of such appliances as pulleys or windlasses is an operation which must be done in several phases in order to be able to calculate the effort of equilibrium.

In the case of heavy objects, a man instinctively tries to hold them as much as possible resting against the body, to take them and put them between the separated legs, in order not to displace too much the line of gravity of the body. On the other hand, the maximum effort is required for lifting with legs and arms rigid.

(7) The effort of equilibrium necessary to lift a weight by means of pulleys and windlasses is nil, if the man pulls on the cord of the pulley or on the crank of the windlass in a vertical direction; it increases when the direction is oblique, and is still more when the direction is horizontal. But practically speaking it is almost nil in every case. As a matter of fact, a man deliberately opposes his weight to the weight of the load in order to save the effort of pulling.

The practical problem of determining the effort of equilibrium in the work of drawing or pushing, whether applied on land or water, presents itself in an almost identical manner. In all work of this kind, the static effort is mixed up with the dynamic effort, so that it is almost impossible to separate them, because a man never holds his body in a vertical position, but inclines it more or less voluntarily, using his weight, when that is possible, to overcome the resistance of the load.

The Effort of Carrying

The expenditure of energy, i.e. dynamic work, in carrying loads naturally depends on a number of variable factors, of which the chief is examined below.

Investigations into the effect of weight and speed on the expenditure of calories in walking with a load have given most contradictory results. According to the experiments of Zuntz and Schumberg, a man of 70 kg. doing 75 metres to the minute (or 4.5 km. per hour) on a level road expends:

<table>
<thead>
<tr>
<th>Calories per minute</th>
<th>Calories per hour</th>
</tr>
</thead>
<tbody>
<tr>
<td>Without load</td>
<td>3.0</td>
</tr>
<tr>
<td>With a load of 22 kg.</td>
<td>3.9</td>
</tr>
<tr>
<td>... 28 kg.</td>
<td>4.2</td>
</tr>
</tbody>
</table>

Whilst walking up a gentle slope of 1 in 10:

<table>
<thead>
<tr>
<th>Calories per minute</th>
<th>Calories per hour</th>
</tr>
</thead>
<tbody>
<tr>
<td>Without load</td>
<td>6.90</td>
</tr>
<tr>
<td>With a load of 22 kg.</td>
<td>7.8</td>
</tr>
<tr>
<td>... 28 kg.</td>
<td>8.1</td>
</tr>
</tbody>
</table>

Amar, by observations on natives of North Africa, carrying 40 to 60 kg. at a maximum speed of 4-5 km. per hour during a daily march of about eight and a half hours, found the average expenditure excessively low, namely 0.311 call. per metre-kilogram. As regards speed, the same authority gives the following figures: speed: 80, 120, 180 metres per minute; expenditure of energy: kilogrammetres: 0.088, 0.119, 0.176 per metre-kilogram.
Kaploun found the following expenditure of energy per 100 kilogrammetres in two women carrying loads:

<table>
<thead>
<tr>
<th>Calories per 100 kilogrammetres</th>

<td>45.8</td>
</tr>
<tr>
<td>70 kg.</td>
<td>44.5</td>
<td>47.4</td>
</tr>
</tbody>
</table>

Some interesting investigations on the most economic method for carrying by man, that is, on the method which will give the maximum weight which can be carried without ill-effect to the body during a day's work, as well as the relative duration of periods of walking with the load and returning unloaded, i.e. of rest, have been made by Kolmer and Brezina in the case of a man of 70 kg. who carried varying loads of 11, 21, 33, 43 and 53 kg. on a track of about 155 metres at a speed of between 3 and 6.6 km. per hour. The smallest expenditure of calories per metre-kilogram was obtained: in walking without a load at an hourly speed of 4,200 metres (0.508 calories); with a weight of 11 kg. and an hourly speed of 4,200 metres (0.554 calories); with a weight of 21 kg. and a speed of 4,200 metres (0.454 calories); with a weight of 33 kg. and an hourly speed of 4,800 metres (0.523 calories); with a weight of 43 kg. and a speed of 4,800 metres (0.600 calories).

With 53 kg. it was necessary to reduce the hourly speed to 3,000 metres in order to have an expenditure of calories below 0.60 per metre-kilogram (the actual expenditure is 0.547 calories).

The best return was obtained when the load was 21 kg. and the hourly speed 4,300 metres. On the other hand, Kaploun found a sharp rise in the consumption of oxygen and in the expenditure of energy (calories) when a weight of 60 kg. was substituted for a weight of 50 kg.

The results would show that increasing the load always has an anti-economic effect, and the consumption of energy increases more rapidly with an increase in the load than in the speed.

Increase of speed can be especially useful in the case of short distances, and, indeed, porters are often seen to quicken their pace when they carry heavy loads. But for long distances and above a certain hourly pace (about 4,500 to 4,800 metres) speed increases in a very pronounced way the energy-cost of work, especially if the load is heavy. A man of 71 kg. carrying a load of 60 kg. was able to cover in a day 22,311 km. at an hourly speed of 4,824 m. But, on the other hand, he could not do more than 12,140 km. (or a little more than half), if the hourly speed was increased to 5,400 metres, or scarcely 576 metres more (Amar).

If, then, the most economic speed per hour is considered to be 4,200 to 4,500 metres the optimum weight should be 21-22 kg. This work becomes less economic as one gets further away from this weight. The observations of Zuntz and Schumberg on a soldier of 70 kg. carrying a load of 52 kg. and doing a daily march of five hours confirm this conclusion. In reality the soldier effected in two hours an expenditure of 4,312 calories, that is to say, much more than the 3,561 calories expended, according to Rubner, by a man doing moderately fatiguing work. By observation on officer cadets of the Frederick-William Institute, these same authorities found, when the loading weight reached nearly half the weight of the body (31 kg.), in spite of improved conditions of marching and of the temperature of the air, that serious physiological disorders were observed.

Further, with a load of 31 kg. young men under observation could not be successfully trained. On the other hand, the signs mentioned above did not appear or disappeared rapidly when the load in use was reduced to 22 kg.; hence, with this load, the young men could always be trained. Only a few cases were able to become inured to a minimum weight of 27 kg. It can then be said, speaking generally, that the normal effort of a man who covers 22 to 25 km. a day at an hourly speed of 4,200 to 4,500 metres is that which consists in carrying about a third of the weight of his own body, i.e. from 20 to 25 kg.

Cailhcart, Bedale and Overton have also confirmed that the limit of load for a woman should not exceed 35 per cent. of the weight of the body. This is also the result of numerous investigations on bodily resistance not only in the case of soldiers, but also on mules and horses which become rapidly fatigued when they carry a load of greater weight than a third of their own weight.

Patrizi, having observed that a load of 22 kg. carried by a man in the upright and right position has on a dusty road caused after some minutes, marked reactions in the cardiac and respiratory apparatus, drew attention to the fact that the weight to be carried should undergo a 'decided diminution.
as compared with the averages accepted by tradition and propounded up to the present time by empirical observation. And he adds: "To recommend that a load of almost 25 kg. can be doubled, or even increased to 60-65 kg. (that is to say, to approach the average weight of the human body, which is the equivalent of compelling an individual to keep mounting a staircase the whole of the working day, even with long pauses), is to display that physiological ignorance so much to be deplored among well-known industrial organisers of labour."

Apart from weight and speed, the greatest practical importance must be given to the length of the period for which the load is borne, and to that of intermediate pauses or times of returning unloaded. Taylor found that whereas loaders of pig iron were able to carry at each journey 41 kg. to a distance of 11 metres on ground partly level and partly slightly inclined (the ascent to 60 cm.), they were scarcely able to do it during 43/100 of the working day of ten hours, and that the 57/100 were occupied in returning unloaded. When an attempt was made to increase the carrying time to 58/100 of the working day, or scarcely 15 per cent. more, it was necessary to reduce the journey half or to 2 kg.

In the experiments of Amar already mentioned, on cases who were quite accustomed to walking with loads, the results indicated, which the author has defined as a "maximum maximum" of the development of energy, could not be obtained except by giving 2 to 5 minutes' rest per kilometre, or one or two minutes every 600 metres.

The inclination of the ground to be traversed is a very important and variable factor. According to Zuntz the expenditure of energy per unit of work is 68 calories per kilometre for a distance of 6 km. with 25 kg. load; 49 calories per 100 metres for a distance of 300 metres on an incline; 58 calories for 100 metres on a steep path with a gradient of 53-68 per cent.; 89 calories per kilometre for an ascent of 3 km. on an inclined path.

If the expenditure per kilogrammetre (horizontal, walking on the level) be considered as equal to 0.51 calories, the expenditure for mounting a staircase can be calculated at almost 8 calories, or sixteen times more (Amar). Coulomb has estimated eighteen times greater, and Haughton twenty times; but the proportion which seems to be the most accurate is that of sixteen times. As regards walking, on an inclined surface, the expenditure is about 7.40 calories per kilogrammetre when the gradient is 0.08 metres per m. and 10.69 calories for a slope of 0.13 metres (Amar).

In the descent, on the contrary, the expenditure was 5.50 calories in the first case and 4.53 in the second (Chauveaux fixed 52/100 the ratio of the expenditure between the descent and ascent in a vertical line. For the descent on an inclined way, with a slope of 13 cm. per metre, Amar found the ratio almost equal, but, with a gradient of 8 cm. the ratio was 85/100 for a man descending without load, and 75/100 for a man descending with a sack of 7.300 kg.

There exist, in addition, other secondary coefficients, of which the most important are the method of transport, the weight of the body, the muscular development, the freedom of movement, fatigue, food and the surrounding temperature.

The expenditure of energy varies markedly according to the method of transport (analysed in the article "Industrial Physiology").

According to Atzler the expenditure of energy in drawing a small truck on a level road is smallest when the man uses cords attached to both shoulders; it increases if the traction is effected by means of a cord pulled by the two hands; and it is still more increased if the traction is effected by a single cord attached to one shoulder. The energy expended in pushing a little truck on a level road is smallest when the man leans on his hands at the height of a metre from the ground; it increases if he leans at the height of half a metre; and is yet a little higher when the height of support is a metre and a half.

If a weight is raised with a windlass, the expenditure is at a minimum when the height of the handle is such that the man is able to keep the body erect; it increases if he has to hold his arms raised; and is still greater when the body is drawn together and bent.

In raising a weight, the expenditure of energy is at its maximum when the weight is raised directly from the ground; it is less if the load has to be lifted from a level at a metre from the ground.

Amar, Imbert and Crowden have made some interesting researches on the maximum strength developed by a man or a woman, and on the maximum load for transport by means of pulling or pushing (wheelbarrow).

The load should not exceed 150 kg. (Imbert) if the object is to avoid, or at least to attenuate, most pathological conditions, such as increase of pulse.
rate, respiration and arterial pressure. The best results are obtained when the load is balanced so that there is little weight on the arms, when it permits of good posture, and when the height of the wheelbarrow is adapted to the height of the individual (Crowden).

**Morbidity and Social Conditions**

For studying the social conditions and morbidity of porters, consideration is restricted to regular porters: porters on railways; at ports on quays, ships and barges; on rivers and lagoons when pulling and towing; and workers attached to the public transport agencies or the big markets. Type personnel of these services is usually disciplined by the local customs, or organised in associations and corporations regulated by special rules, approved by the authorities, except for those who work in the country and do so in an isolated and independent manner.

The mentality and social status of porters are generally of a quite low order, for the occupation is considered as very humble, almost contemptible and unworthy of a free man. Porters are usually of good muscular development, but of slow intellect (the bovine type of Taylor), and have no other qualifications than that of being able to furnish brute strength. Nor is it necessary that these men be of an athletic type, as might be expected according to the capacity for effort and for resistance which is required of them. Having observed that persons of the asthenic type were hardly surpassed by individuals in athletic development in daily work, Brodnitz and Grotjahn consider that the capacity for resistance does not depend on the power of the muscles, but on that of the ligaments. However, an enquiry of the Industrial Fatigue Research Board (1928) indicates the presence in workers of a certain proportion between the weight of the body and the total available strength; a coefficient of resistance exists below which there is inaptitude for heavy work.

Porters are, from the very nature of their work, compelled to eat much and, to take large quantities of drink, often alcoholic. It is also known that they spend frequently a large part of their time, which is not given to work or sleep, in the streets or open air, having as natural companions the lowest dregs of the social scale. But although the moral standard of these workers may not be high, porters — that is to say, those who are organised — do not seem to furnish a large contribution to crime.

Better economic conditions than those of certain categories of workers, and especially those of casual labourers, as well as a torpid psychology, contribute much to the avoidance of the strongest inclinations to crime.

Data on the morbidity and mortality of load carriers are almost nonexistent; official statistics usually confuse these workers with the large category of unskilled workers, or mix them with other categories of the services to which they belong, e.g. railways or maritime services.

Further, crude figures cannot have a great value, if the other conditions are not known; these are very variable from case to case, and include exposure to bad weather, long hours, weight of loads and kind of feeding. However, the morbidity and mortality are in general lower than those of numerous other industrial categories, which is certainly due as much to the rarity of any exposure to poisons or infection during work, as to the fact that this occupation is almost always carried on in the open air. The most complete information which is available deals with the morbidity of dock labourers (see articles "Boatmen", "Dock Labourers", "Seamen", etc.).

According to Mauro, the illnesses experienced by porters who during twenty years attended at the Milan Clinic for Occupational Diseases, were distributed as follows: respiratory diseases, 25.96 per cent.; gastro-intestinal disorders, 25.8 per cent.; rheumatic conditions, 19.5 per cent.; cardiovascular disorders, 14 per cent.; and tumours, 3.6 per cent. As regards the last three groups, porters come before all other workers.

As regards tuberculosis, the rate for this disease found among the transport workers of the Italian iron ore works is higher than that for other categories (Peri). It is also very common among the Chinese rickshaw coolies (Mazzolini).

**Pathology**

Carrying, such as involves heavy work, is sometimes continued without remission and often calls for rapid and strong muscular contractions (see article "Effort").

The body reacts first to these efforts by more or less serious symptoms or disorders of the circulation and respiration, following upon the more or less permanent contraction of the muscles and in particular; those of
the thorax and abdomen. The pulse rate may increase from 30 to 50 per cent.; the cardiac systole is prolonged from $\frac{3}{4}$ to 4; while the diastole is shortened from $\frac{1}{4}$ to $\frac{3}{4}$; respiration is increased to 25 or 25 a minute, while the vital capacity is lowered; and the temperature of the body varies from $\frac{1}{4}$ to $\frac{3}{4}$ degree (Amar).

Some almost identical changes after walking with a fairly heavy load have been found among officer cadets of the Frederick-William Institute who showed also symptoms of general stasis and in particular of the liver (Zuntz and Schumburg). A slight degree of hypertrophy of the heart, especially on the left side, of arteriosclerosis, and of pulmonary emphysema, especially marginal, have been noted among porters who carry loads on the head in Calabria, by Gabbii and Repaci. Gabbi has often found a fatigued heart among the carriers of kegs in Messina; Guffré has studied and clearly described the symptoms of fatigued heart among the fishermen of Siracava. Podkaminsky (1929) has recently contributed a radiographic study of porters' hearts.

Repercussions on the venous system, in the form of varicose veins or varices, are, on the other hand, somewhat doubtful among steel workers (Mazzolani), and porters of carrying-chairs in China (Mazzolani). Brodnitz and Grotjahn found 3.3 per cent. of varicose, 32.6 of serious varicose veins, 24.8 of slight varicose veins, especially on the left side, in the case of porters carrying sacks of flour.

No abnormal frequency, on the other hand, has been found by Vitali among the boatmen of Venice, nor by Diez among railwaymen and Post Office employees in Italy. Diez, while quite recognizing that varicose veins are not an occupational disease, considers that certain occupations are unsuitable for those with varicose veins.

Hypertrophy of the thyroid may also be considered as a consequence of circulatory disturbances. This has been found in young girls immediately after having commenced carrying weights on the head (Repaci, Fratini, Vidoni), as well as goitre, of which Mazzolani has observed 3 cases among 16 porters of chairs in China.

Hernia may be another pathological consequence of strain from carrying; it was found in the case of 14 per cent. of porters, especially those over fifty years, and weakening of tissues predisposing to hernia in 40.3 per cent. by Brodnitz and Grotjahn. Cases of movable kidney are not by any means rare.

Increase of the abdominal-thoracic pressure during lifting and carrying loads has been studied by Kaploune. By means of direct measurements on women, the ordinary type of respiration was found to be changed at the end of one to one and a half months, becoming principally diaphragmatic, and, during the lifting of weights over 20 kg., the intra-abdominal pressure increased, whilst it became lowered sharply and remained normal or almost so during the time of supporting the load. Lowering and a transient deviation of the body of the uterus has been noted. A comparative investigation by Kaploune on women porters and women workers other than porters has confirmed that the carrying of loads exercises an injurious influence on the genital organs of the woman. Women porters attribute a certain number of the disorders of menstruation, metrorrhagia, prolapse or simple falling of the uterus to their work; these affections were not only more important among the first than the second group of workers, but they occurred to a much higher degree among the first class of women after they had taken up the work of carrying loads.

Okuniewa, Steinbach and Schtlegowa have also reported disorders of menstruation in 60.5 to 78 per cent. of women porters, against 26.5 to 39.2 among other women workers. According to the early statistics of Conrad, women employed in carrying loads had 4.5 of stillbirths per 100 births compared with 2.1 for the rest of the population.

Changes in the body, consisting in permanent or transitory changes in the muscles and ligaments of the joints, constitute a second group of ill-effects due to the carrying of loads. The intervertebral fibro cartilages are crushed, which increases the normal curvature of the different segments of the vertebral column. The highest degree of flattening of the cartilages is met with in porters who carry on the head, because the vertebral column is then held in almost a vertical position. It should be mentioned that Gabbi and Repaci have observed a projection of the last cervical vertebra in women porters in Calabria.

The lower limbs also undergo such deformities as curvature of the femurs, genu valgum and flat foot. This latter is only seen in porters who work on flat or smooth ground, never in porters who work on rough ground.
The various changes in the formation of the skeleton naturally depend on the method of transport. When the weight falls on the line of gravity of the body or close to it, the deviations of the vertebral column appear chiefly in the form of kyphosis or lordosis. On the other hand, when the load is carried so that a crucial shoulder is held raised and this leads to dorsal scoliosis with the concavity directed towards the opposite side, with exaggerated raising of the costal arches of the same side and compensatory lumbar scoliosis. If, on the contrary, the load is carried below the shoulder, that shoulder is lowered and the dorsal concavity is directed towards the same side. The “scapulae alatae”, and an exaggerated development of the arms, in comparison to the height of the body, may be met with as a result of any of these methods of transport. The same thing may be said of flattened pelvis in women who carry water (Pen.)

These asymmetries and deformities are aggravated when the effort of carrying is borne by bodies which are still in the course of development. There may here be mentioned the early investigations of Giordano and Vasta, on children who carried sulphur (ca. rust) in the Sicilian mines (see article “Sulphur”).

There are methods used in transport which may cause the formation of a partial cavity in the region of the ribs and the sternum; such as the sub-clavicular fossa in boatmen of the Rhine, the Rhone and the lagoons, due to the application of the extremity of the oar to this part in order to move the boat along. In the same way, repeated pressure of hard substances on various parts of the body, especially on the back and shoulders, causes various and numerous bodily stigmata: atrophy, thickening and callosities of the skin, pigmentation, hypertrichosis, pseudo-oedemas (Levi-Bianchini), fibromata and lipomata, cysts and serous and mucous bursae; asymmetry of the acromion extremitv of the clavicle, due to carrying on one shoulder (Mori); slight hollowing of the bones of the vault of the skull and falling of the hair (Gabbi and Repaci); and deformity of the ear (Hisashi Okajima). Sometimes also this skin, after much irritation, becomes inflamed, and ulcerates in the parts on which the loads are carried.

Local pressure of hard bodies, and the muscular contraction it causes, is the cause of myositis (Devoto), neuralgia and muscular cramps — in the region of the neck and shoulder among porters who carry on the head, or on one shoulder; in the region of the arms when they are held up to support loads (Repaci).

Many diseases of the skin or mucous membranes are caused not by the actual carrying, but by the materials carried; dermatitis alatalis (Mori), which also caused an inflammation of the external ear (Coustan); or to cement (Papanti Pelletier); or to pyrites from Cyprus, which may also cause ulcers of the skin, blepharitis, conjunctivitis (Riedel), and sometimes nasal haemorrhages (Loriga); or to guano, basic slag, and manganese ore. Infestations by itch-mites (Pediculoides ventricosus) have been observed on various occasions among barley grain porters (Sherna, Engelbach, Levi). Among infections anthrax is important, occurring among unloaders of skins in the ports, and plague, due to contact with rats living or dead, or with their excrement in the holds of ships or in warehouses.

The use of such poisonous gases as hydrocyanic acid and sulphurous gas for disinfecting ships may be a source of serious poisoning among labourers unloading ships (Colombani, Rothfuchs).

The risk of accident must be also mentioned, especially among certain classes of porters.

According to Rothfuchs, the number of accidents among 18,000 persons employed in 1926 on transport or unloading work at the port of Hamburg, on the quays and ships, was 5,594 with 40 deaths: a percentage of 31, against only 14.66 found in the shipyards. The most common accidents are due to serious crushing of the abdomen; fractures, bilateral or multiple, of the pelvis; of the thorax or the limbs; and result from the fall of labourers into the holds, or the falling of loads on to the workers. According to Rothfuchs, other etiological factors of accidents are atmospheric conditions, especially humidity, cold and thin coatings of ice in the case of open-air workers; the engagement of fresh personnel not used to this special kind of work, as well as the abuse of alcohol, which is quite common.

Similar causes are found in the etiology of accidents among porters employed on constructional work or on the highways.

**Hygiene**

The principle which should underlie any hygienic measure in the transport
industry is that, as far as possible, the employment of man to do mechanical work should be avoided, and that, on the contrary, he should be used to control and concentrate the energy produced by other sources of motive power.

This principle to-day is largely applied in all organised transport services, in ports, railway stations, large industrial concerns, the construction of buildings and bridges. If it is not possible to use fixed or mobile mechanical devices, animals should be substituted for inanimate motive power; and, when it is necessary to have recourse to the strength of man, it is better from the hygienic point of view as from that of economy, since the energy-cost of the human motor is higher than that of other motors. Further, freeing man from carrying loads contributes to raise his personal dignity, for this labour of transport has always been associated in the mind of the people with the humiliating idea of servitude. It is merely necessary to recall the contemptuous signification that in all countries is attached to the term "porter", as well as other expressions which may be substituted for it, e.g. hatman, coolie, fatigue man, or common labourer, as well as the discussions on native labour which took place at the International Labour Conference in 1929.

Hence it was that the Seventh Italian Congress on Industrial Medicine welcomed a resolution by Peri and Loriga, demanding that legislation should be adopted prohibiting the transport of loads by man except in the case of absolute necessity. In any case, transport work should be work complementary to other occupations and not a definitive and exclusive occupation.

Where carrying loads by man cannot be avoided the ill-effects which may occur to the health should be prevented by limiting the maximum weight and the duration of carrying, as well as by improving the methods of transport.

An enquiry made by the International Labour Office, through the intermediary of the members of its Correspondence Committee on Industrial Hygiene, in 1926, showed that the weights of loads carried on men's backs in the principal European ports is still very high. This weight varies between 85 and 100 kg. in the port of Antwerp; between 100 and 120 kg. at Marseilles and Cardiff, and may reach 200 kg. for certain bales of flax in Belgium. The maximum weight permitted by regulation in the port of Genoa is 100 kg.; but it is often exceeded.

In Germany, weights of 100 kg. and over have been found in three-quarters of the industrial concerns; some sacks reached 200 kg. and, only a few years ago, sacks of potassium nitrate weighed even three hundredweights (Brodnitz and Grotjahn). In Great Britain the loads carried only a few years ago by the workers were 101 kg. and over; in the U.S.S.R., they vary from 80 to 160 kg. for stevedores on the Volga, and from 80 to 220 kg. for porters in Astrakhan. While recognising that these weights exceed by a good deal the physiological tolerance of the body, it must be said that it is not easy to fix a figure for a maximum weight which may be in complete harmony with the requirements of hygiene and those of working conditions, especially if the differences which exist in different cases be taken into account, such as the distances to be traversed; the slope and firmness of the ground; the height to which the load must be lifted; the frequency of the journeys; whether the return journey is without load; and the duration of the working day.

Loriga, in his report presented in 1914 to the meeting of the International Association for Labour Legislation, shows that, according to the researches of physiologists and experience largely acquired from work amongst soldiers, the limit of load physiologically bearable on a march along a level road, with an average hourly speed of 4 to 5 km., cannot much exceed a weight of 22 kg., if the carrying has to be continued for several hours a day and for consecutive days. Several reasons, however, do not permit of the strict application of this limit, which is recognised for soldiers, to stevedores; the latter carry loads for short periods, and enjoy thereafter a period of comparative rest which is at least as long, if not twice or three times as long, during the return journey without a load, and of rest while waiting or preparing to take other loads. But sometimes there must be taken into account aggravation caused by the frequency-
with which the effort of starting to walk has to be repeated; it has been calculated by Chauveau as equal to 2.50 per cent. of the static effort required to support the load; and also the much more considerable effort required by porters in loading and unloading.

The porter can diminish his energy-effort by regulating his step according to the weight, the distance to be traversed, and the irregularities of the ground, while a soldier must march in step; speaking generally, the load is better balanced than with soldiers, and, further, the majority of porters are usually stronger, better selected and more accustomed to the work than soldiers.

Circumstances being equal, the load of a stevedore may reach, without injury to his health, a weight of 60 kg., and be carried for a normal day of seven to eight hours, which includes the pauses and returning without load. But if the loads have to be transported to distances greater than 40 metres, or if the man must ascend steep slopes, or himself load the burdens, then the weight of the load or the daily duration of the work should be diminished (Loriga).

The trade unions have on several occasions demanded the fixing of a maximum weight. Their demands, which have been cited in the report already referred to of the International Labour Office, are that the maximum limits of loads should be fixed between 60 and 75 kg. It is this last figure which was taken by the International Labour Conference at Geneva in 1928 as the basis of discussion for the protection against industrial accidents of men employed in loading and unloading ships.

Hygienists encounter still greater difficulties when they try to fix the maximum weight for women and children. Cathechart, Bedale and Overton have tried to establish a relation between the optimum load and the weight of the body, by taking into account not only the ratio between the weight of the body in two categories, adults and women or children, and the surface of the body (as is done for the calculation of expenditure in calories to determine the food ration), but also the capacity for development of neuromuscular strength, and, especially of the need of preventing work from disturbing the rhythm of growth, and the functions of maternity.

In France, the Decree of 28 December 1900 fixed the limits of loads which may be carried by children, either on the

In 1927 the International Federation of Transport Workers, and the International Federation of Food Workers, demanded that for young persons from sixteen to eighteen years the maximum limits for loads should be 50 kg., and that for women they should be fixed by legislation in the different States.

The limit of the working day during which a man can do carrying on his back is quite as important as the foregoing discussion. As a matter of fact, all the pathological manifestations which have been described as organic disharmony depend more on the duration of the carrying than on the weight of the load. However, this idea is not yet accepted by experts (see below, Legislation: Italy). There has also been a demand that, in the absence of legislative arrangements, candidates for the occupation of porter should be subject to a medical examination, as used to be done in the case of a man seeking employment as a porter in the French markets; this examination would be carried out chiefly to ensure that the circulatory and respiratory apparatus function regularly (Perl).

Very important hygienic results can be obtained by studying the technique of transport and the organisation of work; the use of tools and other apparatus to aid the work of man; conditions of firmness and safety of the ground traversed, such as bridges, foot-bridges and ladders; and also instructions specially laid down to avoid the ill-effects which may arise from some raw materials, capable of causing infections, poisonings and burns; or certain conditions of the atmosphere of the places of work, which may lead to asphyxia, or lack of light.

1 Reply from the Italian Labour Office to the Health Department of the town of Venice.
LEGISLATION

Australia, in South Australia young girls under twenty years are not allowed to lift and carry weights exceeding 13 kg.; in the State of Victoria this measure has been applied to young girls under eighteen years. In Spain children under sixteen years are not allowed to carry weights exceeding 10 kg., nor to draw or push loads representing a greater effort than that necessary to put in motion on a horizontal surface the weights mentioned in section 9.

In Germany (Bavaria) women are not allowed to carry loads in the building industry.

In the United States women are not allowed to lift a weight exceeding 30 kg. in California, or 11 kg. in the States of Ohio and New York — where, however, it is recognised that the weight is of less importance than the manner in which it is raised, the distance to which it is carried, and the effort and strain which it demands.

In Greece children under fourteen years are not allowed to carry loads exceeding 5 kg. and young persons under eighteen years loads of more than 10 kg. They are not allowed to draw or push loads over 300 kg. on small trucks moving on rails, or over 50 kg. on wheelbarrows.

In the U.S.S.R. it is illegal to employ at loading work boys under 11 years and women, and the maximum weight of packages which may be carried by a single person is limited to 48 kg. (3 poods). Beyond this weight, the separate work of loaders is prohibited, and the placing of the load on the back of the porter, as well as the lifting from the back of the porter, must be done by the help of other loaders. The maximum weight of load to be transported without machinery is 80 kg. (5 poods); beyond that wheelbarrows must be used; for loads above 480 kg. (30 poods) special machinery must be employed.

In some countries the Governments have laid down a list of the various kinds of transport work in which the limit of the load varies according to the age and sex of the persons employed. The regulations in force in some of these countries are given below:

Argentina.

Order of 15 October 1913 relating to the administration of the Act of 14 October 1907, No. 5291, regulating the employment of women and children 1.

Section 49. Maximum loads. The maximum weight that workers may carry both without and within the workrooms shall be:

(a) 10 kg. for boys under 16;
(b) 5 kg. for girls under 16;
(c) 10 kg. for women between the ages of 16 and 20.

Section 50. The maximum weight that may be drawn or pushed, including the weight of the vehicle, shall be as follows:

Chile.

Act No. 3915 of 9 February 1923.

Under this Act the weight of sacks containing goods of any kind which are to be carried by man power shall not exceed 80 kg.

Regulation No. 2494 of 27 August 1922 for the administration of the above Act state that a sack containing goods which is to be carried on the shoulder shall not weigh more than 80 kg.

Sacks not provided with handles may be dragged by young females if they do not contain goods likely to be damaged in this way, provided that an agreement has been concluded to this effect between employers and workers.

Sacks containing foreign goods which weigh more than the legal weight shall not be carried on the shoulder unless the weight is reduced to 80 kg. Sacks containing goods liable to increase in weight owing to damp or for other reasons shall be deemed to comply with the Act even if they weigh more than 80 kg.

France.

Decree of 28 December 1909, amended by the Decree of 26 October 1912, regulating the labour of women and children employed in industry and commerce (maximum loads which may be carried, dragged, or pushed by children and women).

The Royal Decree No. 520 of 14 April 1927 confirming the general regulations for industrial hygiene lays down in section 29 "special rules for the work of children, young persons, and women."

The weights to be carried by such persons when engaged in the transport of loads may not exceed the following:

(a) Weights to be carried by hand or on the shoulder:
- Boys under 15: 15 kg.
- Boys of 15 to 17: 25 kg.
- Girls under 15: 5 kg.
- Girls of 15 to 17: 15 kg.
- Women over 17: 20 kg.

(b) Weights to be carried on three- or four-wheeled handcarts on the level:

Eight times the above rates, including the weight of the handcart.

(c) Weights to be moved in trucks running on rails:

Twenty times the above rates, including the weight of the vehicle.

Women, young persons, and children may not be engaged in carrying loads for more than four hours per day.

Children and young persons under 18 years of age may not be employed in moving trucks.

Boys and girls under 15 may not be employed in the transport of loads on barrows or two-wheeled handcarts under dangerous or difficult conditions.

Pregnant women may not be employed in the transport of goods by any means after the sixth month of pregnancy.

Trinitrotoluene

(Tolite; Tolue; Triton; Trotyl; T.N.T.)

French: Trinitrotoluene. — German: Trinitrotoluoel. — Italian and Spanish: Trinitrotoluelo.

**Properties**

Formula: \(C_7H_5(NO_2)_3\) (CH)\(_3\). Trinitrotoluene (T.N.T.) is a stable substance, not affected by exposure to the air or to damp; it is solid at ordinary temperature; it occurs in the form of clear yellow crystals which are very slightly soluble in alcohol, but more soluble in fat solvents such as ether, sulphide of carbon, acetone and benzol. It melts between 80° C. and 112° C., according to the isomers present; in the pure state it melts at 81.5° C. and solidifies at 88.5° C. With a rise of temperature it ignites and burns with a very smoky flame. When melted and hardened again, it can be sawn and filed without danger. It is less sensitive to concussion and blows than picric acid. Its combustion causes a sudden shock, which gives rise to a violent explosion. It is affected by light, which causes a superficial change in colour veering towards dark brown. It is without smell and has a bitter taste. It colours the skin, hair and nails yellow, but this coloration disappears when treated with a mixture of “water-glass” (the product which results from the reaction of silicic acid upon soda) with Glauber salts and alum.

**Industrial Operations**

T.N.T. is obtained by nitrating toluene (see that article) generally carried out in three stages; first, toluene is converted into mononitrotoluene and then into dinitrotoluene. The mono can be transformed directly into trinitrotoluene, but the preparation by three stages gives the best results.

The toluene is heated, keeping the temperature steady at 30°-40° C. in a nitrating apparatus of cast iron, furnished with a mechanical stirrer; a mixture of sulphuric and nitric acids is then slowly added while stirring during half an hour at a temperature of about 50° C. The mononitrotoluene which forms as oil in the upper part of the solution is decanted and washed with water. The product so obtained is added to a sulfo-nitric mixture in a nitrating apparatus and stirred till a temperature of 90° C. is reached. At the end of an hour’s reaction at this temperature, dinitrotoluene forms and is decanted.

If the nitration is effected by putting the mono into a bath containing mother liquor from a preceding process of trinitration, the dinitrotoluene obtained contains 10 per cent. of trinitro. T.N.T. is prepared by dissolving dinitrotoluene in sulphuric acid of 100 per cent. strength in a nitrating apparatus and heating the mixture to 60°-65° C. Next sulphonitric liquor is added in such a way that the temperature is maintained at a fixed degree which however varies according to the different phases of the reaction. Finally, sufficient water is added to weaken the acid to 60° B.; at this stage there occurs precipitation of the greater part of the product in solution. It is then reheated to 90° C. and decanted.

Nitration may sometimes be effected in a single process and trinitrotoluene obtained directly by starting with mono mixed in a nitrating apparatus with sulphuric acid at 66° B. It is then heated to 80° C. and dry nitrate of soda is gradually added until a temperature of 120° C. is reached, which should be maintained for an hour and a half. It is then allowed to fall to 90° C. and the process is terminated as above.

The T.N.T., after being washed in water at 85°-90° C. to remove the acid, is decanted afresh and washed a sufficient number of times. Purification can be further effected by mixing trinitrotoluene with alcohol at 92°. It is then passed through a filter press, but it can also be digested by sulphuric acid at 66° B.

When the melted product is completely neutral, it is poured into cold water, where it solidifies in the form of granules.

**Crystallisation**

In other factories the products derived from the nitrating apparatus are decanted into crystallising vats supplied with large hoods. The acids are deposited and there forms upon the surface a crust of crystallised trinitrotoluene, which is then broken up and put into the washers. The splashings which crystallise upon the inside of the hoods should also be broken up.

The fragments of T.N.T., after crystallisation, are piled into large boilers where they are washed with hot water.

The product, sorted in a large apparatus which empties on to a sieve, is sifted and then packed by hand in barrels lined with paper.

**Uses**

T.N.T. is used for filling shells, and for making detonators and fuses. Shells and grenades are filled with
pure T.N.T. or with amatol, which is a mixture of T.N.T. and ammonium nitrate containing 20, 40 to 60 per cent. of T.N.T., either melted or in powder. The T.N.T. is melted, purified and, if necessary, moulded, moulded and compressed into the shells.

The powder is ground in mills, weighed and put in a hydraulic press. The compressed charges are then trimmed upon a lathe, generally in a compressing room, and plunged into melted paraffin and wrapped in varnished paper. These last processes are generally carried out by women in different rooms to those used for compression or trimming. The charges are then weighed by inspectors who scrape through the paraffin if they are too heavy and peel off with a knife or chisel the quantity of T.N.T. required to obtain the correct weight. The charges are more often moulded than compressed. The T.N.T. is melted in cauldrons which must be fed and supervised. Ladies are often used for charging. T.N.T. debris is sometimes melted in open cauldrons. When the workmen draw the T.N.T. from tubes or receptacles, a certain amount may fall upon the ground and should be cut up and swept together when it has solidified. The melted T.N.T. is run into the shells. If any falls outside the shells, it should be scraped away with pieces of pointed wood or bronze knives, the fragments being removed by brushing and ventilation. This can be avoided by putting round the shell a paper wrapping kept together by an India-rubber band, or by introducing the T.N.T. by means of a steel funnel, so as to pour in the quantity required to fill.

A third method consists in pouring melted T.N.T. into moulds and withdrawing it when it has cooled and hardened. It is then drilled, smoothed, and coated with paraffin, its consistency being that of maple sugar. The solid T.N.T. is drilled for the insertion of the detonator into the shape of the opening of a pointed arch. The thread of the screw in the opening of the shell is cleared unless it has been covered during the operation of filling. The shell is then cleaned and polished. Imperfect shells with defective mouths should be emptied; this is sometimes done by plunging the shells into a reservoir of hot water and allowing the charge to become sufficiently warm to melt.

Other operations carried on in the charging factories are: the filling of bags, made of vaselined silk, and the application of a covering of wax to the shells.

Sources of Risk

During Manufacture

Danger arising particularly from the inhalation of fumes does not constitute a serious occupational risk, if no accident occurs such as an overheating or a leakage when adding the acids. Danger from dust is equally to be guarded against, but to a less degree, in certain processes. Nevertheless it is desirable to emphasise that the dry powder of T.N.T. gives off fumes even at a temperature as low as 32° C. All the processes are liable to be sources of danger. The troubles which arise in the course of nitration have been sometimes attributed to the presence of phenyl nitromethane, C₆H₅CH(NO₂)₃, due to the acid being too dilute in the first phases of the process. Crushing and shovelling do not cause much dust for the material is moist and sticky. The troubles caused generally by this process are due to volatilisation at the ordinary temperature of dinitrotoluene if it is present, or to the handling of the product (which should be avoided).

On the other hand, sorting, sitting and packing are dusty processes. The material gets into the atmosphere of the workshop and is deposited upon the floor, the apparatus, clothes, etc. There is then risk of poisoning by inhalation of dust.

During Use

The risks are greater in the factories where shells, grenades, etc., are filled than in the manufacture of T.N.T. The degree of poisoning is slight in the process of making compared with that of filling. Out of 182 cases, with 52 deaths, which occurred in 19 filling factories, and 6 factories where T.N.T. was made, only 7 cases, none of which were fatal, occurred in the latter.

The filling of shells by pressure causes during manipulation much fine dust which remains in suspension in the atmosphere and adheres to the skin and to the clothing. The workers, even if wearing gloves, get their hands stained a brilliant yellow. Where T.N.T. is ground the workers are covered with dust and large quantities of amatol are scattered on the floor causing dermatitis of the feet and ankles. The packing of paraffined charges and outside varnishing are harmless processes, as the T.N.T. is covered over. But the paraffining and inspection present some risks due to exposure to dust in the course of manipulation. Poisoning occurs even if
the workers wear gloves. In the filling factories the danger is greater, for it arises from the fumes rather than the dust of T.N.T. (the melting cauldrons being allowed to be open). It is the same with fumes set free in the course of washing and shovelling. Moist heat increases the possibility of poisoning, but not of dermatitis which is more common in summer owing to the greater surface of the body exposed.

T.N.T. is supposed not to volatilise below 180° C., but at lower temperatures it is quite possible to find perceptible fumes about the cauldrons. The air in the melting rooms analysed by Philips and Casselmann (United States) contained about 0.006 mg. per litre, so that a worker during 7½ hours' work, inhaled 16 mg. of T.N.T.

Filling the cauldrons is also dangerous on account of the setting free of dust. The worker in charge of this operation has to watch the cauldrons and add T.N.T. from time to time. The cauldrons are usually filled by using scoops, but small quantities of dust arise each time.

Fatal cases of poisoning have occurred during stirring, which should always be carried out by mechanical means. By cleaner methods of work or the use of more adequate methods of filling, it is possible to prevent T.N.T. falling upon the floor and the tables.

The third method of shell filling (see above) does not present any great risk, as the charge sets free very little dust, on account of its consistency. Nevertheless a high rate of sickness indicates absorption by the skin in the course of handling. In that case the danger may be due to dinitro, which is more easily absorbed and is contained in the raw T.N.T. used.

After the filling, danger from fumes disappears, but that due to dust always remains. The cleaning either of the screw thread at the mouth of the shell or of the hole for the detonator by means of narrow brushes for removing dust is a dangerous process. The cleaning of the detonator hole has been carried out in one factory by aspiration. The emptying of rejected shells is a very dusty operation when the extraction of fragments is carried out by means of compressed air. The method of immersion in warm water is much to be preferred.

Some cases of sickness have occurred among workers occupied in filling bags with T.N.T., or grenades by hand with ammonal, in tying them with vaselined string, or again among those occupied in the following processes: sifting by hand, or accessory processes, such as handling trays covered with dust used for carrying the T.N.T. from the magazines to the workrooms.

TOXIC ACTION

T.N.T. can get into the system in three ways: (1) by inhalation of fumes or dust, (2) by absorption through the skin, (3) by ingestion. The chief way seems to be by the skin (according to English writers) and by the respiratory passages (according to Americans). It seems, however, that there are quite remarkable differences of sensibility among individuals attributed to differences of the permeability of the skin, just as the method of poisoning is also variable. According to Lehmann, poisoning by fumes is little to be feared, for they are only slightly diffused in the atmosphere. As a matter of fact while those inhaling fumes of T.N.T. suffered sickness, the proportion of 1 per cent., those who handled the product were sick in the proportion of 10 per cent. and those who handled it with greasy hands (fasteners of bags, cleaners of benches and moulds with oily dusters, and workers who handle lard to grease grenades) in the proportion of 17 per cent. Oily substances seem then to favour the absorption of the poison.

T.N.T. passes through the tissues without being modified and is eliminated by the urine in a modified form (see Symptoms and Diagnosis).

The brown colour of the urine is due to a product of oxidation of T.N.T.; it can be seen without the addition of a reagent and is of great value as a means of detecting trouble. The spectroscope shows haemochromogen in the urine.

The blood of poisoned animals is brownish and contains trinitrocresol and alkaline haematin.

Before the war P. White and Hay (1907) regarded T.N.T. as non-injurious. Nevertheless they had noted that with cats 3.5 cc. and 5.3 cc. of a 1 per cent. solution of T.N.T. caused a slight cyanosis. As regards man, Lewin held that a quite appreciable quantity of poison was necessary to cause trouble. Escaler reported that T.N.T. does not give rise to serious illness either in the process of making or its use. But during the war its use rather than manufacture caused numerous cases of illness of which many were fatal. On the researches of Moore and his colleagues was based the opinion that T.N.T. is absorbed by the skin. In 1921 Haythorne, carrying out experimental work, found with rabbits and guinea-pigs poisoned by the cutaneous
or gastric paths lesions of the liver similar to those seen in jaundice in man: methaemoglobin in the urine in the last stage of poisoning; grave anaemia of the hyperplastic type; fixation for quite a long period of T.N.T. in the tissues. A dose of 5 to 100 mg. per kilogram of the animal causes variable symptoms. In reality with 5 mg. clinical symptoms do not always occur and the dog, like man, shows a very variable individual susceptibility. Moreover, a definite tolerance for T.N.T. has not been confirmed.

According to Moore and his colleagues this substance is reduced in the system to 2-6 dinitro-4-hydroxylamino-toluene, which in its turn is transformed to a dinitro-4-nitroso-toluene. The derivative of hydroxylamine combines with glucuronic acid and is eliminated in this form. The products of reduction have the same action as T.N.T. But up to the present it has not been determined what is the derivative which exercises a poisonous action, or if there is more than one product involved in the disturbances which have occurred in the stomach, liver, kidneys and the bone marrow.

English and American authors consider that T.N.T. is a very virulent poison, but that the impurities which it may contain are not poisonous. They base their opinion on the fact that both pure and raw T.N.T. are shown by experiments on animals to be equally poisonous. According to Stewart the poison acts slowly upon the liver cells, even when the patient is absent from the dangerous work which exposed him to the absorption of the poisonous substance.

The toxicity is attributed by other writers to other poisons which are impurities of T.N.T., especially to dinitrobenzene and to tetrinitromethane which are found in pure non-crystallised T.N.T. Tetrinitromethane, which even in the smallest fractions produces effects, exerts an especially irritating action on the mucous membranes. This opinion is prevalent in Germany where Koelsch, relying upon experiments upon animals and upon his own experience, declared (1917) that T.N.T. is a product relatively slightly poisonous in comparison with nitrobenzenes, and that only exceptionally, among predisposed individuals occupied for prolonged periods under special conditions, such as dirt, insufficient food, alcoholism, and defective apparatus, T.N.T. can cause poisonous symptoms, which are usually confined to the blood, with anaemia, and the formation of methaemoglobin. The comparatively slight danger can be overcome by adequate precautions.

It is necessary to mention at this point that the action of T.N.T. has been different in Germany and in Great Britain, so that whilst in Germany it has generally exercised an irritant action upon the skin and is slightly toxic, in Great Britain, according to Fischer and Koelsch, T.N.T. contains a greater quantity of impurities (especially tetrinitromethane). Generally speaking, the derivatives of the distillation of tar in Great Britain are more injurious than those obtained in Germany, e.g. the frequency of dermatitis and of chimney-sweeps' cancer.

In Great Britain a predisposition to diseases of the liver has been noticed, perhaps due to diet. A certain number of workers seem to be immune to the poison, and others who show slight signs of poisoning on commencing work seem to acquire immunity or not to be liable to react to the poison with serious symptoms. Nevertheless there are yet doubts on this last conclusion. It is admitted generally that T.N.T. is poisonous for a minority of workers who come in contact with it. Fat persons are apparently more susceptible and more frequently victims of serious poisoning and fatal results. Negroes are very slightly susceptible to dermatitis and perhaps to poisoning, but the last point is not proved.

**Statistics**

**Germany.** — Up to 1917 only 50 cases of acute atrophy of the liver had been reported, occurring especially among young men, aged 16 to 26, and women. In a factory at Potsdam which employed in 1916 an average of 143 men and 380 women, and 340 men and 620 women in 1917, the following cases were recorded:

The dermatitis was really due to picric acid and the respiratory affections to T.N.T.

Up to the end of 1917, 7 serious cases were reported in a munition factory, 2 of which were women; in 1918, 4 cases.

**Bavaria.** — During three years Koelsch did not observe any fatal case and very
few specific injuries. But in 1918 he noted
19 cases of poisoning of which 1 was fatal. The compulsory notification start-
ing from January 1915 up to the end of
the war furnished 1,000 definite cases of
poisoning by nitro-compounds (dinitro-
benzene, tri- and dinitrotoluene, nitrated
naphthalene, trinitro-anisol, trinitrophe-
nol).
United States. — During 20 months in
one munition factory 7,000 cases of pois-
oning were recorded, of which 105 died.
During seven and a half months 17,000
cases of poisoning were reported, of
which 475 died. Harrington in 1917 also
reported numerous cases of poisoning.
All statistics furnished, however, present
the disadvantage of difficulty in establish-
ing which of the nitro-compounds has
been used, more especially as mixtures
are very often employed.
As regards the sickness and deaths
which occur in the melting and pressing
departments, where the product handled
was amatol, the following statistics are
given:

In 1927, Fortescue reported cases of pois-
oning amongst men engaged in the trans-
porting of charges of T.N.T. explosives
from a warehouse to a vessel. In spite of
the use of protecting gas masks, measures
of cleanliness (baths), medical supervision
and alternation in the operations, more
than half of the workers showed slight
symptoms of absorption of T.N.T.

Great Britain. — T.N.T. was slightly
used before the war and did not cause
poisoning. It had even been proposed to
replace dinitro by T.N.T.

During the war, however, its use more
than its manufacture brought out new facts.
As early as January 1915 in a T.N.T. fac-
tory there had been reported 6 cases of
poisoning with jaundice and a group of
pathological features resembling those
found in poisoning by tetrachlorethane,
i.e. lesions of the liver and kidneys. Two
other cases were reported in August and
December of the same year.

In consequence of these cases poisoning
was made compulsorily notifiable from
1916. Livingston, Learmonth and Con-
ningthorn described 36 cases in a single
factory in 1916; Panton in 1917 reported
50 slight cases among workers while
carrying on their work; Stewart, 14 cases
of jaundice. Out of 50,000 workers in con-
tact with T.N.T. a sickness rate of 3.8 per
cent. was noted from January 1916 to
August 1917, with a percentage of deaths
of from 0.9 to 1 per cent. From 1916 to 1923
the number of cases notified was 382, of
which 181 (32 fatal) were reported in 1916;
189 (44 fatal) in 1917; 4 in 1918; 3 (all
fatal) in 1919; no known case in 1920 and
1921; 2 in 1922; 3 in 1923, 1 in 1926, and
another in 1929.

Italy. — In 1915 the workmen employed
in an explosives factory suffered from
headache, cyanosis and cardiac troubles.
Small quantities of wine caused giddiness
and headaches, and aggravated the sym-
toms of poisoning.

Netherlands. — In 1917 a fatal case was
reported and numerous cases of conjuncti-
vitis and loss of strength. In 1918, when
supervision had been organised, there
was not a single case of jaundice.

Symptoms

An examination of 50 cases of poison-
ing by T.N.T. has enabled the Ameri-
cans, Putnam and Hermann, to tabu-
late the symptoms.

Quite, a long latent period often
precedes the illness, which sometimes
makes it appearance after 7 to
9 months after cessation of work.
Serious cases are not common, and
for one serious case there are about
30 slight cases.

The prodromal troubles are: symp-
toms of irritation such as sneezing,
coryza, epistaxis, and watering of the
eyes, but especially a chronic cough
which is not explainable by any known
cause; sometimes the workmen com-
plain of catarrh and dryness of the
throat. Unusual dyspnoea is also
present, a feeling of fatigue not
explained by overstrain, and sudden
violent pains in the legs and feet.

There have also been noted headache,
a feeling of intestinal discomfort,
burning sensations, a bad taste in the
mouth, anorexia, spasmodic epigastric
or sternal pains, nausea, vomiting and
acid eructations. There is constipation
followed by diarrhoea which produces
a very marked toxic condition.

Sometimes in the early days cyanosis
is observed. The toxic stage is marked
by troubles sometimes slight (derma-
titis, gastritis) and sometimes serious
(anaemia, jaundice).

Dermatitis due to the local action of
T.N.T. and attributed to its combina-
tion with ammonium nitrate is very
common. The skin and hair present
a yellowish colouration, especially
marked on the hands, where it is
distinctly yellow. The clothing and
linen may on the contrary be some-
times coloured red. A diffuse erythema
appears with symptoms analogous to
those of urticaria and attacks prin-
cipally the back of the hands and
wrists. This erythema may attack
similarly the face, neck, feet and
ankles (when the floors of the factories are dusty) and the genitals. The wearing of respirators, through mechanical action, soon causes lesions around the mouth. The lesions set up an unbearable itching with a rash, and a sensation of burning, often followed by exanthemous lesions which do not respond to treatment at all easily. At a more advanced stage vesicles which cicatrize with a scab are noticed at the flexion folds and between the fingers. On the face the lesions take a papular form, but often lichen or secondary infections are seen.

Dermatitis, which occurs more frequently in the processes of sifting, weighing and packing, is often seen in the course of the first week's work, at the end of which immunity seems to be established. When it persists it is necessary to take the workmen off work.

Gastritis, which usually appears in the first week of work, is caused by irritation arising from swallowing dust of T.N.T., to which the stomach may respond to treatment at all easily. This form is characterised by morning vomiting after taking food, anorexia and salivation. A toxic form of gastritis is due to absorption of T.N.T. by the skin. It is rarely associated with dermatitis, but accompanies other symptoms of poisoning, such as cyanosis of the lips, restlessness, depression, epigastric colic, nausea, and abdominal distension.

Anaemia, which seems to be a pathological condition independent of jaundice, is very common. It is associated with dyspnoea, severe chest pains and cyanosis. Among 100 women taken at random in a T.N.T. factory, 78 were cyanosed and 18 showed a marked cyanosis. A pulse as low as 48 has also been noted (Koelsch). In serious cases petechial haemorrhages were observed. Menstrual troubles are common with women.

The formation of methaemoglobin detectable by the spectroscopic has been noticed as a blood change. According to Litsche it is formed by the reduction of T.N.T. into a hydroxylamine derivative which acts upon haemoglobin transforming it into methaemoglobin.

The first observations were not very accurate and the toxic action of T.N.T. was only admitted by analogy with that of D.N.B. and D.N.T. (Malden, Hudson). Following upon an investigation of 50 workers, Panton formed the opinion that the daily absorption of T.N.T. did not have an injurious action on the blood (4 cases of blood changes out of 28 examined); but Stewart, on the other hand, found 14 cases of serious blood changes. Smith supports the opinion of Panton, basing his opinion upon the negative result of his researches (slight cyanosis). According to 235 examinations of blood made at random in 1910 upon 100 cases of poisoning from various departments of eight factories, Minot found that in 83 per cent. of the cases there was polychromatophila. But whereas the number of red corpuscles, the haemoglobin value and the colour index were generally little altered, the number of white cells was increased and the formula variable, for varying with the cases there were noticed neutrophile leucopenia, neutrophile leucocytosis and lymphocytosis (sometimes the most frequent change is eosinophilia).

Voegtlin, Hooper and Johnson in 1920 examined 237 workers and found 72.5 per cent. with anaemia of varying degree, but only one case with severe anaemia. Among 18 per cent. of those with anaemia, anisocytosis and poikilocytosis were quite marked; in 4 per cent. leucopenia; in 22 per cent. leucocytosis; and in 4 per cent. lymphocytosis. Forty-eight per cent. of those with anaemia had also cyanosis and about 75 per cent. of the workers examined showed premonitory symptoms of poisoning. When the anaemia reaches a certain degree the prognosis is fatal.

Toxic jaundice is less frequent than gastric poisoning, which it does not seem to follow; it is due to the action of T.N.T. upon the liver. There is very often a latent period between the cessation of work and the onset of sickness due, perhaps, to continued absorption by the skin, where it acts as a kind of reservoir of the poison, or to absorption from the hair or soiled clothing. This latent period may vary from 3 days to 17 months, but jaundice usually appears at the end of 3 months. In England 83 per cent. of the cases have been reported as occurring between the fifteenth and sixteenth week, and out of 105 cases not one occurred before the fourteenth week.

The onset of toxic jaundice is often sudden, but may perhaps be preceded by symptoms such as somnolence, giddiness and depression. When the condition has developed, jaundice appears with marked diminution of the liver and ascites, abdominal pains and constipation. The urine contains biliary salts and pigments, albumen and sugar with intermittent glycosuria; the reaction of Webster is positive. The illness is a long and serious one which may last several months, leav-
ing the patient with a liver irreparably damaged. There is a fatal issue in from 25 to 30 per cent. of cases. If the prognosis is fatal, coma occurs generally at the end of three weeks. Among the conditions reported, nerve symptoms are prominent, such as fainting, loss of consciousness, vertigo, apathy, amnesia, inco-ordination, troubles of vision, peripheral neuritis, and cramps; when the illness passes on to a fatal issue delirium and coma develop.

**Diagnosis**

At the onset the diagnosis is often difficult, for serious cases sometimes develop without any premonitory symptoms to which any importance can be attached, while typical symptoms which persist a long time characterise cases which are neither fatal or even serious. When the typical symptoms of absorption do not appear, diagnosis must be based especially upon the detection of T.N.T. in the urine (reaction of Webster), which may be made in the early stage of absorption. To 12½ c.c. of urine add 12½ c.c. of a 1/5 solution of sulphuric acid and 10 c.c. of ethyl ether. Shake, decant, wash with 25 c.c. of water. Decant and add 5 c.c. of a 4 to 5 per cent. alcoholic solution of soda or potash. If T.N.T. is present a purplish pink colour is seen, the depth of the colour increasing in proportion to the quantity of T.N.T. present. This colour passes quickly to brown. The transitory purple colour is what must be taken into account. This reaction, which shows in the absence of any clinical symptoms, indicates absorption and elimination of T.N.T. Taken in conjunction with symptoms of onset it is sufficient indication to take the worker from dangerous work. This reaction is found from the first week of work and continues long after the contact with the poison has ceased. In acute cases of poisoning it is noticed that the reaction gives a negative result, which shows without doubt that elimination of T.N.T. has not taken place.

**Hygiene**

It is practically impossible to avoid contact with T.N.T. during industrial operations. As a matter of fact it is not possible to prevent quantities of poisonous fumes from being liberated when the product is heated, or dust or solid or liquid material falling on the floor or on apparatus and then being diffused through the atmosphere of the workshop. Further, the fumes condense in fine dust and aggravate the danger of poisoning. Prophylaxis must then be rigorous and ensure that fumes and dust do not soil the worker and his environment.

Machines or mechanical devices should be used which should be provided with exhaust draught for effectively removing fumes and dust.

The poisonous fumes being heavier than air, adequate ventilation demands that the inlets for air be at the top of the room, with exits at the level of the floor. The air on entering should be warmed in winter, cooled in summer and distributed so as not to raise any dust. The ordinary metal types of ventilators cannot be used on account of sparks which are caused by friction and may give rise to explosions.

All liquids setting free fumes should be put under ventilating hoods. Covers for closing the receptacles are useful, but insufficient, for there must always be some opening in order to carry out the necessary processes of filling, mixing, and inspection; hence it is essential to have additional apparatus for withdrawing the fumes. Respirators are inefficient and even dangerous, for dust accumulates upon their edges or on the skin, and, through pressure, often causes ulceration of the face.

On the contrary, breathing apparatus is useful, especially in case of large quantities of fumes being set free owing to accidents during work, or for repair work which necessitates entering receptacles and reservoirs. Adequate protection of the skin should be provided for when there is dust or it is necessary to handle the product.

Nitrating ought to be carried out in separate places which are spacious, well ventilated, and provided with easily accessible exits. The nitrating cauldrons must be hermetically closed and tanks of water arranged so that in case of need the mass undergoing reaction can be run into them. No nitrated product should be stored or handled in the nitrating room. The acids should be mixed in receptacles placed in the open air and roofed over. The washing must be carried out in buildings where no nitrated product is stored.

Recrystallisation should also be carried out in isolated departments. All the receptacles containing solutions should be so closed that the fumes are not able to escape into the atmosphere. Hand work and all contact with the products during the processes of crush-
ing and shovelling should be forbidden. Stirrers, at least two metres in length, should be used for breaking up the crystallised mass. The drying ovens must be ventilated in such a way that the hot air coming from the ovens passes into the outside air; the crystallisers must be provided with ventilating hoods so that evaporation can take place; workmen employed in sorting, sifting and packing should be supplied with india-rubber gloves and boots. All the preventive measures laid down for the storage and handling of inflammable solvents and explosive substances must be strictly observed.

In the process of melting T.N.T. for charging projectiles, energetic exhaust ventilation must be carried out; cauldrons must be closed except during the time necessary for the process of charging; the solution must be mechanically stirred; and an additional ventilating system must be installed where the melted product is withdrawn. All filling machines should be well protected by ventilating hoods or cowls. A double cowl, one part external for the raw powder and the other internal for the fine powder, has been tried with good results. The dust is removed to dust chambers and dissolved in water. Careful supervision of the system of pipes must be made to ensure that no dust escapes, as this is a source of danger and of serious illness.

The dust caused by boring should be caught in closed receptacles.

Although some experts consider that the use of gloves and overalls may have no practical value, it will be well to make sure they are provided, together with changes, as well as being regularly washed. It has been proposed to employ special varnishes for the hands, but their use has not given good results in Great Britain. In order to remove T.N.T. from the skin, a good washing does not suffice and it is necessary to employ either a 10 per cent. solution of sodium sulphite or of acetone. Alternation of work reduces the period of exposure. In one German factory the team had a shift of four hours. T.N.T. being rapidly absorbed (but according to certain experts being as rapidly eliminated) it is best to avoid overtime and to give leave of absence during the week so as to avoid any accumulation of poison in the system. These measures are particularly necessary in hot weather, which raises the rate of sickness if adequate precautions are not taken. Medical inspection on engagement will provide for the exclusion from work of predisposed individuals and especially those with anaemia, those who perspire too freely, alcoholics and those with diseases of the liver and respiratory passages.

Periodical medical examination, either weekly or fortnightly, of workers is very important in practice. It enables the removal of workers brought into contact with the poison to be carried out at the commencement of the poisoning. In one American factory where a strict supervising medical service had been organised, no fatal case occurred, or any case of serious toxic jaundice during six years, which shows that adequate precautions will render the risk almost negligible. Nevertheless, periodical examination with early withdrawal of workers, drafting them to other work, will only be beneficial if the skin is completely cleansed of T.N.T. and the soiled clothing is changed. It is important also to have good food, for the poison acts more readily if the stomach is empty. The distribution of milk before the commencement of work, which was compulsory during the war in the English shell-filling factories, was based upon the fact that improved nourishment provided by the management for women who had been hitherto badly nourished diminished the sickness rate.

Workers should be instructed upon the dangers connected with their work and the means of combating them, as well as the measures to be taken in case of sudden illness.

**LEGISLATION**

As regards the employment of women and children the rules laid down for explosive factories in general are applicable. Exclusion of young men of less than 18 years and of women has been adopted owing to cases of serious danger from poisoning and on the advice of the inspectors of factories. Periodical examination is compulsory in Great Britain. In Holland the visit has been arranged in agreement with the heads of establishments.

Compulsory notification had already been adopted in Bavaria in 1915, and is in force in Great Britain, Holland, and generally in the countries where there is compulsory notification of poisoning by nitro and amido derivatives of benzene (see that article). Compensation is provided for in British Columbia, Great Britain and Switzerland. In Germany an ordinance, dated 12 October 1917, provides that fatal cases of T.N.T. poisoning are to be considered as accidents as regards legal compensation.
TRIOXYBENZENE

Trinitroxyylene
(Trinitroxyylol)

Of the three isomeres, meta-trinitroxyylene, used in modern technique, has been studied experimentally by Ilzhofer, who has come to the conclusion that this product is even less poisonous than other nitrotoluenes.

***

Trioxybenzene
(Trihydroxybenzene; Trivalent Phenol; Pyrogallic Acid; or Pyrogallol)

Trioxybenzene (formula: \( C_9 H_6 (HO) \)) (1,2,3) is obtained by heating gallic acid in an autoclave with two or three times its weight of water at 200° C. for half an hour. The acid loses a molecule of carboxylic anhydride and gives pyrogallol or pyrogallic acid which melts at 131° C. and boils at 231° C.
It is purified by decoloration with animal charcoal and by crystallisation or by sublimation.
In industry it is also prepared by distillation of gallic acid mixed with pumice stone in a current of carbonic anhydride, or by making alkalies react upon a dihalogen derivative of phenolsulphonic acid.
This substance has always been used as a developer in photography and is considered one of the best; it has recently been introduced into industry as an additional product in baths for dyeing skins; it is used for tinting the hair and beard, and in chemistry for gas analysis (absorption of oxygen).

Trioxybenzene acts upon the circulation, lowers the temperature and causes clonic convulsions, tetanic movements, muscular paralysis, etc. The poisonous dose for a man by way of the digestive tract is about 10 grammes (Kohn Abrest). It is a blood poison transforming the haemoglobin of the red corpuscles into methaemoglobin.
Its poisonous action is attributed to an increase in the number of the hydroxyl groups, for trihydroxybenzene is certainly more poisonous than phenol which is a monohydroxybenzene.

Lehmann is not aware of any case of industrial poisoning caused by this product. Nevertheless, its action, both local and general, is emphasised by the dermatitis seen, for example, among photographers. It is interesting to learn that this dermatitis sometimes occurs suddenly with persons who have worked for a long time without injurious effects. P. White thinks that in those cases small daily doses create an anaphylactic condition, during which a very small quantity at a given moment may cause in a few hours (12 to 24) a very marked reaction. In slight cases there are noticed irritation and tingling about the nails and in the interdigital spaces with cracking of the skin.

According to Hamilton some cases of poisoning by trihydroxybenzene have occurred in Germany, while on the other hand a case of poisoning has never been seen in an American factory making gallicyanine.

Weickel reported to the Medical Society of Leipzig (1922) the result of experimental investigations, according to which pyrogallol diminishes the number of red corpuscles without affecting the bone marrow, increases the number of blood platelets, and diminishes the viscosity of the blood.

As regards legislation (compensation for diseases) see the articles "Diseases of the Skin" and "Photographers".

BIBLIOGRAPHY

Tripe and Gut Works

Certain parts of slaughtered animals (stomach, head and feet, etc.), sometimes designated by the term "edible offal", are used in the preparation of tripe and other meats, which takes place in slaughter-houses or in wholesale butcher meat establishments. The operations involved in this work comprise, according to the different parts of the animal treated, insufflation, washing, boiling, scalding and scraping. The waste fat after melting is utilised for the manufacture of tallow. Modern technical methods have now substituted treatment by hypochlorite of soda, or Labarraque's solution, for the nauseating operation of putrid fermentation. Formerly, the workers resort to with a view to separating the various layers of the intestinal wall. By this method the intestines lose their odour, the membrane is easily separated, and insufflation takes place without inconvenience for the workers.

Insufflation was formerly done by the mouth by means of a reed introduced into the base of the intestine. At present insufflation apparatus is used. The guts, subsequent to insufflation, are sent to be dried, and after drying are pricked, de-flated and treated with sulphur in order to whiten them and rid them of their odour.

The guts of large animals are used chiefly in the manufacture of products sold by pork butchers, etc. (making of sausages and other varieties of similarly prepared meat); those of smaller animals are used in the preparation of various kinds of gut for musical instruments, the clock-making industry, hat-making industry, etc.

The preparation of catgut forms a part of the tripe and gut industry, which provides a series of waste products for pork butchers, farmers, etc.

Surgical gut and harmonic strings may be manufactured from preserved, dried or salted guts coming from distant countries, or with guts macerated in water and fermented or again with fresh guts taken directly from the dead animal. Authorities on the subject are agreed that catgut should not be prepared from fresh gut. Sheep gut after emptying and washing in the slaughter-house is sent to the gut works, where it is subjected to scraping and steeping in aspecific solutions. Finally, it is split in order to provide a flat strip which is submitted to treatment with hydrogen peroxide. By plaiting several of these strips a cord is obtained which is subsequently dried, polished and sent to the chemical works for sterilisation by steam or alcoholic fumes.

Scraping and plaiting should be effected in separated, well-ventilated work-rooms in the gut works. Strict cleanliness of the workrooms and also of the worker should be required with a view to avoiding contamination with any matter embedded in the walls of the gut. Goldbeaters' skin is made from the caecum of the ox which has been dried, dipped in a dilute solution of potassium, scraped with a knife, lined with a similar membrane, and coated with a dressing of fish glue and white of egg.

Sources of Risk

The work engaged in in tripe and gut works is one of the most filthy tasks imaginable. Apart from the nauseating odours, there must likewise be taken into account the humidity present in the workrooms as a result of the presence of large quantities of liquid used. There is liability to infection due to contact with water and matter containing pathogenic microbes. Cases of anthrax have been known to occur due to manipulation or transport of gut from anthrax infected cattle.

In a catgut factory, Saltikowsky (1929) found workers exposed to continuous inhalation of pumice-stone and chalk dust during polishing of the cords and strings.

He has also drawn attention to the action of products used in the preparation of gut and cord: hypochlorites, soda and potassium lyes, sulphurous dioxide, iodine, peroxide of hydrogen.

Pathology

Medical authors who during the course of the nineteenth century directed their attention to the health of workers in tripe and gut works, at a moment when hygienic conditions in the industry were greatly inferior to what they are at present, reported with a certain amount of surprise that work in these establishments, on the contrary to what might be expected, did not appear to predispose those engaged in the work to disease (Guersant, Parent-Duchatelet, Patissier). However, Chevalier, Guérard and Layet report that the workers in question, from the commencement of their entry into the trade, suffer from fever, digestive troubles, pallor, etc., symptoms which nevertheless disappear fairly rapidly.

Labarraque has reported injuries due to insufflation with the mouth. It was found impossible to continue this operation for more than three days at a time. It gave rise after a time to chronic irritation of the pharynx, with ulceration at the commissure of the
lips, lesions which Vernois likewise
met with, and which he attributed to
the action of the septic liquid on the
skin during insufflation of the guts.

Contact with water and lyes caused
wearing of the epidermis of the hands
which had a raised appearance in
certain places with cracks between
the fingers. There was likewise noted
a certain anesthesia of the hands and
forearms similar to that reported by
Romberg amongst washermen.

Cutaneous lesions amongst workers
making catgut have been more recently
reported by Saltikowsky. A particular
alteration of the hands due to work
in gut works has been described by
Vernois. The internal surface of the
left hand, which usually holds the
bunch of guts was of rose-red colour,
very smooth and presented cracks and
worn epidemis, which had a very thin
appearance, being more injected after
working hours than during work.

The right hand with a callosity in the
centre was equally rosy in colour,
though irritations and cracks between
the fingers were of less frequent occur-
rence; the nails were worn at the
edges and the skin of the hand had a
particular smell.

These alterations were explained by
the fact that intestines were handled
with the left hand more frequently
and more completely than with the
right; by the action on the right hand
of the knife used for scraping; by that
of the skin of old fermented gut; and
by the action of septic liquids.

Saltikowsky noted also deformation
of the fingers amongst workers en-
gaged in making catgut as well as
vasomotor derangements affecting the
feet and hands as a result of pro-
longed contact with water, rheumatism
and diseases of the heart, sore throats,
pharyngitis, and tonsillitis.

Sulphurous dioxide caused irritation
of the eyes and respiratory passages
amongst workers engaged in the sul-
phur process.

HYGIENE

Tripe and gut works should be con-
structed at as great a distance as
possible from inhabited areas, and in
order to complete this isolation it has
been suggested that wherever possible
trees and shrubs of rapid growth
should be planted round these estab-
lishments to a depth of 17 or 20 metres.
Where the odour given off is not
unduly strong and not such as to
constitute a nuisance for the neigh-
bourhood, it suffices that the establish-
ment should be provided with lantern
or raised skylight windows with ven-
etian blinds, or with small chimneys
raised above the roof.

Such establishments should be
constructed of hard, incombustible
material resisting putrefaction. The
courtyards should be paved and the
paving stones joined with cement
mortar.

The flooring of the workrooms
should be impermeable (cemented, tiled,
or covered with bitumen), with a con-
venient slope facilitating the running
off of the waste water. There should
be drains in the flooring provided
with grids to prevent the withdrawal
of solid waste, and these grids should
be connected up with airtight and
watertight piping underground en-
abling the liquids to be drawn off.

The walls should be covered with a
smooth paint, resistant to washing
down with large quantities of water
(cement up to a certain height, plaster
above that as well as on the ceiling).
The woodwork should be painted with
washable oilpaint. The joins between
the walls and the flooring and be-
 tween the flooring and the tiled or
paved spaces round the fixed appara-
tus, machine bases, etc., should have
rounded angles. Hollow spaces and
mouldings should be avoided as far as
possible.

Furnaces built of masonry and hot-
water vats should be provided with
large exhaust hoods for capturing and
removing fumes and steam. The sul-
phur chamber should be made of in-
combustible material and provided
with large ventilating chimneys with
dampers which can be manipulated
from the outside. In a general man-
ner all apparatus, vats, etc., should be
provided with hoods connected up
with suitable piping for withdrawing
the fumes to a hearth or a chimney.
The latter should be of an adequate
height. Certain legislative require-
ments even demand that the top of
this chimney should be equal in height
to the chimneys of the houses within
a radius of 100 metres and that its
direction should be rationally deter-
mined, in accordance with the prevail-
ing winds, with a view to avoiding
nuisance for those living in the neigh-
bourhood.

Good ventilation of the workrooms
should be ensured. Stores of raw
material should be provided with ven-
tilation piping. Tables on which the
materials are sorted should have an
impermeable surface. The premises
should be maintained in a good state
of repair and cleaned frequently by
means of washing down with abundant
water. Nauseating liquids should be withdrawn by means of pneumatic apparatus and directed towards sewers. Where no sewers exist, waste waters should be withdrawn through metallic grids or perforated sheet iron, calculated to retain the particles in suspension. The waste water should be collected in decantation tanks and distributed on cultivated ground or else treated by chemical processes. Solid refuse should wherever possible be collected daily, deodorised, and when necessary disinfected.

Fresh gut from slaughter-houses, where it has been previously washed and emptied, should be worked up immediately in hermetically sealed receptacles.

Gut should be sprinkled with a suitable antiseptic immediately it is received, and should be kept in impermeable receptacles (not wooden) which are hermetically sealed. Material likely to liberate odours should be treated as far as possible in closed apparatus.

The manufacture of manure and the melting of tallow in the same work-room as that used for removal of fat should be prohibited; the fermentation process should likewise be prohibited and replaced by the Labarraque process.

Washing vats should be of impermeable material readily cleansed and provided with separate pipes for introduction of clean water and for withdrawal of waste water.

Insufflation by blowpipe should be compulsory, and workers should be prohibited from entering the sulphur chambers prior to complete ventilation and airing of these.

Spoilt products and refuse should be collected in closed, airtight receptacles and deodorised (formol, chloride of lime). These receptacles should be emptied daily.

Measures for individual cleanliness: working clothes, aprons and waterproof boots should be provided for those workers in contact with the liquids. There should be adequate provision of sanitary arrangements (washing accommodation with provision of hot water, soap, towels, etc.), adequate cloakroom accommodation, etc.

**Legislation**

In Belgium, young persons under sixteen are excluded from slaughtering processes in which intestines and offal are prepared or boiled or where heads and feet of animals are handled; from the manufacture of animal gut necessitating disintegration of intestines with a view to separating the gut from the mucous membrane by putrefaction methods. In Spain, boys under sixteen and women under twenty-one are excluded from cleaning and removal of membrane from bladders and guts and are likewise excluded from workrooms in which processes of cleaning and insufflation are carried out. In France, young persons under eighteen are excluded from processes of insufflation as well as from workrooms in which bladders are inflated and dried; the same measures are in force in Martinique and Morocco, where, however, the age limit of the young persons is reduced to sixteen years.

In certain countries (Belgium, France, Italy, etc.), tripe and gut works come within the category of enterprises scheduled as dangerous, unhealthy and offensive, and are on this account subjected to a certain number of special measures enumerated in the preceding paragraph.

In Great Britain, Order No. 1437 of July 1920 concerning the welfare of workers occupied in tripe and gut works provides for the provision of working clothes, cloakrooms, canteens, lavatories, first-aid boxes, etc., to be placed at the disposal of the workers.

In the U.S.S.R., Compulsory Order No. 333/796 of 13 September 1923 on the installation and maintenance of tripe and gut works includes most of the hygiene measures enumerated above.

**Bibliography**

***

**Tuberculosis**

This article is divided into two parts, as follows: I, Industrialism and the Incidence of Phthisis, and II, Silicosis.

I. — **Industrialism and the Incidence of Phthisis**

The three factors of fundamental import in determining the incidence and evolution of tuberculosis infection are the individual, environment and occupation. It is the third of these factors which it is proposed in analysis in this article, for occupation is often an element of first importance in the aetiology of infection and the degree of development of industrialism in a district or in a country and
The reaction of the human body to tuberculous infection varies with the condition of the body at the time infection occurs. This fact can be demonstrated from study of the disease clinically, or of mortality statistics referring to different conditions of environment or to different occupational groups of a community. In the present stage of the world's history, civilisation and the keeping of vital statistics connote industrialism. Though records are lacking upon which to found knowledge as to the reaction of non-industrialised communities, some knowledge, based on clinical experience, exists as to the reaction of primitive or isolated communities when the infection of tuberculosis is first introduced: the disease, which runs a rapid course, is found far more widely disseminated throughout the body than is the case in industrialised communities.

Records for Sweden at the end of the eighteenth and beginning of the nineteenth century provide valuable information with regard to a civilised community before it adopted industrialism (see Table 1). Leaving on one side the obvious criticism that the data tabulated may have included cases of chronic bronchitis and not merely referred to pulmonary tuberculosis, these records exhibit for both males and females a death rate somewhat similar in age distribution to a "normal" death rate, i.e. it is high in infancy, falls to a minimum in childhood, and thereafter rises, at first slowly and then more rapidly, as life advances. The picture is quite different from that presented by the same country in 1911, after the adoption of industrialism during the last quarter of the nineteenth century. A high mortality in infancy and a fall to a minimum in childhood are still present, but a new thing is found, a rise for both sexes in young adult life which declines towards middle age and shows a tendency to rise again before old age is reached; this late rise is less pronounced for females than for males.

When evidence is sought as to the course of events in the years intervening between 1830 and 1911 — records for which are lacking in the case of Sweden — Ireland from the middle of last century is found to provide suggestive material. Ireland has never been so pronouncedly industrial as England, but it certainly felt the industrial influence earlier than Sweden. The highest death-rate from phthisis in Ireland for both sexes from 1851 to 1860 was experienced, just as in early Swedish records, at the end of life, when the ages did not rise above 65.

Explanation of the figures in heavy type and in italics will be found in the text.
before finally rising again to the terminal age period. By 1871-1880 the death rate for males was highest at ages 25-34, after which age it fell away to rise again at ages 55-64; the curve now resembles in shape that for Sweden in 1911. By 1901-1910 the age distribution of the phthisis death rate in Ireland had undergone further alteration; for both sexes the maximum incidence was now at ages 25-34, after which it fell away steadily with advancing years; there is now no sign of a rise in late life. The curve for the death rates after the age of 15 is now decidedly aberrant; it rises during early adult life and thereafter falls with advancing life.

This type of curve is to be found in England and Wales in 1851-1860 when the full effect of the altered conditions of life brought about by the industrial revolution was being felt (see fig. 157). The same type of curve existed in Czechoslovakia in 1910 when that country had reached a stage of industrialism similar to that which existed in England and Wales between 1851 and 1860.

Other countries, on the other hand, upon which industrialism had much less effect, such as Prussia up to 1914, and Victoria, Australia, have maintained a curve for phthisis death rates throughout life which has agreed more or less closely with the shape of a normal curve of mortality from all causes.

When the course of events is followed for countries where the aberrant type of curve has appeared, a tendency is found, as the conditions of living improve, for the type of curve to alter steadily in the direction of conforming more closely to a normal mortality curve: thus the apex of the curve for males in England and Wales had moved from ages 20-24 in 1851-1860 to ages 50-54 by 1911, while in New York City the apex for males (which in 1868 was at the end of life) moved from ages 45-49 in 1910 to ages 55-64 in 1921.

Further evidence from mortality records of other countries might be quoted to establish the influence exerted upon the prevalence of phthisis by the disturbances which the development of industrialism has caused. The effect of industrialism appears to act by modifying the resisting power of the community at different ages to the infection of tuberculosis.

When the infection is introduced for the first time into any community, it causes a generalised disease of high fatality; if the community is not wiped out by the epidemic, it gradually acquires a degree of resistance to the disease which now becomes statistically endemic and clinically more chronic. When the disease has become truly endemic, the mortality it causes at different periods of life resembles that due to other forms of mortality, such as enteric diseases and bronchitis, i.e. it claims its victims among the newly-born possessing an atavistic lack of resisting power, and among those, particularly the old, whose initial power of resistance has been broken down by the wear and tear of life.

Should, however, the resisting power of a community among which the disease is endemic—such communities as all civilised nations in the Middle Ages—be modified by such changes in environment as followed upon the industrial revolution, then the type of the disease changes statistically and clinically; statistically it attacks at that period of life—adolescence—when the changes are most felt; clinically it becomes more active and less
The disease at this stage in its manifestations now stands midway between an acute infectious epidemic and a chronic endemic disease. Whether the maleficent process could be pushed further so that the disease reverts to an acute endemic type, there is no sure evidence to show. Fortunately the further development of industrialism has brought better environmental influences into existence, and the tendency has been for the disease to resume its more chronic endemic type. As the prevalence of the disease dies down, it finds its last stronghold in late life when the resisting power of the body is growing weaker with age, and among males whose occupational activities subject them to considerable strain and stress.

The food supply has become more plentiful, has fallen rapidly and the age most concerned in the fall has been early adult life, even though the maximum incidence shows a tendency to remain at that age.

When consideration is given to the changes produced by the industrial revolution, at once the question of food supply is recognised to have been of the utmost importance. In England the population, which up to 1700 had been almost stationary for at least 300 years, multiplied rapidly and soon the countryside could not provide locally the needed food. Road transport was thoroughly bad. Canals at first were practically non-existent and at best provided inadequate means. Railways were only started about 1840. Increased earnings drew the food supplies into the industrial centres and soon the farm labourer could only afford a little meat once a week and milk not at all. Importation of food commenced, but so long as ships depended, as they did for the most part up to 1870, upon wind power, only material which did not rapidly deteriorate, such as grain and cotton, could be carried; cold storage and quick voyages were not yet.

Disturbance of food supply has probably been the great factor exerted by industrialism upon the incidence of phthisis, and its influence has been most felt in England the population, which up to 1700 had been almost stationary for at least 300 years, multiplied rapidly and soon the countryside could not provide locally the needed food. Road transport was thoroughly bad. Canals at first were practically non-existent and at best provided inadequate means. Railways were only started about 1840. in young adult life. The adequacy of food supply must, however, always be measured by the need for energy output; a dietary adequate for the sedentary life of a clerk is quite inadequate for a navvy or a coalminer. Here modern industrial methods, by introducing labour-saving devices, help to lighten the strain placed upon the food supply of the community.

Alcoholism

Another important social factor has been an increase in the alcohol habit as compared with the Middle Ages; this increase was synchronous with the birth of industrialism, and probably was closely related to it. The conditions of labour in those early years, with long hours spent in close atmospheres at uncongenial work, lowly paid, tended to produce that irritable tiredness associated with thirst for which an alcoholic beverage seems a heaven-sent panacea. The habit so implanted in the community is only now slowly being lifted as conditions of work and the social status of the workers are being ameliorated. Statistics exhibit occupational groups, such as innkeepers and casual labourers, brewers and barmen with high mortality from alcoholic diseases, as well as high mortalities from other causes of death, amongst which phthisis stands high. (See the article "Alcoholism ".)

OCCUPATIONAL INFLUENCES

The existence of a close association between occupation, particularly of industrial type, and phthisis mortality is seen when the mortality for males is compared with that for females in selected (non-industrial) rural and (industrial) urban counties in England and Wales. These are contrasted for different age periods in figs. 159 and 159A. The female death rate from phthisis in early life in both town and country exceeds the male, giving some indication that, given similar conditions, females are as liable as males to phthisis; this fact is further exemplified by countries such as the Netherlands and Japan in recent years and England and Wales in 1851-1860, where the female phthisis rate for all ages is found to exceed the male. From ages 20-24 onwards occupation is particularly the distinguishing characteristic of the male, even though some females are occupied, particularly in industrial areas. From this age period the male death rate exceeds the female; the excess is most pronounced in the industrial urban counties and at middle age.
The female death rate in the industrial counties exhibits some occupational influence in that the age of maximum incidence is later than in the rural counties. Up to the age of 30 the death rates for both sexes is higher in the rural than in the urban counties, due possibly to the greater command of food in the urban areas brought about by greater wealth.

The main point brought out is that the adult male seems quite definitely in Great Britain to be subjected, so far as phthisis is concerned, to more adverse influences than the female, and these influences are definitely associated with industrial occupation. Hence further investigation of these influences may with most advantage be pursued by examining mortality statistics for males, distributed according to occupation.

**General Influences**

Two general influences are exerted upon the prevalence of phthisis by occupations; these depend upon (a) the infectious character of the disease, i.e. its communicability from person to person, and (b) the capacity of the human organism for having its resistance to the infection modified by occupational environment.

An infectious disease is obviously more prevalent the greater the opportunities for transmitting the infection. If the possibility be accepted that at least a proportion of cases of phthisis in adults is due to adult infection, then the undue prevalence of the disease in certain industries is open to explanation; examples of the industries for which this explanation is required are, in England and Wales, printing, tailoring, and shoemaking. Each has, during the period covered by the statistics quoted in table II, been carried on indoors in factories where the aggregation of workers has been such as to facilitate the transmission of infection. Clerical occupations, as exemplified by law clerks and commercial clerks, present somewhat similar opportunities for infection, and here also phthisis is found to be unduly prevalent.

Examination of the mortality, due to other causes of death, experienced in these occupations does not support the idea that the resistance to disease in general is decreased by these occupations, since apart from phthisis no other disease provides a mortality distinctly above the standard. While the phthisis death rate, in each decennial period, quoted in table II, stands out for each of these occupations as particularly high, it fell greatly between 1890-1910; but this fall is synchronous with a somewhat similar fall in the phthisis death rate for all males. The evidence is compatible with the hypothesis that, while the prevalence of phthisis in these occupations is a function of opportunity for infection, it is also profoundly influenced by the resisting power to disease in general of those exposed to infection.

In contradistinction to the Industries just mentioned, come the textile industries — cotton, woollen and hosiery. Here the physical exertion called for is comparable with that of printing, tailoring and shoemaking, and the industries are similarly carried on indoors in factories; but the aggregation of operatives is less pronounced owing to the size of the looms, spinning frames, knitting and other machinery. The machines separate individual from individual, and the prevalence of phthisis in these industries is not unduly high, even though in the case of certain operatives, e.g. the strippers and grinders of cotton carding machines, the lungs are adversely affected by inhaling dust, as is shown by the high mortality from respiratory diseases other than phthisis.

Attention has already been directed to the influence exerted upon phthisis mortality by food; the influence of this factor is further stressed by noting the high incidence of phthisis in occupations of low social status of which unskilled labour provides examples in dock labourers and costermongers. Low social status, however, is associated with other things besides, and among these stand a tendency to indulge to excess in alcohol; indulgence in alcohol is recognised to lower resistance to disease in general. Hence the high incidence of phthisis in the industries quoted cannot be simply attributed to the poor food supply necessitated by a low income. The influence exerted by occupation in this instance is a social rather than a purely occupational one.

Attention may here be directed to the way in which a high mortality from phthisis is found associated with different combinations of mortality rates from other causes which vary with the prevalent factor in the phthisis causation. Thus, when opportunity for infection is the prevalent factor, as in the case of printers, tailors and shoemakers, the mortality from phthisis is the only one which is unduly high; when the prevalent factor is alcoholism, which lowers the resistance...

1 Figures printed in heavy type exceed the standard set by all males for the same decennial period.
to disease generally, mortalities from all other causes are high; but when the prevalent factor is dust inhalation, as exemplified by silica dust, vide infra, a high mortality from phthisis is found associated with high mortalities from bronchitis, pneumonia and Bright's disease, but not from any other cause of death. This method of detecting by differential mortality the factor influencing the prevalence of phthisis in any occupational group is one of great statistical value.

II. — Silicosis

The general influences, so far as they have been traced, exerted directly or indirectly by occupation upon the prevalence of phthisis have been stated. There remain for consideration particular influences, by which is meant those specific influences, peculiar to definite industrial processes, which render workers more than normally liable to succumb to pulmonary tuberculosis.

The typical example of such an influence is the inhalation of silica dust. Knowledge as to this form of phthisis is based nearly entirely upon study of statistical, clinical and pathological manifestations in industries where risk of inhaling silica dust exists. It exists in many industries; in most gold mines, tin mines, and lead mines, and generally in mining and quarrying in flint, chert, granite, millstone, quartz, or buhrstone; in dressing and grinding of wheels of sandstone, millstone, or buhrstone; grinding articles on wheels of sandstone, millstone or buhrstone; in dressing and carving granite, millstone, millstone grit, or buhrstone; in flint knapping; in crushing or brocking silica, sometimes called secondary white mica, belonging to the mica group of minerals containing SiO₂ 45.56 per cent., Al₂O₃ (37.46), Fe₂O₃ (0.80), MgO (1.16), K₂O (6.35), Na₂O (0.66), traces of CaO.) In every silicotic-lung section examined, fibres of sericite were particularly numerous, although many small grains of quartz were also present. Following a survey of the chemical analyses of the ash and the mineral residues of silicotic lungs and a comparison of the silica rocks causing silicosis with those which did not, Jones discussed rocks low in their content of free silica which nevertheless caused silicosis. More certain mills crushed pure quartz 99 per cent. free silica without the incidence of a single case of silicosis. The question whether sericite is a primary factor of silicosis still remains open to discussion.

Statistical Evidence

The inhalation of dust has long been recognised to be injurious. Many early writers noted the fact, from Pliny the elder and Georgius Agricola to Diemerbroek and Ramazzini. Metallic-ferous miners, stonecutters, potters, hemp and flax workers are mentioned as affected; but in times when phthisis was not clearly distinguished from other respiratory diseases, the precise disease alluded to cannot always be recognised. Certain events in the nineteenth century came to help; first, phthisis was more definitely recognised as a clinical entity, mortality statistics were collected; thirdly, the tubercle bacillus was discovered. Medical opinion continued up to the commencement of the twentieth century to hold as a broad truth that the inhalation of any kind of dust predisposed to diseases of the lungs which pulmonary tuberculosis was the chief. The intensive investigations prosecuted by E. L. Collis into the prevalence of phthisis in certain occupations and into the amount and kind of dust present, indicated that, at any rate so far as phthisis is concerned, the kind of dust was of primary importance, and that workers, such as makers of cement and masons dressing limestone, could be exposed to extensive amounts for many years without exhibiting any tendency to succumb unduly to phthisis. On the other hand, wherever phthisis attributed to dust was found in excess, one element, silica, was always found to be present. The fact is well brought out in table III.

Here in all industries involving exposure to dust containing appreciable amounts of silica phthisis is found to be unduly prevalent; but the silica must be present as SiO₂; dusts of silicates do not exhibit this phenomenon. The order stated in the table is arranged according to mortality and exhibits a close relation to the amounts of silica present in the different dusts; exceptions to this rule are caused by the exposure being more intense in some processes than in others, for example, the pneumatic tool of the granite cutter raises more dust than the chisel and mallet of the stone-mason.

Further examination of mortality records disclosed that mortality from phthisis as exhibited by groups of persons exposed to the inhalation of silica dust displayed certain definite statistical characteristics. One of these has already been mentioned, namely, that the excessive mortality from phthisis is associated with

1 Where not otherwise stated, the records are taken from the Supplement to the Seventy-fifth Annual Report of the Registrar-General for England and Wales, Part IV.

Excessive mortalities from bronchitis, pneumonia and Bright’s disease; this combination, in the absence of excessive mortalities from other causes of death, is quite distinctive. Silica dust shares with various other dusts, such as vegetable husks, emery, and basic slag, a capacity for overtaxing the ciliary mu cosa of the air passages and rendering them more prone to succumb to bronchitis and pneumonia; but these latter dusts are not associated with excessive mortalities from phthisis and Bright’s disease. The reasons why the mortalities from the last-named diseases are excessive will be discussed when the pathological action of silica is described.

The combination of high mortalities from phthisis, bronchitis, pneumonia and Bright’s disease is also found in groups where alcoholism prevails; but in those groups the mortalities from other causes of death, particularly from alcoholism and cirrhosis of the liver, are also in excess.

The second statistical characteristic is that the age of maximum incidence of phthisis in a “silica group” is, and always has been, late in life. This point is brought out in the figures given in Table IV. This characteristic is one of some importance and will be used as a means of statistical differential diagnosis later. Its exact meaning is not clear; it would agree with the idea that silica, by gradually damaging the lungs, lowers their general resistance to disease, and so prepares the way for phthisis which in late life is an accompaniment of wear and tear, attacking those whose lungs have

</table>
been impaired in the battle of life; this
idea, however, hardly accords with ex-
perimental work which portrays silica as
exerting a specific influence favourable to
tuberculosis: such an influence should
make itself felt soon after it comes
into play; yet phthisis among sandstone
masons from ages 15 to 24, and among
tin and lead miners up to age 20, is rather
less than more prevalent than usual.
Possibly this absence in early years of
any undue prevalence of phthisis in these
industries is due to a combination of two
influences; in the first place, the con-
ditions in these industries do not favour
the transmission of infection; secondly,
are much smaller, 1 μ and less. These
particles in the alveoli are engulfed by
macrophages which then either move
within reach of the ciliated epithelium
lining the bronchioles when they are
expelled in mucus, or pass through
the walls of the alveoli into the pul-
monary lymph spaces. The macrophage
cells take up some forms of dust, such
as coal, far more readily than other
dust, such as silica. Particles of dust
too large to obtain access to the alveoli
are caught on the walls of the air
passages and expelled in mucus.

FIG. 160. — Moderate degree of simple silicosis. The lung shows considerable excess of pigmentation,
with moderately numerous "small" to "medium" sized palpable silicotic nodules. (According
to L. G. Irvine and W. Stewart, Johannesburg.)

evidence supports the view that tubercul-
ous silicosis is less infectious than or-
dinary pulmonary tuberculosis to persons
not the subjects of silicosis; hence new-
comers would have to develop some
degree of silicosis before becoming liable
to infection from their fellows. (See article
"Gold Mines ".) 

PATHOGENIC FACTORS

Size of Dust Particles

In order to gain access to the
alveoli of the lungs, dust particles must
be below a certain size, roughly 5 μ
in diameter; the majority of particles

Action of Silica Particles

Many forms of dust when carried
into the lymph channels remain inert
and unchanged (unless, like limestone,
they pass easily into solution and are
so removed); particularly is this so in
the case of carbon particles which can
be seen lying in physiologically healthy
tissues. Silica dust behaves differently;
the fine particles have in relation to
their size an enormous surface exposed
to the surrounding medium, and a
variation in the normal laws of solu-
ability is to be expected; even in distilled
water the rate of their solubility is
relatively high and rapid. Silica in
solution forms a colloid, and possesses
definite toxic properties; an overdose
of solution or of dust injected into
animals produces death. Smaller doses
produce local necrosis which is fol-
lowed by the formation of fibrous
tissue. When silica dust is inhaled the
macrophages carrying the particles out
of the alveoli are poisoned. They
appear to become mummified and die
without breaking up. These cells
collect in the lymph nodes and glands
where the toxic process continues and
affects the surrounding tissues; the
reaction of the poisoned tissues takes
coalesces with its neighbours; finally
the alveoli in large areas become
equipped. As the condition
progresses, the X-ray appearances
become more distinct and what were
at first small punctate spots become
larger and denser shadows dotted fairly
symmetrically over the two lungs.
Shadows branching into a network
and marking out the course of the
pulmonary arborisation are present,
just as they are present in the case of
other dusts associated with bronchitis,
but not with tuberculosis; these shad-
oows tend to be obscured in advanced

Fig. 161. — Very well-marked degree of silicosis, with many large irregular nodules and some
areas of fibroid consolidation. No overt tuberculosis. (According to L. G. IRVINE and
W. STEUART, Johannesburg.)

the form of a multiplication of fibro-
blasts which block the lymph channels
and wall off the noxious particles.
Thus there are formed symmetrically
in the lungs on both sides a vast
number of fibrous foci or pseudo-
tubercles which at this stage may be
detected by X-ray examination. Each
focus by blocking the lymph channels
forms a centre where more dust-bearing
macrophages collect, just as a branch
on a river caught against a rock
collects other debris and branches
brought down by the stream; the
process thus started tends to extend,
until one fibrous patch meets and
cases by more pronounced particulate
motting.
The process is usually more pro-
nounced at the apices and least at the
bases; the pleurae are always involved
and the fibrous formation affects the
parietal pleurae, so that extensive,
firm, tough adhesions are formed.
The formation of fibrous tissue may be
so rapid and extensive, that on section
the resulting nodules can hardly be
distinguished from fibromata; or the
process may be slower when contrac-
tion of the fibrous tissue becomes a
feature. In the first case so massive
is the fibrosis which may occur that
the lungs bulge out when the chest is opened after death as though they had had too little room; in the second they are found withered and contracted while bronchiectatic cavities may be present. The condition found depends on the extent of the exposure to dust inhalation and on the period intervening before death during which the fibrous tissue has had time to contract. In this way a condition of diffuse, symmetrical, chronic fibrosis, or pulmonary silicosis comes into existence; work, has been made that silica exerts its action by passing into solution in the body, when it becomes a tissue poison. When such a solution is introduced into the body it is eliminated by the kidneys which become acutely inflamed, while the liver also is affected. The possibility of small amounts of soluble silica escaping from the lungs into the circulation to be eliminated by the kidneys in cases where silica dust has been inhaled, must be contemplated; in some individuals such action may be more pronounced than in others, and, if so, the kidneys would tend in time to develop a fibrotic condition which would terminate as Bright's disease. Here is a possible explanation of why among those exposed to silica dust, e.g. tin miners and sandstone masons, the mortality from Bright's disease is high. Moreover, English mortality records for 1921-1923 display such high death rates from myocardial diseases among groups ex-

Fig. 162. — Gross fibrosis, partly infective in type. (According to L. G. Irvine and W. Stewart, Johannesburg.)
posed to the silica-dust hazard as to suggest that degenerative changes in the heart muscle also result.

SYMPTOMS

The symptoms exhibited will depend on the extent to which the disease has advanced; the rapidity of advance varies directly with the intensity of, and period of exposure to, dust inhalation. Even in a rapid case the advance, spread over several years, is comparatively slow and chronic, while the inch; the first heart sound on the right side may be accentuated. The arterioles in the front of the chest may be dilated. The man has a cough, paroxysmal in type, and frequent at night, but sputum is scanty, although haemoptysis may occur. A history of pleuritic pain is frequently given. In old-standing cases where fibrous contraction has occurred, both the heart and liver may be more exposed than usual, but the development of emphysema may mask this effect; in cases of rapid and massive fibrosis the opposite con-

FIG. 161. — Gross fibrosis, silicotic in type. Advanced silicosis. (According to L. G. Irvine and W. Stuart, Johannesburg.)

disease may take more than twenty years to develop when the dust-risk is not intense. Even a pronounced case may look robust, feel well, and be able to work, except for getting rapidly out of breath on exertion; he is unable to breathe deeply, and his respiratory action is entirely carried on by the diaphragm, the intercostal and extraordinary muscles of respiration not playing any part. Chest expansion at the nipple line seldom exceeds half an inch; the first heart sound on the right side may be accentuated. The arterioles in the front of the chest may be dilated. The man has a cough, paroxysmal in type, and frequent at night, but sputum is scanty, although haemoptysis may occur. A history of pleuritic pain is frequently given. In old-standing cases where fibrous contraction has occurred, both the heart and liver may be more exposed than usual, but the development of emphysema may mask this effect; in cases of rapid and massive fibrosis the opposite con-

dition may be found. Blood pressure is usually above normal; the number of red corpuscles is increased. Finally the heart dilates under the extra strain thrown upon it, and cardiac failure, sudden or more protracted, ends in death.

Tuberculous Infection

Cases of uncomplicated pulmonary silicosis may end fatally, but in the majority of cases the progress of the
pathological condition is interrupted by tuberculosis infection. The exact reason why subjects of pulmonary silicosis are especially liable to tuberculosis still awaits explanation, but silica appears to exert some specific influence in this direction not exerted by other agencies which cause pulmonary fibrosis. Kettle has established by experiments on animals that tissues which have been damaged by the presence of either fine silica dust or colloidal silica provide a more favourable nidus for tubercle bacilli than tissues similarly damaged by other factors; while Gardner has shown that silica dust, when inhaled, is more potent than any other dust in reactivating quiescent tuberculous lesions in the lungs. Gardner further holds that only silica and some silicates are capable of exciting significant reactions in the connective tissues of the lungs.

The course taken by tuberculosis in these cases is modified somewhat by the existing pathological condition; haemoptysis and night sweats are less common; pyrexia is less pronounced; and sputum is less copious than at a similar stage of ordinary pulmonary tuberculosis. Nevertheless, although the symptoms resemble those of a chronic type of the disease, the course taken is frequently rapid and very often fatal.

The question has been discussed as to when the tuberculous infection occurs. The sudden alteration for the worse in a case of simple silicosis which betrays the presence of tuberculosis, suggests that the infection may be a new thing not previously present. Another hypothesis, however, has been put forward, viz. that the infection is not necessarily new, but may have occurred when the dust particles were originally inhaled and have remained within the fibrotic centre of the pseudo-tubercles. Probably both types of infection occur. When present from the commencement, the fibrotic centre shows early signs of necrosis; when the infection is superimposed later, a firm necrotic centre may be found surrounded by necrotic tissue containing giant cells and tubercle bacilli. But every stage between the two may occur; thus an infected necrotic centre may break down and release its bacilli to be superimposed on non-infected fibrous nodes. Both hypotheses presume infection taking place during adult life through direct inhalation.

A condition of silicotic fibrosis undoubtedly paves the way for pulmonary tuberculosis; on the other hand, the occurrence of tuberculous infection hurries on or, as it were, precipitates a latent condition of silicosis. The two diseases play one into the hands of the other.

Differential diagnosis between the two conditions is often a matter of some importance; the following points when taken together are distinctive:

**SIMPLE SILICOSIS**

Fever absent.
Pulse normal.
Blood pressure raised.
Night sweats absent.
No loss of weight.
No malaise.
Sputum negative for tuberculosis.
Dyspnoea on exertion pronounced.
Toxaemia absent.

**SIMPLE PULMONARY TUBERCULOSIS**

Fever present.
Pulse rapid.
Blood pressure not raised.
Night sweats present.
Loss of weight.
Malaise present.
Sputum positive for tuberculosis (not necessarily).
Dyspnoea only in advanced cases.
Toxaemia present.

**Radiographic Appearances**

Particulate mottling.
Bilateral and symmetrical.

**Blood Count**

Haemoglobin normal or raised.
Red cells increased.
Leucocytes normal.
Polymorphonuclear cells normal.

**Other Dusts and Fibrosis**

Clinical observations and examination of mortality statistics for occupations with risk of exposure to dusts other than silica brought to light others (apart from asbestos, which is dealt with in a separate article) concerning which the evidence is at least suspicious.

**Oxide of iron (Fe₂O₃).**—The first instance to be quoted is provided by
iron-ore miners, even though like coal miners, their total phthisis rate is not high. English statistics for mortality among iron-ore miners were not separated from those for iron-stone miners before 1910-1912; nevertheless the figures for the whole group have always exhibited a definite rise in the phthisis mortality in the later years of life. For 1910-1912 this phenomenon was not found among iron-stone miners, but only among iron-ore miners, which suggests that in the two previous decennial periods the phenomenon was due to the inclusion of iron-ore miners with iron-stone miners; iron-stone is carbonate of iron; iron-ore is oxide of iron, \( \text{Fe}_2 \text{O}_3 \), but the ore contains a proportion of silica. Iron-ore miners have high mortalities from bronchitis and pneumonia; their mortality from Bright's disease is definitely above that of iron-stone miners, but it is not excessively so. The picture presented resembles that for coal miners on coal-fields where the phthisis rate is comparatively high.

Examination of certain iron-ore miners by X-ray disclosed the presence of punctate shadows varying directly in intensity with length of exposure to dust. Later, when one of the men died from pulmonary tuberculosis, the upper parts of his lungs showed definite whorls of fibrosis obliterating the alveoli; the fibrous tissue gave a definite reaction when stained for iron, a reaction not given by healthy parts of the lungs or by the red cells. The pathological evidence favoured the assumption that the fibrosis found was originated by the iron-ore dust to which he had been exposed, but the presence in the dust of a certain amount of silica must be kept in mind.

Another industry with exposure to dust of oxide of iron is that of boiler-making; in this instance no silica is present. Here also the age of maximum incidence of phthisis mortality has been uniformly late in life, even though the total mortality has not been high. The mortalities from either bronchitis or pneumonia, or from both together, at each decadental period have been high. That from Bright's disease is less definite. Here again, as in the case of iron-ore miners, is found in less pronounced form the statistical characteristics already quoted as distinguishing mortality in "silica" groups.

Alumina.— The dust of alumina, \( \text{Al}_2 \text{O}_3 \), calls for consideration because this substance, like oxide of iron and silica, in solution forms a positive colloid; if, therefore, silica and oxide of iron exert their influence by chemical action, alumina might be expected to resemble them. An occupational group exposed only to dust of alumina is not easy to find; thus potters, exposed to dust of china clay, are also exposed to dust of flint (silica). The best available example is the group slate-quarriers, but their mortality statistics have only been kept distinct for 1910-1912. The claim has often been made that slate-quarriers suffer from fibroid phthisis and pathological findings of definite fibrosis have been put in evidence. But the absence from the industry of any obvious undue prevalence of phthisis, such as occurs among tin miners, sandstone masons and grinders of metal, notwithstanding the amount of exposure to dust, caused the question to be left sub judice. Now, however, that fairly reliable figures are available, the phthisis mortality is found to be above normal and the age of maximum incidence is quite definitely in late life. The industry of slate-quarrying is carried on in North Wales where the age distribution of the phthisis mortality for males differs from that of the slate-quarriers. No excessive mortality is present among the men for bronchitis, pneumonia or Bright's disease; but dust of slate may not overtax the bronchial mucosa in the same way that does silica and other dusts, nor is it known whether colloidal alumina is excreted from the kidneys. The evidence, however, is in favour of slate-quarriers experiencing some amount of pulmonary fibrosis and exhibiting a mortality from phthisis which resembles that of "silica" groups in being highest in late life; in other words it is not unfavourable to the view that dust of alumina may exert an influence upon the pulmonary tissue akin to that exerted by silica.

Experiments in which animals were made to inhale dust of pure china clay tend to confirm the statistical evidence that dust of alumina reacts with living tissue in the same way as silica, even though the reaction is less pronounced.

Coal dust. — Investigation has disclosed that on British coal-fields mortalities from pulmonary diseases among miners are below normal on some fields, but are high on other fields. Bronchitis, pneumonia and tuberculosis vary together on these fields; but tuberculosis is never so excessive as bronchitis may be. While these variations are in some degree accounted for by the amount of sandstone rocks which may have to be manipulated in getting to the coal seams with consequent exposure to silica dust, there is...
evidence that the dust of anthracite coal induces a form of pulmonary fibrosis in every way similar to that induced by silica except that it does not prepare the way for tuberculous infection; dust from bituminous coal, on the contrary, does not induce such fibrosis.

In each of the above three injurious dusts, however, small, but varying, proportions of silica in the form of quartz particles are present in the respective minerals, and may be responsible for their toxic properties.

**LEGISLATION**

*Compensation for Silicosis and Tuberculosis*

**Argentina and Brazil.** — Compensation is granted in respect of tuberculosis.

**Australia.** — Compensation is granted (i) in New South Wales for silicosis or other disease of the lungs due to dust by the Silicosis Act, 1911 under which a scheme has been made for the sandstone workers in the County of Cumberland, and by the Broken Hill Acts, 1920 and 1927, under which uncomplicated tuberculosis is also compensatable; and (ii) in Queensland for silicosis; while the matter is under consideration in Western Australia, Victoria and Tasmania.

**South Africa.** — Compensation for pulmonary silicosis or tuberculous silicosis was first awarded to underground workers in South African gold mines. The first Act, which was passed in 1911, was modified several times before the present Act, the Miners’ Phthisis Act, No. 35, 1924, was adopted. The Act of 1919, No. 40, recognising three stages in the disease: (a) ante-primary, wherein damage to the lungs has occurred short of definite physical signs of silicosis, (b) primary, wherein physical signs of silicosis are present sufficient to impair capacity for work although not seriously or permanently, (c) secondary, wherein the physical signs of silicosis are sufficient to impair capacity for work seriously and permanently.

A fund is raised by a levy on each employer assessed as follows:

(a) 30 per cent. of the amount in proportion to the earnings in a scheduled mine during the previous period of three months of the miners employed by such employer;

(b) 50 per cent. of the amount in proportion to the silicosis rate for each mine;

(c) 50 per cent. of the amount in proportion to the sum for which such employer was assessed for normal income tax during the penultimate accounting period.

A Board is appointed to administer the fund, but on all purely medical questions the advice of a Medical Bureau must be accepted.

Any person wishing to work underground must undergo an initial medical examination, and miners must be examined periodically every six months. At any examination any man found affected may be suspended from work, when if he has been employed for at least two years, compensation is awarded, the benefit varying with the stage of the disease; tuberculosis not complicated by silicosis is ranked for compensation as the primary stage.

The Act contemplates that its provisions throughout will be worked by the industrial machinery constituted without any reference to the ordinary courts of jurisdiction.

For compensation of bricklayers and stonemasons, see article “Building Trade”.

**Canada.** — Compensation has been granted (i) in Ontario since 1926 for silicosis and other pulmonary diseases due to dust occurring in mining, quarrying, crushing and grinding stone, and in grinding metal; (ii) in Quebec, since 1931 for silicosis and miners’, stonecutters’ and grinders’ phthisis; (iii) in Alberta since 1925, for miners’, stonecutters’ and grinders’ phthisis; and (iv) in British Columbia and Nova Scotia if the workman can prove that the disease arose out of his occupation.

**Germany.** — Compensation is granted according to a schedule of industrial diseases, which includes a severe disease of the lungs due to dust (silicosis, or tuberculosis accompanying silicosis) in (a) sandstone quarrying and dressing, (b) grinding of metals, (c) pottery works, (d) mining.

**Great Britain.** — Fibroid phthisis or silicosis is recognised in Great Britain as a specific trade disease in certain industries, and special legislation has been passed with a view to provide compensation for this disease. It was not found possible to schedule it under the general Workmen’s Compensation Acts owing to the slow development and other special features of the disease.

Under the Act of 30 July 1918 (since embodied in Part II, section 47, of the Workmen’s Compensation Act, 1925, and in the Workmen’s Compensation (Silicosis and Asbestosis) Act, 1930) power was obtained to deal with the disease by special schemes for particular industries or processes involving exposure to silica dust. These Acts do not themselves require payment or compensation to workers killed or disabled by silicosis, but it lays down certain principles for inclusion in any scheme. Thus it provides for the establishment of a general compensation fund to which all employers in the industries should be required to subscribe and out of which all claims for compensation and all expenses arising under the scheme should be paid. In this way the burden of compensation is borne, not by the individual employer, but by the industry as a whole. They also provide
for the appointment of Medical Boards with expert knowledge of respiratory diseases for the purpose of making medical examinations and giving the necessary certificates and for the appointment of local joint committees representative of both employers and workmen in the industries with an independent chairman, who are entrusted with the settlement of claims and other matters arising under the schemes.

The Acts require that the scales of compensation shall, as regards silicosis or silicosis accompanied by tuberculosis, be those prescribed in the general Workmen's Compensation law. No provision is made in the Acts for compensation for tuberculosis unaccompanied by silicosis.

A scheme may also provide for the determination of any dispute arising between employers and the authority administering the compensation fund either by the Secretary of State or by an arbitrator.

In addition to providing for compensation, the legislation is of a preventive character in that it gives power to prescribe a standard of physique for all new entrants into the industry concerned and provides for a system of periodical medical examination and suspension, designed to secure the removal of a workman affected by silicosis or tuberculosis as soon as it becomes dangerous for him to continue work in the industry.

A scheme under these Acts for the refractories industries has been in force since 1 February 1919, and has recently been amended in accordance with the recommendations made by a Departmental Committee. The refractories industries are a group of industries engaged in the getting, handling, moving, breaking, crushing, grinding, and sieving of material containing not less than 80 per cent. total silica, and in the manipulation of such material in the manufacture of brick, or other articles for lining furnaces.

During 1929 somewhat similar schemes were made extending the provisions of the Acts to other industries, including (a) the metal-grinding industries, in which metal articles are ground on sandstone wheels; (b) the sandstone industry, in which sandstone is got or manipulated; (c) processes in mining and quarrying, in dressing and carving, in crushing and sieving, silica rock, i.e. quartz, quartzite, ganister, sandstone, gritstone and chert, and in crushing and grinding flint; (d) foundries and metal workers in the processes of crushing or grinding silica rocks or silica bricks, or in dressing or sanding of castings; (e) the granite industry; (f) the potteries with regard to exposure to flint dust; (g) tin mining; and (h) the asbestos industry.

The right to compensation under any scheme is afforded the worker or his dependants in cases of (1) death, (2) total disablement, (3) suspension from employment by reason of a diseased condition, which may or may not involve incapacitation for work rendering it dangerous for the workman to continue in the industries. In every case it is dependent on a certificate being issued by the Medical Board appointed under the scheme.

No compensation is payable in cases where the Medical Board certifies that the silicosis cannot have been contracted in the respective industries owing to the shortness of the time during which the workman has been employed therein, nor if the workman has left the industries, unless it is proved that since his last employment he has not been employed in any of the specified industries and occupations involving exposure to silica dust, which have otherwise been brought within the scope of the Acts.

Furthermore, the right to compensation is subject to the reservation that it shall be the duty of every workman:

(a) to submit himself to the periodic and other examinations provided for under any scheme;

(b) to furnish true information with respect to his previous employment in the particular industries or in any industry or occupation involving exposure to silica dust;

(c) not to re-engage in the particular industries after having been suspended under the scheme in force.

If, however, the worker acts in good faith and fails to comply with the foregoing requirements it has been due to circumstances outside his control, such circumstances being left to the judgment of the court, compensation may be paid.

The schemes vary somewhat for different industries; that for the refractories industries, which is the oldest and most complete, may be quoted.

Under pain of an increase in their subscriptions, employers are required to arrange for the initial examination of newly-engaged workmen, to furnish facilities for the prescribed examinations, and not to employ any workman who has been suspended or has refused to submit himself to any periodic medical examination (paragraph 43 of the scheme).

The general compensation fund required to be established under the scheme is administered by a company registered as the Refractories Industries Compensation Fund Limited, whose duty it is, subject to any directions of the Secretary of State, to fix, levy, and enforce all subscriptions which may be necessary to enable the fund to meet its liabilities. At present every employer engaged in the industries is required to pay a fixed rate per cent. of the wages earned by him in the industries, but the scheme gives power to the Secretary of State to require the company to adopt different rates of levy for different risks.

In addition to the compensation payable in the case of death or disablement, provision is also made for payment of two weeks' full pay and half wages for a further period not exceeding eleven weeks for a workman who has been suspended before their general physical capacity is impair-
ed, and for the payment of removal expenses not exceeding £5, if on suspension a workman is compelled, in order to obtain other suitable employment, to remove from the district (paragraph 7 of the scheme). An award may be reviewed by a Joint Committee if the condition of health or the circumstances of the worker undergo any change or for any other reason (paragraph 8).

The working of the scheme on the medical side is entrusted to a Medical Board consisting of two or more experts in respiratory diseases who are appointed by the Secretary of State (paragraph 3). They have power to make or cause to be made radiographic examination of any workman and to obtain the opinion of a radiologist on the case.

The scheme is not a rigid one, as it may be modified by subsequent Orders published in pursuance of the law, but it is interesting to note that the Departmental Committee regarded the scheme as amended as a suitable basis on which to frame schemes for the other and larger industries for which schemes have since been made.

Mexico. — Compensation is granted in respect of silicosis and tuberculosis. United States of America. — Compensation is granted in most of the industrial States of America for “diseases arising out of employment”, but silicosis is in no instance specifically named in any schedule of occupational diseases; hence the onus of proving that his disease has, in any instance, been caused by his occupation rests upon the worker.

See also the articles “Pneumoconiosis”, “Stoncutters”, and “Coal Miners’ Diseases”.

The problem of compensation for tuberculosis of occupational origin is, however, a much wider one than provided for by the scope of these laws and calls for detailed study. Yet since the basic principles of compensation are the same for other types of infection to be studied in the light of occupation, it appears preferable to deal with this question thoroughly in the special article devoted to compensation for occupational diseases [See article “Occupational Diseases (Compensation)”].

Tumours of Occupational Origin and Occupational Cancer

The term “occupational tumours” is applied to cancers which originate from the regular and prolonged exercise of an occupation. This article will therefore not deal with tumours incurred by workmen as the result of accidental injury sustained during their work, for in these cases the appearance of the tumour can in no way be attributed to the nature of the occupation.

The object of this study is to combine and co-ordinate in one general description all the occupational tumours which have been dealt with in such different articles of this Encyclopaedia as “Arsenic”, “Tar”, “Pitch”, “Aniline”, “Anthracene”, “Naphthalin”, “Tumours of Occupational Origin: Urogenital System”, and Roggen Ray Operators (Industrial Pathology of), and to discuss particularly their pathogenesis and etiology — a matter which more especially concerns industrial hygiene.

The connection between cancer and occupation is alluded to in the publications of Vesiliius, Von Forest, and Ramazzini; but credit for the first scientific observation is due to Percival Pott, who in 1775 described scrotal cancer among English chimney-sweeps. Since then there have been numerous investigations, and the list of occupational tumours has increased. Volkman has identified the cancer of tar and paraffin workers with that of chimney-sweeps; and Manouvrier, of Anzin, has extended this resemblance to occupations concerned with coal and its by-products.

On the other hand, the discovery of X-rays and radium has enabled an undue incidence of malignant tumours to be observed among those whose occupation it is to handle them. Thus the progress of the knowledge of cancer and the more intelligent use of statistics have brought under suspicion certain occupations, wherein cancer, without appearing to be directly derived from or clearly connected with the handling of this or that product, occurs with a significant frequency.

This study will be a general review. No attempt will be made to consider the special aspect presented by each of the trades involved; descriptions of these varieties are to be found in the different special articles of the Encyclopaedia.

This general study is justified because occupational cancers not only possess common characteristics, but also a general behaviour which distinguishes them.

1 It would be more accurate to say “tumours caused by the exercise of an occupation”. The nomenclature “occupational tumours” has, however, been adopted because it is clear and everyone understands it. These advantages compensate for the incorrectness of the term adopted.
from other cancers, as well as a more definite aetiology, although it is still very incomplete, and also a better-known pathogenesis; and because measures for efficient prophylaxis can be more easily realised than in other forms of cancer. It is further justified because, generally speaking, these cancers have not been studied up to the present time with the minuteness that ought to be given to the subject, while many of their characteristics have been passed over too lightly by investigators.

**General Study of Occupational Cancers**

Knowledge of the pathology of occupational cancers has radically changed during recent years in consequence of the new light which has been thrown on the origin and development of malignant tumours.

The somewhat simple conception that cancer originates from a previous irritation, which irritation is sufficient to cause the appearance of a new growth has been replaced by the conviction that, for a certain number of tumours at least, general changes in the body play a considerable part in their origin.

Instead of envisaging cancer as an element which is just added to the organism as the result of an irritation, it is regarded as the final result of a series of biochemical changes in the body. It becomes an integral part of a general reaction affecting the composition of the fluids of the body.

This subject is clearly inexhaustible; there shall merely be indicated the present-day tendency of cancerology, such as is found in the works of Waterman, de Roussy, Maisin, Slosse and Reding, Bayet, Dustin, and many others.

It is not known at the present time whether this conception applies to all cancers, but it is improbable, considering the variety of affections included under this heading. Yet henceforward it is certain that occupational cancers, or at least the most important of them, i.e. those arising from the by-products of coal, belong definitely to a group of neoplasms and definitely to those in which the demonstration of this preliminary change in the body fluids is the easiest and most evident, as will be seen further on. The importance that this conception of the origin of malignant tumours presents for prophylaxis can be grasped; as a matter of fact, if the malignant tumour is only the result of a preliminary irritation, prophylaxis will be concerned with the local irritation; this is what has been done too exclusively up to the present. If, on the contrary, occupational cancer is the final stage of a poisoning which alters the body fluids, then the prophylaxis of these tumours becomes chiefly that of occupational poisoning.

When put in this way, a real dilemma has to be faced and calls for closer examination. It is, however, a mistake to place the two conceptions in radical opposition. The conception of cancer as a disease arising from irritation and the conception of cancer as a general disease. In reality they are combined and complement one another, as will be seen further on, at least in the case of the occupational diseases dealt with in this article.

The biochemical changes in the body fluids which must be present if an irritation is to cause a cancer often occur without any external sign. They usually depend on delicate analyses of biological chemistry, remarkable examples of which will be found in the recent works of Waterman and Slosse and Reding.

It is not always the case, and just in the most important group of occupational tumours — that due to the by-products of coal — they manifest themselves, by distinctly visible signs.

Are these changes of a general kind sufficient to cause cancer? It seems not. As will be seen, it is necessary that upon this prepared ground an irritation of physical or chemical nature must be produced, or of both together. But it must constantly be borne in mind that, in the case of certain cancers at least, this irritation alone is not sufficient to cause the tumour; the ground must be prepared.

Thus is seen once for all that the general prophylaxis of occupational cancer has a double basis: the prevention of poisoning and of irritation.

**General Aetiology**

Their aetiology allows occupational cancers to be divided into two groups.

The first includes occupational cancers the cause of which is evident, such as those caused by the by-products of coal, e.g. soot, tar and anthracene oils, and those resulting from radiations from X-rays or radium.

In addition to these are formed those where radiation is only presumed to be the cause: for instance, the action of light in the case of sailors and agricultural workers, and again, the influences not clearly defined which determine an excessive cancer mortality in certain occupations, such as among brewers and furriers, without it being possible to determine exactly by what mechanism the tumours are produced. As a matter of fact, it is possible that
factors essentially outside the occupation come in, such as those resulting from the habits of alcoholism and smoking, which cannot be directly attributed to any occupation.

**STATISTICS**

General statistics of occupational cancer are extremely difficult to establish. The difficulties encountered are those common to all cancer statistics, viz., insufficiency of the information received; absence of uniformity of conditions in the same industrial group, and, to a much greater extent, in different groups; interplay of activating influences; the action of influences outside the occupation itself and resulting from habits, i.e. tobacco, alcohol and general hygiene; and the effect of hereditary receptivity.

In Great Britain the number of cases of epitheliomatous ulceration due to pitch, tar, paraffin and mineral oils, was: in 1926, 187 cases, with 49 deaths; 1927, 174 with 49 deaths; 1928, 175 with 59 deaths; 1929, 365, with 56 deaths; 1930, 194, with 36 deaths.

A study on the mortality from cancer, made by Young and Russell with the collaboration of Brownlee and Collis (1926), confirmed the close relation between certain kinds of cancer and certain occupational risks (chimneysweeps' cancer, cotton spinners' cancer). Such a causality relationship was not, however, proved to exist between certain kinds of internal cancer and certain industrial operations. It was observed in certain occupations that habits of excessive smoking and drinking — acquired, it was pointed out, as a result of the exercise of these occupations were important factors in creating a predisposition to disease. It was also noted that the incidence of syphilis in certain occupational groups appeared to have some connection with cancer of the tongue. The study also emphasised the difficulties of interpreting statistical records.

The British statistics for 1921-1923 are occupationally even more reliable; they give the following comparative figures:

<table>

*Standardised Mortality of Males Aged 20-65 Years from Cancer*

All occupied and retired males taken as: 1,000

All males: 985

Coal miners making and repairing roads: 1,072

Smelters, rollers, converters of iron and steel: 1,156

Glass-makers, brewers, tin and copper miners: 1,300 to 1,400

Brass finishers, cotton card tenders, slaters, drivers of horses, stevedores: 1,400 to 1,500

Pottery dippers and glazers, and kilnmen, glassblowers, puddlers, metal-grinders, bookbinders, gas-stokers, porters, musicians, chimneysweeps: 1,500 to 1,600

Cotton-spinners, hat-formers: 1,600 to 1,700

Tin and copper miners: 1,885

Barmen: 2,100

Cellarmen: 2,801

Cutlery grinders: 2,938

Waiters: 2,953

When cancer of the skin only is considered, the following list contains occupations with highest ratios of "actual" to "expected" deaths.

It is a somewhat curious fact that nearly all the occupations noted as of excessive skin cancer mortality record a cancer mortality for sites other than the skin also in excess of the average.

Behla and Kolbe have also studied occupations in which cancer occurs, and their figures may be summarised as follows:
According to British statistics for 1910-1912, cancer of the skin is located as follows in the occupations most affected.

**Face:** fishermen, bargemen, hosiery makers, gardeners, cotton-spinners.

**Ears:** fishermen, agriculturists.

**Lips:** agriculturists, plateayers, sailors, stablemen, engineering labourers, navigating seamen.

**Hands:** sailors, gardeners, agriculturists, blacksmiths.

**Nose:** workers at gasworks, bakers, coal-heavers, plasterers, potters, leather and brick makers.

**Tongue:** dressers, brushmakers, wire-drawers, cutlers, tobacconists, hairdressers, brewers, messengers, ironfounders.

**Oesophagus:** furriers, photographers, brewers, electric apparatus makers, scientific instrument makers.

**Stomach:** miners (iron, lead), slate quarriers, wool-sorters, cotton-weavers, electricity supply, and makers of cycles.

**Scrotum:** chimney sweeps, cotton-spinners, workers in the chemical industry, and costermongers.

As regards the situation on the scrotum, which is one of the most frequent for occupational cancers, it is interesting to give the result of a British enquiry, published in 1926, which analyses 539 cases of cancer among cotton-spinners; 75 per cent. were located on the scrotum. Systematic periodical examinations of pitch workers enabled Dr. Body the certifying factory surgeon at Middlesbrough, to report 11 cases of epitheliomatous ulceration localised on the scrotum among 220 workmen examined in 1926. The incidence of cancer of the scrotum among workmen in various occupations, expressed as an average annual death rate per million, England and Wales, 1911-1920, was as follows:

**GENERAL SYMPTOMATOLOGY**

If the general characteristics of occupational cancer are reviewed, it is found that:

1. These tumours all belong to the group of malignant tumours of the cancer type. In the large majority of cases they are epitheliomatous; it is only exceptionally that endotheliomata and sarcoma are found.

2. These tumours should not be considered as isolated lesions, as is generally done in the case of other cancers. They are part of a general reaction developing by successive stages, of which the malignant tumour is only the final stage. This is a point of fundamental importance in the study of these tumours, and herein lies an explanation of the importance attached to symptoms in the precancerous period.

In the different groups of tumours about to be dealt with there is always found this preparatory general reaction. It differs, however, according to the kind of cancer considered: in the case of cancer from arsenic or the by-products of coal, it appears in the form of a general poisoning of the body; in the case of cancer from radiations, it retains as a characteristic local preparation which is detected by changes in the skin at the site which has been subjected to the direct action of the radiations. But one thing is certain — a tumour is never seen to appear isolated without preparatory signs.

It is essential to understand thoroughly and define clearly this preliminary stage before the appearance of the neoplasm, for it is impossible without it to have a true conception of the pathogenesis of these tumours, or to suggest logical and efficient measures of protection.

3. These tumours often appear early in life and are found at a period when cancer, especially of the skin, is as a rule seldom seen.

4. They are often multiple, which is rather rare for other cancers, apart from metastases.

5. They only appear after the occupation has been followed for a very long period.

**PATHOLOGY**

There shall first of all be examined occupational tumours in which the appearance of the neoplasm is a direct result of the trade carried on; and, in the second place, occupations with excessive mortality which seems to result from the trade, without, however, it being possible to establish a direct connection between the effect of that trade and the appearance of the tumour.

**Occupational Tumours the Direct Result of Occupation**

This aggregate of occupational tumours is composed of three principal groups, according as they are due to:

(i) *chronic occupational arsenical poisoning*; (ii) *such by-products of coal as*
soot, tar, pitch, aniline or anthracene; (iii) prolonged exposure to X-rays and to radio-active bodies.

First Group. — Chronic arsenical poisoning, whether its origin be medical, alimentary or occupational, gives rise to a general reaction which in a certain number of cases ends in cancer. The quantity of arsenic necessary to provoke this state, preparatory to cancer, and to develop it, is extremely small; and the tumour usually only appears after many years of working with or exposure to arsenic.

These last two facts cannot be too strongly insisted on, for, as will be seen further on, they apply also to cancer caused by the by-products of tar. They can be most easily studied in arsenical cancer.

Investigations made among patients suffering from an arsenical cancer due to the taking of medicine show as a matter of fact that the quantity of arsenic absorbed was extremely small, only amounting to some milligrammes a day.

A more important feature than the weight of the toxic metal is the necessity for a very long period of action; this explains the fact, which surprises some people, that large quantities of arsenical drugs do not cause tumours, even after two or three years' administration; this period is quite insufficient.

The general reaction is very constant: it is that of a very slow poisoning which impregnates and causes changes throughout the entire body before the appearance of the cancer; the different phases of this poisoning always follow one another in the same order.

First, there is hyperchromiasis; then follows hyperkeratosis, upon which the cancer develops.

The pigmentation are of two kinds: general hyperchromiasis, or arsenical melanoderma, and localised hyperchromiasis, exhibiting black spots and freckles.

Hyperkeratosis generally appears in the form of a flat patch, as palmar and plantar hyperkeratosis. This localisation on the palm of the hand and the sole of the foot is almost pathognomonic of chronic arsenical poisoning. Independent of this very characteristic form, hyperkeratosis may also appear in the form of localised warts. Attention has not in general been sufficiently directed to this last variety of hyperkeratosis, which is much less rare than is believed.

Fig. 164. — General arsenical pigmentation. (Note the contrast with the forearm of normal colour.)

FIG. 164. — General arsenical pigmentation.

Arsenical cancer presents a collection of distinct characteristics:

1. Arsenical cancer always develops on a pre-existing hyperkeratosis.

Fig. 165. — Localised arsenical pigmentation in the form of brownish spots (case from the epidemic of arsenical poisoning at Manchester).
2. The positions of the tumours are very characteristic. Just as the palms of the hands and soles of the feet are generally the sites of hyperkeratosis in chronic arsenical poisoning, so it is in these places that arsenical cancer most often develops. But, besides these situations, arsenical cancer develops with a special frequency on the genital organs and quite particularly on the scrotum. In the statistics of Dubreuilh, which include nineteen consecutive cases of cancer from chronic arsenical poisoning out of twenty-four different cancer situations, other than the hand and foot, cancer of the scrotum was found nine times and of the groin twice.

3. Arsenical cancer is multiple in a relatively high number of cases. Out of the nineteen cases of Dubreuilh, there were thirty different situations, with an average of nearly three for each case.

4. Arsenical cancer appears at a comparatively early age. The average age of its appearance is forty-six years. Hutchinson reports a case in a woman of twenty-four years.

5. The period necessary for the action of arsenic to cause cancer is a very long one. In cases where it has been possible to measure it, the exposure to arsenic extended over fourteen, twenty-five, thirty and forty-eight years (Dubreuilh).

As regards the kind of cancer, arsenical cancer is an epithelioma of the basal-cell or perickle-ceil type; and the last appears most commonly. If it is not treated in time, it frequently causes death by spreading to the glands, with metastases and final cachexia, just as with cancer from other causes.

The occupations which expose to the risk of arsenical poisoning are numerous (see article "Arsenic"), but by no means all cause cancer. The symptomatic picture — hyperchromiasis, hyperkeratosis, cancer — is only rarely complete; as a rule only the first stages are seen either because the poisoning by arsenic has not acted sufficiently long, or because it lacks an auxiliary existing cause, which would have given rise to general poisoning and enabled the arsenic to develop its carcinogenic power.

Also, whereas observations on arsenical cancer following the prolonged taking of arsenical medicines are comparatively numerous, observations on malignant tumours of occupational origin are, on the other hand, rare. Three cases of cancer of the skin from "sheep-dip" have been reported (see article "Arsenic") and some cases among workmen employed in the hand-
be found that it stands in the front rank in assisting to elucidate the problem of the origin of other occupational cancers especially those which are connected with the handling of by-products of coal.

Second Group. — As a rule cancers due to the by-products of coal among men working among tar, soot, pitch, paraffin anthracene or aniline, are described separately. This plan disregards the obvious aetiological and symptomatic unity of these cancers, all of which, with the one exception of cancer from aniline, appear with identical symptoms as to behaviour, situation and development. This similarity is striking and would be sufficient by itself to justify grouping all these tumours under one heading. But there is more: all these bodies capable of causing cancer, however different they may be in appearance, structure and chemical composition, are found, on final analysis, to be derived from coke, coal or lignite; this common origin makes it still more legitimate to group together the tumours which they cause under one family name, viz. that of cancers due to by-products from coal.

The credit belongs to Manouvrier, of Valenciennes, doctor to the Anzin collieries, of having in 1877 recognised the common nature of these cancers. This is what he said at that time: “The particular affections of gas-workers, of chimney-sweeps from coal soot, of men who tar iron bolts, of dyers of flannel-ette of poor quality using chlorohydrate of aniline, of glove cleaners who use benzine, and of workmen employed in factories of chemical products derived from coal, present curious analogies with illnesses caused by pitch. In fact, poisoning by pitch, a solid residue from the distillation of tar, is only one of the numerous forms of this poisoning by coal and its derivatives, to which it is proposed to give the name of coal poisoning.”

Some years earlier, Volkmann had recognised the identity of chimney-sweeps’ cancer with that caused by tar; but he did not arrive at such a far-reaching conclusion. His chief error was in not recognising that a general poisoning of the system was involved. Moreover, whatever may be the nature of the causative substance, it is a fact that general poisoning exists, and it was of considerable merit to have discovered and reported it. At the present time the similarity of the clinical picture seen among all workmen who handle by-products of tar, the characteristics of the tumour, similar in every case, whatever may be
the by-product handled, justify the consideration of all the cancers now being studied as the final phase of a general poisoning caused by by-products from coal.

The industries of the by-products of coal in which the occurrence of tumours among the workmen has been observed are numerous. They may be divided into three series.

(a) **Soot series**: chimneysweeps and packers of soot; gardeners who handle soot as a fertiliser;

(b) **Tar series**: tar distillers; bitumen in the tarring paper trade; bitumen workers and asphalters; men who tar iron bolts, railway sleepers and earthenware; workmen employed in the manufacture of anthracene and anthracene oils; and paraffin workers.

(c) **Aniline series**: some workmen in the aniline industry.

The following table shows the industries of coal by-products, in which the occupations where cancer has been noted are in italics:

**SYMPTOMS**

The symptoms shown by workers in these industries affected with cancer are identical in their chief points. They only differ in certain details connected with the nature of the substance treated and with the special irritation which it causes.

After a certain length of time spent in the factory the workman's skin shows a general hyper-pigmentation, which is at first of an amber colour, deepening with the length of the period of work, until, after a few years, it may present the appearance of a true melanosis (fig. 171). Then after a certain time, which varies according to the industry, epithelial proliferations or keratoedema make their appearance, generally in the form of warts. Finally, in some cases cancer develops.

The *pigmentation* is of two kinds: general, in the form of diffuse melanosis (fig. 171), or localised, in the form of small lenticular macules, often having the appearance of pigmented spots (fig. 172).

*Hyperkeratosis* generally occurs in the form of warts (figs. 173 and 174), elongated or flat. They disappear sometimes spontaneously; more often they remain stationary; but sometimes certain of them become changed into epitheliomata.

In some cases, which are rare, but, as will be seen, are significant, hyperkeratosis of the palmar and plantar surfaces is seen (Kleyenberg, Dubreuilh, Bayet). This kind of cancer presents the following characters:

1. It develops on a pre-existing keratosis, i.e. on a wart or on thickened epidermis in a xerodermal area.

2. It is very frequently situated on the scrotum. In the statistics of Bayet, out of 10 cases of cancer from pitch there were 6 situated on the scrotum, or 60 per cent. (figs. 176, 177, 178, 181, 185 and 186). Liebe's figures relating to workmen at tar distilleries give, out of 14 observed cases of cancer, 10 situated on the scrotum; among mule spinners in English cotton mills the percentage is 75. According to a report by Schamberg, 18 out of 24 cases of cancer in chimneysweeps were situated on the scrotum, or 79 per cent.; and out of 22 cases of tar and paraffin cancer, 17 were situated on the scrotum, or 77 per cent.

It is remarkable that the proportion is almost the same for all these industries and trades in which the materials manipulated are so different from the point of view of physical structure and chemical composition.

In some industries where the contact with the irritating substance is chiefly
on the forearms, as in the case of men employed in handling paraffin, the statistics of Schamberg and of Liebe show that the situation of the cancer is frequently the scrotum. The other situations are in order of frequency the face (fig. 182), the forearm (fig. 184), the penis (fig. 170).

3. The cancer is often *multiple*. Out of 14 of Liebe's cases among paraffin workers, 2 had more than one site.

4. Cancer from by-products of coal frequently occurs early in life. Out of 10 pitch workers, 5 cases occurred at forty years and a sixth at forty-one (Bayet). Chimneysweep's cancer is found on an average between the ages of thirty and forty, in some cases between the ages twenty and thirty. Earle (the son) noted one case that appeared at the age of puberty. Earle (the father) saw a case of cancer occurring in an eight-year-old child who had been employed as a chimney-sweep. These extraordinary statements are explained by the fact that children used sometimes to be employed as chimney-sweeps when they were four and a half years old.

5. The date of the appearance of the cancer comes a long time after entering the injurious occupation; among paraffin workers it never appears until quite twenty years after the commencement of the occupation; among pitch workers and mule-spinners, the average period necessary before the appearance of cancer is forty years. So it is a question of very slow poisoning and a precancerous period of very long duration. Here again, as in the case of arsenic, the need is apparent for a very prolonged exposure to the injurious substance. It is, therefore, extremely probable that the quantity of this poisonous agent must be very small, as is the case with arsenic. Here, once more, appears this type of poisoning which is eminently chronic and evolves under the stimulus of extremely minute doses of the poisonous substance.

Such is the general reaction of tumours due to by-products of coal. But in each occupation there are differences which will now be described.

In the case of chimney-sweep's cancer, the scrotal position is by far the most...
In the case of tar-distillers and of those employed with paraffin, the forearm is the usual situation; but the scrotum is also very frequently affected. In the case of workmen who handle pitch, the position most often observed is the scrotum, next the face. These are only slight differences, which do not seriously alter the general symptomatic picture.

The same thing is not found with aniline. Here the symptomatic picture is so different from what results from the other by-products of coal that the tumours observed among aniline workers deserve a special description.

It was in 1895 that Rehn reported three cases of tumour of the bladder among workmen at an aniline factory at Frankfort-on-Main. Since then the cases have increased; the number of tumours from aniline reported up to 1926 was as high as 177. It is true that Curschmann analysing the cases reported since 1913 estimates that the number of authentic cases only reaches 28; but Leuenberger, who has studied the cases at the surgical clinic at Basle, found proof that sickness from cancer among aniline workers was far greater than the figures of Curschmann would lead one to suppose. The Prussian medical inspectors in 1925 reported a case of cancer caused by aniline; and in 1926 the English medical inspectors had heard of 4 cases, of which 2 were fatal.

Workers in aniline factories are not all equally exposed to the risk of tumours of the bladder. The conditions under which they work vary considerably, depending upon the department to which they are attached. As a matter of fact it is only a minority which is exposed to the risk of poisoning, for the manipulations are very often carried out in closed vessels. The figure of 177 cases observed is in reality quite small, if one bears in mind that the German aniline industry employs from 80,000 to 100,000 workmen. Nevertheless, it must not be forgotten that Rehn reported 3 cases of vesical tumours out of 45 workmen employed in a workshop where fuchsine was produced.

The products which according to different observers have been incriminated as being the cause of tumours of the bladder in aniline workers are the following: nitrobenzene, nitrotoluene, aniline, toluidine, fuchsine, benzidine, anthracene, naphthylamine, diphenylamine, xylidine and mixtures of these.

According to some authors, out of all these substances aniline and benzidine are alone responsible for tumours; and, even then, the part played by the latter is doubtful. On final examination aniline alone is responsible. It seems that the injurious products only act when they are in the state of vapour (Nassauer). According to the works of Rehn and Nassauer, the entry into the system takes place by inhalation of very fine aniline dust.
ing results, but at the present time the question still remains unsettled both as regards the aetiology and the pathogenesis (see later).

The type that tumours take in aniline workers is generally that of papilloma and carcinoma of the bladder. Out of 28 cases reported by R. Scheidler in his inaugural thesis he found only two of sarcoma and seven of benign papilloma. Vesical symptoms only appear on an average sixteen years after the commencement of work in the factory (Nassauer). The vesical tumours observed among these men show nothing which can distinguish them from those due to any other cause. (See article "Occupational Diseases: Urogenital System".)

S. Henry, N. M. Kennaway and E. L. Kennaway (1931) investigated the incidence of cancer of the vesicle and of the prostate in certain occupations by examining the death certificates issued in England and Wales from 1921 to 1928. In 8 out of 10 occupations involving exposure to coal, gas, tar, pitch, soot, cancer of the vesicle was found to be more frequent than among the rest of the male population. In 5 out of 10 of these occupations, this difference varied from one-half to four times. The findings on cancer of the prostate were less conclusive.

Quite independent of the vesical tumours, the workmen show premonitory symptoms to which it is important to draw attention. The earliest and most characteristic of these symptoms is profuse sweating on the hands with swelling of the back of the hand; it is a typical occupational condition of aniline workers. Next follows eczema of the hands, with superimposed papillomata, with a sharp outline, of the size of a pea, similar to what occurs on the arms of paraffin workers. Then, in some cases, a more acute cutaneous affection is found, generalised, with oedema, which affects the hands, face, ears and, in a remarkable way, the penis and scrotum. In some workmen handling aniline, hyperkeratosis has been noticed which has the appearance of papilloma.

Thus it is seen that the diseases caused by aniline differ from those of other by-products of coal, in the fact that a different situation is concerned which is closely related to a change in type. Papillomata are to mucous membranes the homologue of cutaneous warts and it is the degeneration of these papillomata which gives rise to cancer, just as that of warts causes cancer of the skin. Thus then, in spite of certain divergences in appearance, easily explained by the difference of the substances handled, aniline cancer, up to a certain point, conforms to the general type of cancer caused by the by-products of coal.
Aetiology

A fact which first strikes the attention, if the lesions caused by the by-products of coal are examined, is that in spite of the physical and chemical differences between the injurious substances handled by the worker from soot to anthracene, including tar, pitch and lamp black, the symptoms remain strictly identical in all.

This observation suggests in an overwhelming way the idea that there should exist, to explain this stereotyped train of symptoms, a single cause to be found in all the by-products of coal.

This is the idea which has naturally presented itself to all writers who have dealt with this question. They have successively blamed: phenic acid, creosote, ammoniacal vapours, naphthaline, coal from points of straw, and radioactivity.

When examining the foundation of these hypotheses, a fundamental observation must be recognised: before an agency can be assigned as causing poisoning by by-products of coal, such as can account completely for what occurs, it is obviously essential that this agency, separately applied to the body, should reproduce the symptoms which are so characteristic of this form of poisoning.

Now of all the causes mentioned above not one so far has fulfilled these conditions. Neither clinical observations, nor experiments have exhibited a disease entity which tallies with that manifested by workers among by-products of coal.

It is under these circumstances that, as the result of long and thorough investigations, A. Bayet, in collaboration with A. Slosse, of Brussels, basing his opinion on clinical observation, on comparison of observations and on biochemical analyses, has come to the conclusion that he has recognised the agency in arsenic, which is found in definite quantities in coal and is found in all the by-products. He feels warranted in developing at some length the arguments which in his opinion support his idea, not with the object of pressing his views, but rather with the intention of furnishing a basis for discussion on this point which is so important for prophylaxis. At the present time this is the only hypothesis supported by a group of arguments, which confers upon it a high degree of probability. The practical importance of this hypothesis, if it is found to be accurate, appears to its author to justify the developments which he has based on it. Arsenic as a matter of fact fills the requirements formulated above; it reproduces feature for feature the symptomatology of the by-products of coal. Not only are the symptoms identical in the two series, but they occur in the same order of succession.

The description of the symptoms just made, and comparison of the accompanying illustrations, are convincing. The following table makes this similarity clear at a glance.

**TUMOURS OF OCCUPATIONAL ORIGIN**

**CHRONIC ARSENICAL POISONING.**

</table>

This comparison shows that chronic arsenical poisoning reproduces exactly the lesions caused by the by-products of coal. Moreover, this finding is of the highest importance for occupational hygiene, for it gives weight to measures of protection which are applicable to the numerous industries in question.

On account of the importance of this conclusion, it is important to strengthen the comparative examination of the clinical symptoms by other considerations which support this view in an extraordinary degree.

First and foremost stands out, on the one side, unusual frequency of the localisation of cancer to the scrotum in chronic arsenical poisoning, and in that from the by-products of coal on the one hand, and, on the other, its great rarity in any other morbid group.

It has been seen how common this typical situation is in these two kinds of poisoning — about 70 per cent. of cases. Accurate statistics, on the contrary, show how exceptional this situation is, apart from this group of cancers; at the General Hospital at Vienna in eleven years, out of 2,400 cases of malignant tumours among men there was only a single case of

1 This idea had already been advanced by Dr. Smith in 1913. See his article "Arsenic Cancer", in the Lancet, July and Aug. 1913.
cancer of the scrotum; and at the General Hospital at Prague in nine years, out of 360 cases of malignant tumours in men again only a single case was found. At the Charity Hospital at Berlin in eight years a single case occurred.

It is then very significant that only two kinds of poisoning, that by arsenic and by the by-products of coal, cause a considerable proportion of scrotal cancers; and this statement demonstrates clearly that the facts are only explicable if for the two morbid groups reaction to the same causative agent be admitted.

Another fact perhaps still more convincing is the following: at the present time on account of hygienic measures adopted by modern methods, poisoning by the by-products of coal is slow, the symptoms are weakened, and the date of their appearance is retarded. But it has not always been so. Forty years ago the conditions under which briquettes were made were extremely defective and it was possible to observe cases of acute poisoning caused by pitch (see that article). Such cases were reported at the briquette factory of the Anzin collieries. The pitch arrived hot and fuming and was collected in pans open to the sky, where it cooled on contact with the air. Some of the workmen were employed to hasten the cooling by stirring the mass. During this manoeuvre acid and irritating vapours were liberated in profusion and were inhaled by the men. Further the dry pitch was crushed in a cellar, through the vent hole of which it was discharged. Hence there resulted a fine and abundant dust which penetrated everywhere, and into the respiratory and digestive passages of the workers.

The consequences of this impregnation of the system by the emanations of pitch were: bronzing of the skin, various eruptions, cancerous growths of the scrotum and face, similar to chimney sweeps' cancer, inflammation of the eye, defective eyesight, coryza, ulcerations of the nasal fossae, suppurations of the ear, bronchitis, digestive troubles with black motions and a particular coloration of the urine 1.

Here then are found, apart from symptoms which are common to chronic arsenical poisoning and to sickness caused by the by-products of coal, such as bronzing of the skin and cancerous growths of the scrotum, other lesions, including inflammation of the eye, defective vision, ulceration of the nasal fossae, suppuration of the ear, bronchitis, digestive troubles with black motions and abnormal coloration of the urine, all of which form part of the symptomatic complexus of subacute poisoning by arsenic.

Some of these illnesses are quite common place and are found in a certain number of workers employed on any kind of irritating substance: inflammation of the eye for example. But there is a sign which, by its rarity and its special situation, is absolutely characteristic of arsenical poisoning, viz, coryza with ulceration of the nasal fossae. It is sufficient when reading observations made on persons employed on Schweinfurt green (copper arsenite) to note the frequency of this sign in arsenical poisoning. Except for arsenic there are really only cobalt and the chromates which cause it, and there is no proof that traces of arsenic which they may contain are not the causative factor 1.

It is seen then that pitch can, under thoroughly defective conditions of occupational hygiene, cause subacute arsenical poisoning.

---

1 Ulceration with perforation of the nasal septum, as caused by copper arsenite, can result from inhaling fine dust of sodium chloride or any other hygroscopic substance (Collis).
lamp black, or aniline, but also, in a comparatively large amount, in bituminous schists.

Further, he was able to point to the presence of arsenic in a strength two hundred times greater than the physiological strength in the hair, blood and urine of men working with pitch, and also to demonstrate that this arsenic is contained in the air of the workshop where it is carried about in the dust.

Two objections have been raised to this suggestion for interpreting the pathogenesis of occupational tumours.

The first objection is the statement of Ross to the effect that, according to analyses made at the Lister Institute, tar does not contain arsenic. This statement, accepted and repeated unchecked by authorities who are working on tar cancer, and particularly by Fibiger, who is an authority on the matter, has seemed sufficient to close the debate and lead to the rejection of the arsenic theory of the cancer. However, according to a statement by Dr. Ross himself, these analyses were not made in view of biological research, but to an end of industrial nature. In consequence they were not able to detect the comparatively small quantities of arsenic which tar contains, and which are only from 10 to 20 microns per kilo. These quantities have been detected by means of special methods never used before the work of Slosse in this kind of investigation 1.

The second objection is that of Fibiger, to the effect that the tar which he used to cause cancer in mice contained quantities of arsenic too small to cause a general poisoning. However, these quantities which Fibiger considers too small (3 mill. per kilo.) are of the same order of magnitude as those contained in tar. Then again there must be taken into account the fact that with man we are dealing with an impregnation lasting not months, but some tens of years.

The denials of those who refuse to accept the resemblance between cancer from by-products of tar and that from chronic arsenical poisoning are not based on sufficiently minute clinical analysis, nor on chemical analysis sufficiently delicate to be taken into consideration.

In endeavouring to make the two hypotheses agree, Gilbert (1919) was prepared to admit that the cancer producing power is not in the arsenic itself, but in a special arsenical compound 2.

As regards the tumours which occur among aniline workers, the proof of an absence of arsenic: (1) isoprene, (3) yeast, (4) human skin, to temperatures ranging from 700° to 928°. Acetylene is the simplest organic compound from which a carcinogenic material has so far been obtained. A petroleum which produced no tumours of any kind in mice in a prolonged experiment showed very active cancer-producing properties after exposure to a temperature of 880°. The cancer-producing substance present in coal tar is formed only in very small amounts below 450°; at 560° it appears in much larger quantity, and this increase continues at a slower rate up to 1,250°.

1 KENNAWAY has studied (1924-1925) experimentally the possibility of obtaining cancers in mice by means of substances obtained by heating: (1) acetylene (the acetylene used con-
arsenical origin for these tumours is, as a matter of fact, less obvious than that of the other tumours caused by by-products of coal. There can here only be indicated the arguments which might support this origin, without disguising the fact that the demonstration is less rigorous than the preceding. They are rather suggestions inspired by certain clinical analogies. Among those there is the general fact — already pointed out — that papilloma and carcinoma observed in the bladder are the homologues of the warts and cutaneous carcinoma arising from the other by-products of tar. Further, the cutaneous symptoms, comparison between which have generally been neglected, are somewhat similar in poisonings by aniline and by arsenic. Particularly is this the case with hyperhydrosis of the hands, so special to these workers. Moreover, this symptom is found to be quite as characteristic in arsenic poisoning. The presence of this symptom in the two diseases must be emphasised. It derives its significance by virtue of its rarity under other circumstances.

Eczema of the hands with deep ulceration, having clearly defined edges, makes one think of the ulcerations among workers on Schweinfurt green and even of those cases where the ingestion of arsenic takes place internally.

Finally, the acute oedemas of anilism closely resemble those of acute poisoning by arsenic, and, curiously enough, occur with quite a particular predilection on the scrotum. The bullous dermatitis of anilism is found in exactly the same form in arsenical poisoning; and anilism can cause hyperkeratosis, through this is rare. Here is found a collection of clinical facts which should attract attention. Let it be added that anilines always contain arsenic, that Wignale (of Manchester) found in the urine of aniline and benzi-
dine dye-workers traces of arsenic (0.03-0.2 mill. per 100 c.c.), and that in the opinion of A. Hamilton the vesical tumours of aniline workers can be attributed to arsenic, and, more particularly, to arsenic-hydrogen gas present during the reducing process. Thus there is a group of arguments worthy to be taken into consideration in judging of the final origin of tumours among aniline workers.

It is certainly difficult in a given case to separate what arises from internal action and what from external irritation. But a simplification of the solution of this problem must not be sought by attributing all the illnesses observed to the external action of the substances used, without taking into account the complete clinical picture presented by the workers. It would be too summary and simple to do so. As a matter of fact if the lesions which are produced under the influence of the internal administration of an arsenical product be examined, without the intervention of any external irritating action, such as chronic poisoning of medicinal origin, it is found that they appear in the following order: (1) general and localised pigmentations; (2) cutaneous eruptions; (3) hyperkeratosis in plaques or warts.

It is on these hyperkeratoses that cancer develops as we have seen. There is every reason to admit that it is the same with the absorption of arsenic from carrying on an occupation.

In the case of poisoning by the by-products of coal, this test is not possible; but there are means for separating the phenomena of general pigmentation which arise at the beginning of the period of work at the factory — generalised pigmentation — from those which only arise later, after a stay of two years — hyperkeratosis in the form of warts.

The pigmentations are a clear sign of poisoning of the body and have nothing to do with external irritation.
On the subject of warts, the argument might, if necessary, be advanced that they can be caused by external irritation; nothing is more plausible; but careful observation of facts shows that in the case of many of the sites it is impossible to attribute the condition to irritation, for the warts frequently occur on sites little exposed, such as the eyelids and the groin. It is possible that without preparatory poisoning the irritations would never cause warts.

The essential part of the symptoms which precede and prepare the way for the appearance of cancer depends on internal poisoning, that is to say, on that produced by the inhalation and swallowing of harmful dust. This is a statement to be utilised in the prophylaxis of cancer.

The slight comparative importance of external irritation is shown by the fact that the physical nature of the substance handled does not appear to have a pronounced influence on the appearance of cancer. The illnesses have no relation to the physical structure of the products handled. It is thus with soot, the consistency of which is very soft and almost impalpable; it cannot mechanically cause any irritation. Yet it is soot that causes the most definite sicknesses, while pitch from blast furnaces — the dust of which is angular, cutting and irritating — never causes cancer.

The following table drawn up by Ross furnishes the proof of this:

<table>
<thead>
<tr>
<th>Substance handled</th>
<th>Mechanical action</th>
<th>Incidence of cancer</th>
</tr>
</thead>
<tbody>
<tr>
<td>Gas works pitch</td>
<td>Slight when it is soft. Liquid substance.</td>
<td>Considerable.</td>
</tr>
<tr>
<td>Tar.</td>
<td>None.</td>
<td>Several cases</td>
</tr>
<tr>
<td>Soot.</td>
<td></td>
<td>The most frequent of all</td>
</tr>
</tbody>
</table>

And again it might well be asked, if the causative agent was the physical
As regards external chemical irritation, it may be said that for many of the by-products of coal this irritation is very slight. If one excludes burning splashes it is not possible to prove it. If they really come into the case as the one and only cause of cancer, one may well wonder how it is possible to explain the similarity of action between substances so dissimilar chemically as soot, tar, and the mineral oils. The accumulation of soot in the folds of the scrotum has been blamed. Nothing is less proved than this assertion. In one briquette works, where 37 per cent. of the workmen were affected with cancer (Bayet), the workers take a soap bath each day and the dust is removed daily from their working clothes, and the medical examinations made during working hours have never revealed the existence of this accumulation in the folds of the scrotum.

But, if the external irritation has only a secondary part, its action must be taken into account all the same. However it is powerless by itself to cause lesions on a normal individual. Objections are raised to this statement in view of what happens in the case of mice which have been painted with tar: the cancer appears at the irritated place and this fact is quoted in favour of the possibility of the production of cancer from external irritation. But a careful study of the facts shows that the appearance of cancer is preceded in mice by a change in the general condition which leads to the production of neoplasms (Maison, Mertens, Roussy).

The usual course of what occurs in man can be thus formulated: general poisoning, which is necessary and precedes the appearance of the cancer; that is followed by degeneration of a hyperkeratosis which may be irritated or not, but it requires the preliminary existence of this general poisoning.

This course can be best seen in its development, freed from all accessory external action, in cases where warts and cancer develop in individuals who have left the factory a long time, sometimes for ten years, and have carried on occupations which do not give rise to any special irritation. In these cases the development of the disease has the value of an experiment.

OTHER CAUSES OF OCCUPATIONAL TUMOURS

1. Tumours have also been observed among workers who handle by-products in the distillation of bituminous schists. (See article "Shale Oil Industry").

Cancers found among mule-spinners are connected with cancers due to schists. (See article "Cotton Industry"). The Cancer Committee, set up at Manchester to study this question, has for several years been investigating the carcinogenic properties of mineral oils. According to its 1929 report, it has been found that, in the distillation of tars, the carcinogenic products begin to form at a temperature ranging from 500° to 600° C. and reach a maximum at between 800° and 900° C. The addition of sulphuric acid at the time of use suffices to make the oils harmless without injuring or modifying their lubricating power.

2. Some cases of cancer have been reported among petroleum workers. About thirty-three have been recorded in literature, most of them observed in Galicia. (See articles "Lignites", "Paraffin", "Petroleum").

Tumours are seen only as the result of prolonged exposure to X-rays or to radium. (See articles "Radium" and "Röntgen Ray Operators").

The cancer which occurs shows the characters which have been noted for industrial tumours in general; it develops on a hyperkeratosis; it is the end result of a precancerous local change; it is often multiple; it occurs early; it only appears after a prolonged period in the occupation. The persons exposed to risk are radiologists and those who handle radium, whether workmen, doctors applying radium for treatment, or hospital nurses (for luminous rays see later).

There should be noted here cancer among the miners of Schneeberg (Saxony), among whom the appearance of cancer is decidedly the direct and obvious result of the occupation.
The disease consists essentially of cancer of the lung with metastases (see articles "Cobalt" and "Uranium").

There have been reviewed the cancers which can, without any possible dispute, be connected with the exercise of an occupation. There are others where this connection is not so evident, but where the unusual frequency of cancer is bound to draw attention to a possible connection between the occupation and the existence of cancer.

In certain occupations the malignant tumours seem to be the result of handling a chemical substance (to be defined by further research); in others the cancer seems to be dependent on the action of physical agents.

In the first group are found:

1. Maltsters, Brewers, Publicans

It has been noticed that the mortality from cancer among brewers and maltsters (see article "Indiarubber and Chemical Industries") is much above the average. The proportion of deaths from cancer among them is 70 per 100,000 compared with 48 per 100,000 for the population in industrial districts and 47 per 100,000 of the general population.

In order to explain this high mortality, the variations of temperature to which these workers are subjected has been blamed, but without succeeding in justifying this effort at explaining the aetiology of these cancers.

Alcoholism has also been blamed. It is indisputable that alcoholism plays a certain part in the production of cancer in the upper part of the alimentary canal, as can be established by noting the frequency of cancer in the occupations where intemperance is common, for example among commercial travellers, tavern keepers, butchers and coachmen.

It may be noted, without dwelling further on the fact, that beer at times contains arsenic, glucose up to 0.08 per cent. and the sulphuric acid contained up to 1.4 per cent. of arsenic was found in arsenic contained in sulphuric acid used for the treatment of cancer. There is here a theory worthy of investigation.

The appearance of cancer is preceded by changes in the skin which resemble rodent ulcers and epithelioma of the skin, especially of the face, among these carriers of light, as confirmed by other authorities, atmospheric humidity is a powerful absorbing medium of X-rays, while light only plays a secondary part. The evolution of cancer from light certainly is relatively long.

Light appears to be the cause of tumours of the skin, especially of the face, among agricultural labourers, sailors and fishermen. In 1865 Thiersch put forward this theory, confirmed later by other authorities. Thus, for example, carcinoma of the lips and face have been found among agricultural labourers to account for 27 per cent., as compared with only 10 per cent. of all cases of cancer in the Vienna clinic. We know that the skin protects itself against the injurious action of light rays by pigmentation. But the direct action of ultra-violet rays on the cellular protoplasm leads to atrophy of the skin among even comparatively young persons, and the lesion (xeroderma pigmentosa) easily becomes carcinomatous. Through the recognised stages — hyperaemia, pigmentation, hyperkeratosis with atrophy — cancer is reached.

Lawrence (Australia) has recorded a relatively high number of cases of keratosis, rodent ulcers and epithelioma of the skin, which he attributes to the action of light aided by the slight humidity of the atmosphere. According to this authority, atmospheric humidity is a powerful absorbing medium of ultra-violet rays (1929).

Other experts, on the contrary, hold that some other cause plays a more important part in the aetiology of cancer, while light only plays a secondary part. The evolution of cancer from light certainly is relatively long.
PROPHYLAXIS

1. The prophylaxis of cancerous growths caused by by-products of tar is mixed up to a certain extent with prophylaxis of chronic arsenical poisoning and prophylaxis of the by-products of tar (see the articles concerning the different by-products of coal).

What has been said above emphasises the decisive part which general poisoning plays in the production of these tumours, dominating all prophylaxis. In drawing up prophylactic measures, especially in assigning to external action the exact place which belongs to it, account must above all be taken of the danger of general poisoning — the necessary and sufficient cause for the appearance of cancer. It is that which must be dealt with.

The ideal prophylactic of course lies in the abolition of dust. But it is difficult to realise this desideratum in practice, and, if attention be confined to considering the tumour, it may be claimed that it is not even necessary to go as far as total suppression; the same result may be obtained by reducing the amount of injurious dust present as near as possible to a definite limit.

Clinical observation has shown that there must be a certain quantity of injurious dust in the atmosphere of a factory to determine the formation of cancer. As a matter of fact, among pitch workers cancer was most common among those working in places where dust was most abundant (Bayet and Slosse).

When the quantities absorbed are small the course of the illness does not develop as far as cancer; this is the case for example with the men employed at gas-works, with those who work on lamp black, and those who work in the open air. With these the first symptom of a general poisoning, viz. hyperpigmentation, is found but not cancer. There is then some chance in this direction of avoiding cancer by reducing the quantity of arsenical dust inhaled.

Cessation of work, as has been seen, does not save the man from cancer. From the time a hyperkeratosis comes into being the workman is exposed to the eventuality of cancer, even if it is slow in developing. A well-arranged prophylaxis must therefore consist in making the workman cease his work and in giving him a post where the dust is less abundant.

As regards the tumour itself, the prophylaxis is of the simplest. It consists in excising the warts before they undergo cancerous changes, or of removing the cancer as soon as it appears.

Regular medical supervision should be sufficient to prevent any appearance of cancer, and all the more easily as cancer from the by-products of coal progresses slowly and it is possible completely and definitely to extirpate it before the neighbouring neighbouring lymphatic glands are involved (see also article "Occupational Diseases: Urinary and Genital Tracts").

When the cancer has reached this first stage, it must be treated as any other cancer by free surgical removal, by penetrating X-rays or radium, and sometimes by the two methods combined.

2. Prophylaxis of cancer caused by radiations lies entirely in treatment of the pre-cancerous state: removal of the tumours; application of infra-red rays which have a special action on radic and radium dermatitis; and, if the disease is advanced, by necessary amputations. There should be noted particularly the remarkable effect of applications of radium on those warts which are of recent appearance due to X-rays and to radium, as well as on those in process of cancerous degeneration, and the excellent results obtained by Brodier by electro-coagulation.

As Teutschlaender points out (1930), the struggle against both external causes (carcinogenic substances) and internal causes (constitution) is extremely arduous and preventive measures should aim at diminishing contact with carcinogenic substances.

LEGISLATION

Epitheliomatous ulcerations and cancer of the skin are compulsorily notifiable in Germany, Great Britain, and Holland, in the industries of asphalt, briquettes, cyanisation, petroleum, textiles, chimney-sweeping, dyeing and X-ray work, and in France any sickness due to X-rays. In Russia, diseases of the bladder from analine are compulsorily notifiable. Compensation is granted in Germany for ulceration from soot, tar, pitch, paraffin and anthracene; in Western Australia for tar, pitch and mineral oils; in the United States (in Minnesota, Ohio and New York) from tar and pitch; in France, radiologists' cancer; in Great Britain (from tar, pitch, mineral oils); in Mexico (from paraffin, tar and similar substances); in Queensland (from tar and pitch); in the U.S.S.R. (from resin, soot, tar, paraffin, anthracene, radium and X-rays); in Venezuela (from tar, pitch, asphalt, mineral oils, petroleum, paraffin and all other derivatives of tar). Epitheliomatous ulcerations of chimneysweeps are also compensated in Great Britain, Western Australia and the U.S.S.R.; in Great Britain those occurr-
ring in cotton spinners. (See articles "Radium", and "Ronigen Ray Operators (Occupational Pathology of").

BIBLIOGRAPHY

Bibliography is very important. See the following in particular:

Reports presented to the Intern. Congresses on Cancer held in London (1928) and Madrid (1933).

Tungsten

Tungsten or wolfram (symbol Tu or W) is a grey metal in a powdered state, which becomes brilliant white when molten. It melts at 3,000° C., and may be drawn out in a fine wire up to a diameter of 0.005 mm. The breaking load for traction is very high — up to 460 kg. per sq. mm.

So far tungsten has not been discovered in a free state. On the other hand, it is almost all parts of the world it exists in large quantities in combination with other ores, the most important of which are: wolframite (FeO[MnO] WO₃), a tungstate of iron and of manganese; scheelite (CaWO₄), a tungstate of calcium; hubnerite (Ca₂WO₄), a tungstate of manganese, with 72 to 77 per cent. of WO₄, which is; however, the least abundant mineral, etc. Tungsten is usually met with in tin, lead, molybdenum and copper ore, etc.

Of the various ores, wolframite is particularly abundant. The commercial product, after being subjected to bolting in the mine, is placed on the market in the form of concentrated ore.

After bolting and separation by magnet, the ores are enriched by mechanical and also frequently by electromagnetic treatment, and quartz is thereafter removed by means of levigating with water. The tungsten ore is obtained in a pure state if lime water is added during the above operations. Usually the ore is combined with soda to facilitate extraction of the tungstate acid (WO₄). The latter serves as the starting point for the preparation of the free metal by reducing the tungstate acid with powdered aluminium, in the presence of a flux, in the electric furnace.

It is not necessary here to enter into detail in regard to the other processes adopted for the preparation of tungsten. It suffices to recall that it is used in metallurgical work for the manufacture of tungsten steels, which are known for their resistance; their high breaking load for traction, their hardness and their elasticity, and it is further used in the metallic form in the incandescent lamp industry, tungsten filaments possessing a high ignition point and a low heating capacity. By reason of these qualities they have now supplanted almost all other metallic filaments.

The numerous compounds of tungsten are also of great importance in the colour industry, in pottery, in the manufacture of phosphotungstic acid, and as reagents in laboratory analyses, etc.

Starting with tungsten chloride, on which carbon monoxide and phenylmagnesium bromide has been made to act, it is possible to obtain, by means of a special method, tungsten-carbonyl in the form of colourless crystals. The nitric acid becomes immediately decomposed, setting free carbon monoxide (Mond).

The use of tungsten oxide in the manufacture of filaments for incandescent lamps is not without interest from the health aspect. In 1924, Karantasis studied experimentally the toxi-
city of tungsten and of sodium tungstate, both by way of the gastric system and by hypodermic administration. The guinea pigs used for the experiment suffered from anorexia, colic, lack of co-ordination in movement, trembling and dyspnoea. Tungsten was found in the stomach and intestines, the liver, the kidneys, the lungs, the blood and the urine. When administered hypodermically the guinea pigs also suffered from loss of weight. Tungsten was detected in the urine and faecal matter throughout the duration of the experiments on the animals which died after sixteen or seventeen days. It was likewise found in the lungs, blood, liver and kidneys, etc.

Tungsten salts act as slow poisons, and cause death by asphyxiation. Their toxicity is not high, but they may produce chronic intoxication by accumulation. (See also article "Molybdenum").

Though tungsten and its compounds are employed on a large scale both in laboratories and in industry, so far no case of occupational poisoning has been brought to notice, with the result that this product is not so far of great importance from the point of view of industrial hygiene. The estimation of quantities of tungsten below 0.1 grm. is a very delicate matter. The colorimetric determination is based on the colour assumed by tungsten dissolved in concentrated sulphuric acid in presence of phenols, hydroquinon and rhodamine.

**Turpentine**

Turpentine is a resinous oil, that is to say, a product of exudation from coniferous trees, and particularly from the pine. It is also obtained from the turpentine tree (*Pistacia terebinthus* Linn.), which abounds in the isle of Chios (Chian turpentine).

All turpentines are of unnatural origin in the sense that they are extracted from trees by means of incisions, more or less deep, made into their trunks. The only natural turpentine — that which flows or transudes spontaneously from the tree — is the so-called Strasbourg turpentine, which is obtained from the *Abies pectinata* D.C. (*Pinus picea* L.).

Several varieties of turpentine are found in commerce, which are named according to their place of origin: Venetian turpentine, extracted from *Pinus larix* L.; French turpentine, also called Bordeaux or Landes turpentine, extracted from *Pinus pinaster* Solander or *Pinus thunbergiana* Poiret; American turpentine, from Canada or Boston, obtained from *Abies balsamea* Miller and from *Abies Fraseri* Lindl.; from Virginia, obtained from *Pinus taeda* Linn.; and Austrian or German turpentine from *Pinus larix* Poiret and from *Pinus Sylvestris* Linn.

Other varieties of turpentine are: Hungarian, Russian, Grecian, Finnish and Portuguese.

In commerce there are also a large number of synthetic turpentines or substitutes for turpentine, composed in large part of colophane, oil of resin and turpentine oil; the oil extracted from pine wood is added.

Turpentine is composed of a liquid part, called gemme, and a sticky part, called galipot or barras, which hardens rapidly and remains stuck to the edges of the incisions. The gemme, which is at first liquid and transparent, soon becomes thick and viscous on contact with air. During the process of collection, the galipot is almost always mixed with the gemme; the impurities are separated by melting in boilers and by clarification, decantation and filtration.

Fine turpentines — Venetian and those from Alsace and the Carpathians — are semi-fluid or viscous like honey, and slightly fluorescent; they have a yellowish or yellowish-green colour, a labilical aromatic agreeable odour, and a bitter, somewhat acrid, taste.

Ordinary French and American turpentines are, on the other hand, somewhat thick and granular; in time they form a micro-crystalline resinous deposit, and dry quite readily in the air.

Chemically, turpentines are made up of various resinous or resinic acids, among which pimaric acid (*C₃₆H₅₄O₃*) predominates, neutral resins, a volatile oil, small quantities of bitter principles, succinic acid, colouring matter, water and various impurities.

Turpentines are soluble wholly or partially, according to the quality, in ethylic alcohol, ether, amyl alcohol, chloroform, acetone, sulphide and tetrachloride of carbon and benzoil, and in turpentine oil in the proportion of 1 : 3.

Their direct use is limited. They are used generally in pharmacy for preparing plasters or ointments, either soothing or vesicatory, and in industries for preparing colours or sealing wax, and sometimes varnishes.

**Turpentine**

For the most part turpentines are, on the other hand, subjected to distillation to obtain a volatile or essential oil, *spirit of turpentine* and *colophane* or Grecian pitch, which remains as residue and becomes solid at the ordinary temperature. After standing a few days for the water to separate, the spirit of turpentine is rectified by a fresh distillation, in the presence of lime, with the object of refining the odour and getting rid of the fatty and resinous substances which it contains in solution.

**SPIRIT OF TURPENTINE**

Spirit of turpentine, which is also known in commerce under the name of Venetian, French or German turpentine, according to the source and quality of turpentine from which it comes, is a colourless, limpid liquid, sometimes yellowish or greenish, with a characteristic penetrating odour, and a burning, bitter taste. When exposed to air and light, spirits of turpentine absorbs oxygen, and so becomes oxonised or resinified; at the same time it condenses and turns yellow. With a density between 0.863 and 0.875, it boils between 155° and 180° C., but the largest part, 80 per cent., distils below 160° C. It ignites at 33-36° C. and burns with a yellow flame. For the most part turpentines are on the market in the form of spirits of turpentine, especially decaline, and are found in commerce as solutions.

Commercial spirit of turpentine is often adulterated by the addition of naphtha, oil of pine wood, light tar oils composed of benzene and its homologues, and of spirit or oil of resin.

The numerous substitutes which constitute industrial or synthetic spirit of turpentine are found in commerce (see article "Solvents") under fancy names have, for the most part, a basis of naphtha, light oils of tar, terpenes, oil of pine wood, oils of resin, and, particularly, a basis of decaline and tetraline.

In industry, spirit of turpentine is used to prepare terpine and terpinol, substitutes for camphor, and for adulterating numerous essential oils, particularly the essences of such acid fruits as oranges and lemons. But its chief use is based on its solvent and actively oxidising powers and on its volatility.

As spirit of turpentine is a good solvent for fats, resins, rubber, asphalt, bitumen, phenol and sulphur, it is used for cleaning textile fabrics, type and the rollers of printing machines, for decolorising ivory and dissolving rubber; but, chiefly, for preparing resin-varnish and as a drying oil for paints, for which it is practically indispensable, for it encourages the oxidation and drying of both. However, the solubility of resins in spirit of turpentine and of other substances used for the preparation of varnishes is not always the same. Spirit of turpentine reacts strongly, with great evolution of heat, with nitric acid, sulphuric acid and with iodine. In the first case there is a copious production of red nitrous fumes, in the second of sulphurous anhydride, and in the third of carbon, with a tendency to spontaneous combustion.

**STATISTICS**

Only one or two fatal cases from the inhalation of turpentine fumes are known. On the other hand, cases of dermatitis caused by this substance or its substitutes are very numerous.

E. Glaser mentions forty-six monographs, almost all by German authors, and A. Perutz in 1927 made a fresh contribution to the question. In Italy, Preti in 1911 described 4 cases of dermatitis in painters; Aiello in 1926 observed 15 cases in a metal factory; Filippini found 51 cases among 450 painters, 11.3 per cent., in the employment of the State Railways from July 1926 to March 1927.

In Switzerland, the National Accident Insurance Office has compensated 8 cases of dermatitis due to turpentine. Factory inspectors in Austria and Germany have reported several cases caused either by spirit of turpentine or by its substitutes in laboratories during galvanising; and by pine oil in laboratories during lacquering.

In Great Britain, turpentine and its substitutes caused 66 cases of dermatitis in 1928, 67 in 1929 and 49 in 1930.

**PATHOLOGY**

The cutaneous lesions caused by spirit of turpentine are polymorphous. They may be grouped as follows: an erythematous form, accompanied by a sensation of heat and itching, which resembles the erythema of scarlatina; a papulous form with itching; an urticarial form, which is not uncommon; a vesicular form, which is the commonest form of occupational dermatitis due to turpentine; and a vesicular form.

Local action of long duration, or often repeated, exerts an irritant and vesicatory effect which is well known, and leaves somewhat deep wounds which heal slowly. Generally speaking, substances used as substitutes for spirit of turpentine, especially decaline, tetraline and wood oil, cause a der-
matitis similar to that of spirit of turpentine, but more severe. On the other hand, mineral oils are quite well tolerated; but they have rather a tendency to cause acneiform dermatitis, which is clinically different from that caused by turpentine or by wood oil, or by the derivatives of naphthaline, decalone and tetraline (Filippini).

McCord in 1924 investigated 10 cases of dermatitis due to wood turpentine, and formed the opinion that these cases of dermatitis have no specific characteristics, the affections produced resembling those reported in dermatitis due to various chemical agents, such as naphtha and benzene.

Perutz in 1928 also described 15 cases of dermatitis, and concluded that the acute form presented an allergic character, a hereditary tendency to sensitisation encouraging the action of the irritant agent. The sub-acute form is a combination of specific cutaneous changes which result from the effect of the irritant; the chronic form appears as a chronic eczematous condition, independent of any allergic reaction. The disappearance of this last condition would appear to be due to the skin becoming accustomed to the injurious substance.

Gebert in 1913 attributed to impure turpentine a papulous and vesiculo-papulous eruption of the hands and forearms found among printers. Knowles in 1913 also observed 8 cases of this condition. Coleophane or "rosin" used alone or mixed with such other substances as mica, shellac or fat, or even glass-makers' grease, which is applied to the hands and the mould while melting glass, has also a very irritating action on the skin.

Stein in 1904 attributed to colophane dermatitis of the hands found among glass-blowers. Beinhauer found in a violinist a relapsing dermatitis of the second and third fingers of the left hand due to the use of colophane.

Casazza (1928), on the other hand, proved that cases of eczema among painters were due to turpentine rather than to substances used in the varnish (coleophane).

Concentrated spirit of turpentine causes an intense irritation on the mucous membranes; on the other hand, if it is diluted or in the form of vapours mixed with steam, it is tolerated quite well. Absorption takes place by the skin and the digestive and respiratory organs. But the effects vary considerably, according to the sensitiveness of the individual.

As regards toxicity, Lehmann found that spirit of turpentine in the strength of 3 to 4 mg. per litre of air caused in a cat sudden signs of strong irritation of the mucous membranes, especially of the eyes, and, after a few hours, slight convulsions. With 8 mg. per litre of air, after thirty to sixty minutes, it caused serious disorders of the sense of equilibrium and tetanic convulsions; and, after two and a half to three hours, paralysis. With 16 mg. per litre the animal died in from three-quarters of an hour to one hour. A strength of 4 to 6 mg. caused in a man after one hour a pricking sensation in the eyes, cephalalgia, vertigo, nausea and an acceleration of the pulse.

Daily paintings with spirit of turpentine caused serious dermatitis in a dog (Lehmann).

Some animals exposed to the inhalation of turpentine vapours exhibited such signs of malaise as salivation, a tendency to diarrhoea, and strabismus, in less than two hours after, when the strength of the spirit of turpentine did not exceed 10 mg. per litre of air (Goadby). At the autopsy, inflammatory lesions of the kidneys were found, which were more marked in the tubular elements than in the interstitial. The tubes, blocked by detritus, showed an irregular and eroded contour, and a pale and almost hyalin appearance; there were, in places, zones of swelling, thick with small haemorrhages. Cardiac muscle was flaccid, and the cavities were dilated; capillary haemorrhages were seen with the microscope.

The acute form of poisoning by the digestive organs has no interest from the point of view of industrial medicine. On the other hand, that caused by the inhalation of fumes of spirit of turpentine must be taken into consideration.

Painters, as well as persons who have slept in places freshly painted, are particularly exposed to this kind of poisoning, which has been described by Bouchardat. But these cases are slight and of short duration. G. Porrini in 1908 observed symptoms of somewhat serious poisoning due to spirit of turpentine in 27 out of 89 ship-painters he examined who worked ashore, and in 106 out of 145 who worked on board ship. These 145 painters comprised 91.17 per cent. of those who worked in closed places (cabins and corridors of ships), 69.56 of those who were employed on board and 57.89 of all the painters in the shipyards.

Alcoholics and neurpaths are unusually sensitive to spirit of turpentine.
After working for half an hour to an hour workers suffer from irritation of the oculcar and nasal mucous membranes and of the throat; headaches, mental confusion, and a state of excitement, resembling drunkenness. If the inhalation of the fumes does not cease, there may follow a state of anxiety, accompanied by buzzing in the head, visual disturbances and vertigo, which end in the sufferer falling to the ground.

In a polish-making factory four women workers complained of pains in the stomach, nausea and a feeling of constriction in the throat. One of them fainted and developed oedema of the glottis which required tracheotomy (Adler Herzmark). A fatal case has been reported in a worker who applied varnish (A. Drescher); but it seems that this is the only fatal case recorded.

Working painters have also reported a hot bitter sensation in the pharynx, lack of appetite, weakness or fatigue, a general feeling of heat and sometimes profuse sweats, with the breath smelling of the spirit, and a burning thirst. The pulse is hard and frequent; there is slight strangury; the urine is red and has an odour of violets.

In two cases described by McCorkle in 1930 there was nephritis characterised by a diminution in the quantity of urine and by albuminuria.

Goaebby, after investigation of the renal lesions, has deduced that the pathogenic action of spirit of turpentine, as inhaled by painters, is to increase that of lead. Lehmann has also expressed the opinion that turpentine has a definite influence on the diseases of the kidneys.

From the clinical and anatomo-pathological point of view, the two most important and durable manifestations caused by turpentine on the body seem to be hypertension and tubular nephritis, which after a time succeed vasomotor disturbances. It is a matter for discussion as to whether the first can be regarded as the cause of the second, or whether the two conditions occur independently. But the discussion is only of theoretical value. On the other hand, it is of great practical importance to fix what part lead plays in the origin of the condition or in the diseases of painters, and what is the part played by spirit of turpentine.

An opinion in favour of the pathological influence of the latter predominating over the former was put forward by Leclaire as long ago as 1861, in a communication presented to the Paris Academy of Science, but was forgotten; but the opinion was taken up again and maintained by Goaebby and others during the discussion on the prohibition of the use of white lead in painting at the Third International Labour Conference, Geneva, 1921. If the matter is considered from the point of view of the nature of the pathological manifestations caused by spirit of turpentine, the conclusion seems justified that they are indeed certainly less serious and present a clinical and anatomical aspect quite different from that found in lead poisoning (Loriga). It is in fact not possible to attribute to turpentine the majority of the morbid conditions hitherto attributed to lead. In addition to the reserves that must be made as to the frequency of their appearance in working painters, Loriga rightly emphasised at the above-mentioned Conference that "every practising doctor is able to make, with very great accuracy, a differential diagnosis between renal irritation due to turpentine — a slight and not serious illness — and true Bright's disease — a chronic and incurable disease caused by lead; and that every doctor is easily able to distinguish between the acute and occasional headache arising from simple vaso-motor disorders, caused by turpentine, and the same symptoms, when resulting from saturnine cephalopathic lesions; and that no experienced doctor can mistake abdominal pains, followed almost always by diarrhoea when caused by turpentine, for true dry lead colic".

In the cleaning of printing-machine rollers it has been proposed to replace spirit of turpentine by Borneo benzene which is considered less irritating for the mucous membranes. This oil evaporates slightly more rapidly than the spirit of turpentine, but its repeated action may cause serious and even fatal troubles. A premonitory symptom is, for instance, gingivitis. As soon as this appears, an examination should be made of the blood, the characteristic lesion of which is leukaemia with myelocitls (particularly with eosinophilia accompanied by punctate basophilia). This clinical picture corresponds to that of Naegeli myelosis (A. Brandt).

**Detection**

A colorimetric method of estimating the strength of fumes of spirit of turpentine in air was proposed by Rogatzky and Biber: mix 30 litres of the air in 50 cub. cm. of alcohol at 96°; take a sample of 5 cub. cm. of the solution so obtained and add to it an equal volume of a 1 per cent. solution of vanilla in concentrated hydrochloric acid; mix and compare the colour.
obtained at the end of a quarter of an hour with that of standard solutions. This method was tested by Koreman in 1930; he found that it entirely lacked exactness.

A colorimetric method proposed by Andreev and Gavrilov (1929) is based on the property of turpentine to colour sulphuric acid; the coloration is appreciable for a strength of less than one in a million.

HYGIENE

The resin oil industry has two principal inconveniences, the resinous odour and danger of fire.

Governments require that factories should be constructed of non-inflammable materials; that workplaces must be well ventilated; and that the floor should be impermeable. They prohibit lighting with lamps which have a naked flame and require lighting to be by daylight or by lamps placed outside and protected by glass in a fixed frame. The furnace openings must be external to the workplaces; the distilling apparatus must be separated by a wall from the condensation apparatus; the gases which are not condensed are to be directed under the bars of the furnaces, so that they are burnt; a very high chimney must be provided for the factory. The workplaces must be isolated and at a distance from the warehouses for storing raw materials and manufactured products. Loose sand should be provided, and measures taken against fire.

Prophylactic measures to be taken against dangers from turpentine must vary according to whether it is a case of protecting the skin against contact with the liquid, or the respiratory organs or the eyes.

The recommendation to avoid using turpentine as a solvent of fats, and for cleaning clothes, ivory, or rollers and type used in printing should be readily accepted, since turpentine can be replaced by other solvents which are more active and less costly, such as petrol spirit, benzene, or carbon bisulphide; but no advantage would accrue from the health point of view, since the fumes from these solvents are much more injurious to health than those of turpentine. The paint and varnish industry cannot dispense with varnish, which is used as a solvent of resins, as a diluent and expedient of other ingredients, as a means favouring the oxidation of varnish, and as a corrector of too rapid drying; so it is necessary to provide the means calculated to prevent the injuries referred to above. It has been noted that the affections from which painters suffer occur exclusively, or almost exclusively, during work done in closed places, which are small and badly ventilated, especially when the temperature is high, as in cabins of ships. For prophylaxis, it is necessary that the ventilation of these places be kept active, and of the volume of air. As regards stain-removing operations, they can in some cases be carried out in closed vats; but even so, adequate ventilation of the place must be maintained.

Protection of the skin of the hands and forearms cannot be obtained by wearing rubber gloves, as they do not resist the action of turpentine. Gloves of other materials become impregnated and adherent to the skin, aggravating the condition instead of improving it. Smearing the hands and forearms with linseed, or vaseline may be recommended, or, better still, with a mixture of olive oil and beeswax. The use of detergents for removing turpentine or varnish on leaving work must be avoided. These detergents irritate the skin and aggravate the action of the turpentine. The use of sand, chalk, and alkali soaps which dissolve the fat from the skin, and attack the chitin, which is the cement of the cells of the corneal layer of the epidermis, must be avoided. Crude linseed oil should be used as a deterrent, and sawdust, for mechanically aiding the cleansing, should be provided for workers.

The working clothes must be kept clean, especially the sleeves and neck. Persons showing special sensibility to turpentine must be excluded from work; and also those who show cutaneous lesions or who are affected by seborrhoea, hyperhydrosis, prurigo or who have anaemic skin. Filippini advises testing the cutaneous sensibility of workers before admission to work, by applying for twenty-four hours on the skin of the arm or chest a little square of linen impregnated with the substance under consideration, whether turpentine, substitute, or varnish already prepared, and covered with a larger square of jackinette. In the normal person, there is no reaction, or at most a superficial erythema. Sensitive persons show a reaction, infiltrating erythematous, vesicular and papulo-serous eruptions; after only a few hours, these persons experience a sensation of burning and itching to such a degree that they are obliged to remove the irritating substance.

LEGISLATION

Women and children are protected by Orders in many countries which regulate...
Type is made from a special alloy, the composition of which is generally as follows: lead, 60 to 75 per cent.; antimony, 30 to 23 per cent.; tin, 10 to 2 per cent. It should, however, be noted that as a rule a distinction is made between two different alloys according to their content of lead: a black alloy, hard and brittle, made of lead, tin, and about 40 per cent. antimony, and a white alloy, made almost entirely of lead and used for interlines, clumps, quadrats, and spaces which have to bend readily without breaking under the pressure of the machines. For printing large advertising placards in relief, bronze type is used (a German special line).

**INDUSTRIAL PROCESSES**

The manufacture of printing type necessitates the use of dies and matrices into which the melted metal forming the letters is poured.

The cutting of the dies in steel, which used to be done by a highly skilled workman, is now done by perfectly accurate engraving machines, which are really exceedingly delicate pantographs. But this technique necessitates very carefully prepared designs for reproduction.

A small block bearing the letter in relief is passed on to the engravers for finishing, and the removal of mould marks. The cut letters, retouched and cleaned, are then passed into a nickel-plating bath, from which, after about forty-eight hours, they emerge covered with a thick layer of nickel which reproduces the design of the letters. These matrices, mounted on a metal stand, are passed on to rectangular men who set them square and rectify the depth of the face. The matrix is then ready for starting type casting.

The alloy is melted in open crucibles in Belgium and France, or in closed crucibles in Germany, Great Britain and Italy. Some factories have adopted electric heating for the crucibles. First, some lead is melted, then the antimony is added and the remainder of the lead; finally, the tin is added, and, as required, any other metals which the alloy is to contain.

One workman attends to the fire and refines the melted metal by removing with a ladle the scum which rises to the surface of the molten metal. By means of analyses and the addition of metals not present in sufficient amount, the composition of the alloy can easily be kept accurate.

The casting of the type is sometimes done by hand, for the preparation of large type, rules, interlinings, quadrats, and clumps; but it is more often done by machinery.

In the manual foundries, the letters are cast one by one in a mould, the workmen pouring the molten alloy by means of a ladle. When the mould opens, the metal liquefies and is then extracted, and the mould again, when the process is repeated. When he is making clumps and quadrats, or when he wants to obtain long lines, he hastens the solidification of the metal by rapid contact with a moistened rag.

By solidifying the metal in this way he stops the flow into the feeding channel.
In casting by machinery, a pump throws a jet of molten metal into a melting pot which adjoins the machine, into a mould which is in two parts and opens to allow the letter which has been cast to fall out. Sometimes it is a case of a matrix being fixed in a mould, movable in a slide, into which a jet of molten metal is injected.

Remnants or "masselottes" of molten metal adhere to the type thus formed. By striking each letter on a metal table a sharp blow, these remnants are broken off at the level of the foot of the letter. Type, cast by hand or by machinery, is next subjected to the finishing processes — shaping, dressing and calibrating, by means of magnifying glasses. Type in which the stem is diagonal, or projects beyond the thickness of the letter, is subjected to special fraising under the portions which extend beyond the body of the letter — a long and tedious operation.

Type used in different countries differs in height, so the letters are placed on long composing-sticks and passed to shortening-machines which cut them down by means of special milling.

Machines are often used which do all these operations automatically and reduce contact with the alloy to a minimum.

After classification, packing follows.

Men are almost exclusively employed at the melting crucibles; all the other operations of sorting, polishing and packing the letters, women are employed by preference, as has been reported by A. Hamilton in 1916, in the type foundries of the United States.

In the department of wood engraving small blocks of wood are prepared of the size required for the work of the type foundry. Dust is removed by suction and adequately withdrawn so as to fulfil the requirements of hygiene.

Stereotyping plays a very important part in the printing of newspapers. Stereotyped plates, prepared in single pieces, reproduce a page of composition ready for printing, obtained by assembling movable blocks. The plate makes it possible for successive editions to be printed conforming to the first without disturbing the type of the blocks. Its use is essential for printing on rotary machines. Plates are prepared by moulding, i.e. by taking an imprint of the composition by means of a sheet of special papier-maché, or by superimposed leaves of paper, between which is spread a paste mixed with Spanish white. Into this mould, dried flat for an ordinary plate, or on the curve for a rotary plate, the melted type alloy is run, and so forms the actual stereotyped plates which are used for printing. (As regards plates used in electroplating and "electrotyping," see articles "Photo Engravers" and "Electrotyping."). After moulding, the edges and seams of each plate are pared; and the plates are adjusted and corrected.

**Sources of Danger**

There will now be enumerated the chief sources of danger during the various operations of preparing the type metal, and casting and finishing the letters:

1. **Metallic dust of lead and antimony.** Some of these dusts are light and easily absorbed by the respiratory and digestive organs; others are heavy, and danger results from rubbing against the metal, which adheres to the skin.

There is considerable danger from dust generated during the removal of the oxidation scum where the founders adopt the deplorable habit of dropping it on the floor. Metallic dust may also arise from splashing from the machines. Thiele has drawn attention to the projection of molten metal on to the floor. Microscopical analysis of the dust has shown that lead occurs in the form of fine dust of a dark colour, and also as larger particles, with a metallic lustre, varying in shape.

Heavy dust comes chiefly from the operations of scraping and polishing. Its greasiness makes it adhere to the skin, whence it can only be removed with difficulty by washing. Its direct absorption is doubted; if it occurs, it may be facilitated by abrasions or by thinness of the skin.

Seitz has collected from the hands of a number of typefounders, even after the hands had been washed, quantities of lead weighing more than 7 mg., and more than 8 mg. in the case of women polishers, and also minute quantities of antimony.

By analysing samples of dust collected in the workshops and even from tables reserved for meals, the same authority found appreciable quantities of lead and antimony as the following figures show:

**Typefounders**
Further, workers carry dust on their clothing; they eat it, drink it, and smoke it. This explains why, although the quantity of lead manipulated is much less than in the lead foundries, the danger of lead poisoning is not less acute; moreover, the work is at times carried out in small, unhealthy, badly ventilated workshops, annexes to the printing works, where the atmosphere is easily loaded with unhealthy products which are not removed quickly enough.

During an enquiry made in the United States, A. Hamilton found that the absorption of dust is often facilitated by the fact that the work of finishing requires such close attention that the women who are employed work with the head bent close over the work. The dust covering the svork benches is especially thick as the finishing process is often effected in the same workshop as the type-casting department.

Considerable quantities of lead have of course been found in dust from hoods and ventilating shafts, and from window fittings. The Public Health Authority for Saxony collected 34 samples of dust from 29 works and found in them as much as 22.5 per cent. of lead. Even so, in foundries having as many as 20, 30 and even 50 melting places, but where the spacing, ventilation and cleanliness were adequate, there was very little danger. In a foundry having 58 melting pots without exhaust ventilation, a foundry which, about four weeks before the samples were taken, had been whitewashed, only 0.17 per cent. of lead was found in the dust. This danger may be greater in stereotyping, where there is considerable liberation of dust, especially when the casting is done by hand. It should be remembered that this danger is not always in proportion to the number of melting pots.

Thus, in a foundry with a single pot and a cubic space of 144 metres, the dust was found to contain 4.7, 6.7 and 11.6 per cent. of lead. In a foundry set up in a cellar, 12.6 per cent. of lead was found, whilst in the stereotyping room of the same works, situated high and well ventilated, the proportion of lead was only 0.7 and 2.6 per cent. Actual appearances are not sufficient for judging the relative cleanliness. Some works, regarded as healthy by factory inspectors, have given contents of lead as high as 7.81, 8.88, 11.45, and 13.66 per cent.; others, where the workshops had been whitewashed and where the rules laid down for cleanliness were observed, only gave lead contents of 0.85, 0.68 and 0.51 per cent.

2. Metallic fumes of lead, antimony, or arsenic. Fumes are produced when type alloy and old type are heated to melting point over an open fire. This question of the giving off of fumes is, as is well known, somewhat controversial.

According to some experts, including Silberstein and Seltz, metallic fumes cannot be given off, for the temperature of the alloy, varying between 500° and 520° C., is always lower than the temperature at which lead volatilises, 1,525° C. According to Lewin, however, this limit is lowered when lead contains impurities, or is alloyed with other metals, such as tin. Frois and Gerin found that fumes given off from the molten alloy are free from lead. Seltz, at all events, could not detect, by testing with yellow sulphide of ammonium, lead fumes in melting shops, even when the melting pots were heated to such high temperatures as 508° C. In tests made in the laboratory, however, with pots the temperature of which varied between 423° C. and 588° C., he detected in a first test 0.2 mg. of lead and in others 0.35 mg.

An enquiry made in the Government Printing Works at Berlin enabled Heise to form the opinion that, when the technique is adequate, there is no liberation of lead in the state of fumes from above the melting pots.

Roth, on analysing the air of type foundries, did not find lead fumes in 10 litres of air drawn from the surface of melted metal at a temperature of 550° C. The presence of lead fumes was only observed at a temperature above 650° C.

Another test made by an engineer of the name of Fischler shows the following results:

<table>
<thead>
<tr>
<th>Grammes per 100 litres of air</th>
<th>Lead</th>
<th>Antimony</th>
</tr>
</thead>
<tbody>
<tr>
<td>The Kunstmann system of melting machine (over 450° C.)</td>

<td>0.0025 to 0.0016</td>
<td>0.0016 to 0.0005</td>
</tr>
</tbody>
</table>

It may thus be concluded that the evolution of fumes is associated with temperatures over 500° C. and need only be considered in connection with the few melting pots which require a particularly high temperature.
Insufficient supervision of the furnaces may, however, cause fumes to be given off. As a matter of fact, variations in the temperature of the pots are not estimated by such accurate instruments as pyrometers, but by the workmen, who rely on their working experience; hence arises the possibility of errors in appreciation, especially when comparatively old workmen are concerned, whose senses may be somewhat dulled.

At Leipzig, for instance, in a large type foundry, 18 per cent. of the workmen were between fifty and sixty years and 25 per cent. between sixty and seventy. So there is an absence of any accurate regulation of the temperature at the surface of the molten metal; and the sources of heat are not regulated as they ought to be. Seitz was able, on the same morning, with the same founder, to observe the following temperatures in an alloy bath: 556° C., 517° C., 533° C., and 519° C. He several times noticed differences in temperature of 30° and 40°. In this way temperatures may be reached which are sufficiently high for the partial volatilisation of lead.

Thiele, on the contrary, denies the statements of Seitz that danger from lead fumes is slight in type foundries. He does not believe that the exhaust hoods placed over the melting pots provide a good means of protection.

Further, even if there is but slight evolution of lead fumes, it must not be overlooked that the risk is continuous, that the small quantities accumulate, and that the founder is undoubtedly exposed to risk not merely when he leans over the surface of the metal to remove the oxidised scum, but similarly when charging the crucibles with unmelted metal.

The fact that antimony may contain arsenic as an impurity must not be overlooked.

3. Organic fumes. These arise in general from grease and dirt from the colours and inks which adhere to the lead scrap, to the type and used interlines, and come off, as acrolein, etc., during melting.

4. Heat and comparative humidity constitute two factors which are prejudicial to the health of the workers. In one foundry the cubic air space was 23 m. per person, the temperature 34.9° C. and the relative humidity 72 per cent.; in another the cubic air space was 15 m., the temperature 27° C. and the humidity 50 per cent. (Seitz).

At Vienna temperatures of 35° and 40° C. were noticed and at Berlin of 30° C. (Sommerfeld).

Some firms, including the Turin firm Nebiolo, have completely done away with gas for heating the melting pots on the casting machines, and have replaced it by electric heating which ensures the uniform temperature desired for melting the metal in the pot and eliminates all the inconveniences of gas, such as the radiation of heat. In this way the workshops are rendered perfectly healthy.

Cleaners of old type, before passing it on to be melted, may be exposed to the poisonous influence of the various solvents used, such as benzine and methyl alcohol (see those articles).

Among accidents may be noted burns, from splashings of molten metal, on the hands, arms, chest and face, occasionally on the feet, and more rarely the eyes.

**Statistics**

According to the statistics of Grotjahn dealing with 200,000 persons employed in the German printing industry (1907), 15,000 were founders and type engravers.

The statistics of the sickness offices show that the occupation of typefounder is among the most dangerous of the graphic arts. The percentage of incapacity for work among 1,044 typefounders of Leipzig, of whom 318 were women, in 1923 was 10.6 for men and 27.3 for women, whereas in 1914 out of a total of 516 workers, 159 of whom were women, the percentage of incapacity was 2.1 for men, and 28.9 for women.

During the period which elapsed from 1 January 1922 to 30 June 1923, the sickness offices counted 326 members who were typefounders, among whom were 53 cases of sickness (16.2 per cent, of all cases); 317 stereotypers and type engravers had 108 cases (34.1 per cent). The longest duration of service was found among stereotypers and typefounders, 22.2 per cent. of whom had worked more than 40 years.

As regards the number of days of sickness the following figures are given per 100 members:

<table>
<thead>

</table>
A large proportion of poisonings and especially of lead poisoning, without taking into account a high sickness rate from tuberculosis and from rheumatic pains, has been met with.

According to Seitz the various causes of sickness for 1922 can be classified according to occupational groups as follows:

<table>

</tbody>
</table>

In Germany an examination of typefounders gave, from 1910 to 1922, 21.1 per cent. of positive cases of lead absorption and amongst polishers 50 per cent. According to the statistics of the Leipzig office (1911) there were 3.4 per cent. of cases of lead absorption among typefounders compared with 1.90 in other categories of the printing trade (Seitz).

Examination of the blood, carried out during the period 1913-1922, in a German factory, employing on an average 228 workers, showed a percentage of 5.2 cases of lead absorption. In another firm with sixty workers, examination of the blood showed 1.6 per cent. Most of the positive results related to women polishers (42.8 per cent.); next came the typefounders with 26 per cent.; the other branches of the industry showed much lower figures. During the year 1923, the following were the percentages: typefounders (metal pour-

1 A slight increase of porphyrin found in one case was not detected on a second examination.

2 One of whom had a slight increase of porphyrin.

The typical lead colour was not found in any case.

According to figures of the sickness office for the printing trade in Vienna, 241 stereotype founders and 74 workers in typefoundries showed, during the period 1901-1908, the following average rates of sickness per 100 workers:

---

**Fig. 150.** — The engraving tool (firm of Nebiolo, Turin.)
The only cases of lead poisoning met with by the Commission of industrial diseases of Illinois among women employed in the printing industry related to women employed in founding type: 4 women employed in finishing type by hand and having a length of service varying from three years to thirty-five years suffered from chronic lead poisoning (Hamilton).

In France the statistics given by Orliac show 1.80 to 9.50 per cent. of lead poisoning among the founders; but these figures only concern the acute cases. Typefounders treated in the hospitals of Paris for lead poisoning during the period 1899-1901 numbered 41, with an average of ten days in hospital, and, during the period 1902-1905, 76 with twelve days in hospital (Orliac). In other countries the statistics relating to typefounders are given with those of printers (see article "Printing Trade").

One of the first studies on the hygienic and sanitary conditions of typefounders is that of E. Bertarelli (1903) which was made in an Italian factory at Turin. It extended over two years and dealt with the sanitary conditions of workmen and the hygiene of workplaces, including the presence of carbon monoxide and of lead fumes in the atmosphere.

The alloy used by the factory contained 55 parts of lead, 35 of antimony and 10 of tin: it melted at about 450° C. The work of melting was done mechanically and the temperature only rarely went beyond 500° C. Generally, only large type required to be trimmed with the file, and this process was done by women by hand.

The statistics were not proved to be absolutely accurate. Typefounders to the number of 131 were distributed in age-groups as follows: 15-30 years, 55; 31-50, 66; over 50, 10. The 50 women employed in work on type were distributed as follows: 15-30 years, 37; 31-50, 13.

Of the 131 men, 73 were employed in melting, 44 in cleaning and trimming, 10 in the warehouse and on additional work, and 4 at type cutting.

According to the works doctor, about 40 per cent. of the founders suffered from gastritis, sometimes troublesome; 25 per cent. from stomatitis; 30 from arteriosclerosis; 10 to 15 from nervous and muscular affections. During twelve months only one case of lead colic and one serious case of gastritis was reported. Tuberculosis was rare.

Nevertheless, Bertarelli admits a certain frequency of cases of gastritis, stomatitis and slight albuminuria, which he attributes to the effect of lead. Examination for lead in the urine of 12 founders and 10 women workers was negative; but about 30 per cent. of the women, who had worked in the factory for five years and over, showed signs of lead absorption.

The workers were exposed to the effect of rather high temperatures; but only rarely were traces of carbon monoxide detected in the air of the foundry. The measures adopted by the management did not eliminate the injurious effect of the lead, especially in the case of the workers in the trimming department. For this reason the author classes (1903) the industry as an unhealthy one, offering dangers to the health of the workers, dangers which are inevitably associated with the nature of the industrial operations.

Although recommending the management to improve the ventilation in the vicinity of the machines for melting type, to install exhaust ventilation for poisonous dust and to provide such means of personal cleanliness as baths and douches for the workers, the author was not able to prove the presence of lead in the state of fume in air taken at 50 cm. from the furnace, and could only find very slight traces of lead in the form of dust.

**PATHOLOGY**

Lead poisoning holds the first place. While, as Orliac says, acute conditions are somewhat rare, stealthy impregnation of the organs, on the contrary, appears to be the rule. This shows itself sometimes by serious attacks and sometimes by giving rise to slight illnesses, which the least cause, whether due to exhaustion, to fatigue, or to drink, aggravates.

The article "Lead, Poisoning by", records the frequency of pallor and anaemia. In the case of an apprentice founder whose symptoms seemed to indicate slight lead colic, Schwarz detected the existence of 2,000 erythrocytes with basophilic granules per million, traces of albuminuria and an increase of porphyrin in the urine. In the same
way an enquiry at Frankfort recorded pallor and subjective signs of lead poisoning in 13 apprentices examined, and in 7 an increase of eosinophilic leucocytes. Schrumpf and Zabel only rarely noticed in apprentices definite signs of lead poisoning; but, on the contrary, they found in several cases a clinical picture consisting in a tired facial expression, nervousness, irritability, fatigue, insomnia, vertigo, headaches, muscular pains, nausea, anorexia, intestinal disorders and constipation. Examination of the blood showed a diminution of leucocytes, with a comparative increase of eosinophilia, according to Seitz, examination of more than 90 founders and of the rest of the personnel of typefoundries did not reveal the presence of basophilic granules, although the personnel was exposed to a risk of lead poisoning. On the contrary, a relative lymphocytosis with diminution in the number of thrombocytes seems to be characteristic of the blood of founders. During an enquiry carried out at Frankfort, Schwarz found in 33 subjects indications of Schmidt's basophilia as follows: compositors, 19; typefounders, 4; stereotypers, 2; printers, 3; foremen, 1; proof readers, 2; printing machine minders, 2.

The answers elicited by Seitz disclosed, among other symptoms: cephalalgia, especially frontal, in 65 women, and in 62 men; vertigo in 8 women and 10 men; malaise, loss of appetite, and disorders of the stomach in 13 men and 15 women. Tuberculosis was found to be as common among typefounders as among printers. In 1919 Ranelletti reported that the incidence of lead poisoning amongst typefounders in Rome was twice as frequent as that met with amongst compositors, and eight times that noted amongst printers.
Mauro (1929) also has reported that lead poisoning amongst typefounders in Milan attained an incidence of 30 per cent. of the general morbidity. Whilst the typical symptoms of sub-acute lead poisoning are very rare, forms of arterio-sclerosis especially among young workers are very frequent. Mauro explains this by the penetration of lead into the system, and by time spent in overheated workrooms, causes which lead to injury of the heart and blood vessels favouring the development of changes of a toxic origin. (See article "Printing Trade").

**HYGIENE**

First and foremost the provision of machines and apparatus must be adequate and must be erected according to the latest ideas of modern technique. In addition a sufficient air space must be adopted for the workplaces (an instruction of the Swiss Inspectorate lays down 13 cu. m. per worker) as well as good general ventilation. The floors must be solid and smooth, varnished or polished or else tiled, so that they can be easily washed and the dust removed. Arrangements must be made for washing and whitewashing the walls. Desks and shelves must be placed in immediate contact with the floor, or sufficiently high for the floor to be easily cleaned. Daily cleaning of the floor and furniture, generally by the damp process, should be compulsory. No sweeping should be done before work is started, or during the meal interval. Complete change of air should be effected morning and evening. Most of these measures are laid down in Switzerland.

Melting pots, supplied with exhaust ventilation to remove fumes and dust, should be properly installed and maintained. The temperature should be accurately controlled.

**Fig. 191. — Casting machine-room (firm of Nebiolo, Turin).**

An important technical advance is represented by heating the pots electrically.

The preparation of the metallic alloy and the removal of dross should be done outside the workshops.

It is obviously desirable for the lead in the alloy to be replaced by something else, but, in view of the technical impossibility, it would perhaps be advisable to limit its use to ordinary type, by substituting blocks of iron or hard wood for the clumps of lead which keep the pages in position.

These general measures should be completed by strict enforcement of measures of personal cleanliness; lavatories and separate towels; washing
before meals; wearing of special overalls; protection of food against dust.

Spitting on the floors and smoking in the workshops should be prohibited.

Medical supervision of the personnel should also be established. Some experts think that it would be sufficient to limit this supervision to apprentices (Schwarz) and that it can be based on an examination of the blood and urine carried out on commencing work, and thereafter every three months.

LEGISLATION

***
Ultramarine

Ultramarine was obtained in the past by pulverisation of natural lapus lazuli, but since its exact chemical composition has become known and likewise means for preparing it artificially (Guimet, 1826) it is produced in accordance with two alternative processes:

(a) Calcination of a mixture of kaolin (30.5 per cent.), of sodium carbonate of sulphate (27 per cent.), of sulphur (31.5 per cent.) and of charcoal previously pulverised (4 per cent.); washing in water of the product obtained which constitutes azure ultramarine;

(b) Calcination of kaolin, sulphur and carbonate of soda, with exclusion of air, in crucibles placed in a furnace. This operation liberates sulphur dioxide, carbonic acid and sulphuretted hydrogen.

Ultramarine is at present used as a substitute for cobalt colours in the colouring materials industry.

Ultramarine colours may be classified as follows: inorganic colours, derived from borium, selenium and tellurium, which are true ultramarines; organic colours, organosols of varying composition which may be utilised as organic sulphur colouring agents; organo-mineral colours, hydrocarburetted ultramarine (ethyl or butyl ultramarine); temporary inorganic colours (isolated borium phosphates and ultramarine); and temporary organic colours (cyanuretted ultramarines).

Ultramarine colouring withstands even the presence of dissolvents or products which disintegrate sulphur compounds (cyanides, sulphur dioxides). The composition of ultramarine may therefore vary within wide limits.

Dust given off during crushing and pulverisation of the products utilised for the manufacture of ultramarine may prove dangerous since they contain silica. Ultramarine dust is neither hard nor irritant, but its colouring capacity is at times inconvenient. Gases given off during calcination (sulphur dioxide, sulphuric acid) may injure the health of workers engaged near the furnaces, whenever ventilation is defective.

Modern literature contains no mention of specific injuries occurring amongst workers in ultramarine factories. Nevertheless, there has been noted during autopsy the presence of large quantities of alumina in the lungs of these workers, side by side with silicotic, siderotic or chalciotic foci (Ultramarinlungen). The sputum had a greenish blue colour. The autopsy generally proved that the injuries were slight and localisation was restricted to the bronchial tubes.

Ultramarine factories should be constructed far from inhabited areas. The flooring of these factories should be impermeable and should have grooves to facilitate the running off of liquids. Furnaces should be so constructed that gases and fumes liberated may be neutralised and condensed. Only those products of manufacture which cannot be directly condensed should be evacuated by very high chimneys. Extremely effective ventilation should be provided.

Grinding and bolting of materials used should be effected in hermetically sealed apparatus in special workrooms designed for the purpose. Noisy machinery (mills) should be appropriately isolated from other departments. Waste waters should be decanted in special vats before being evacuated by way of the drainage system. Purification of these requires to be effected with care; deposits left should be removed and evacuated fairly frequently. Solid residues should never be thrown on to public highways or into water courses.

BIBLIOGRAPHY

Uranium

French: Uranium. — German: Uran. —

Uranium (symbol U) is an element
belonging to the group of rare metals. It is not widely distributed in nature, but enters into the composition of several ores: pitchblende, an amorphous ore containing various oxides of uranium, uraninite (crystalline variety of pitchblende), carnitite (hydrated vanadate of potassium and uranium), etc. The most important deposits are to be found in Bohemia (Joachimsthal), Saxony, Colorado, Utah and Katanga (Belgian Congo). Uranium is a white silvery metal with a silky fracture. Its atomic weight is 238.7, density 18.7, melting point 800° C. It is, however, more volatile at high temperature than iron, notwithstanding the fact that its melting point is higher than that of iron. Though resistant to air at ordinary temperatures, uranium burns with explosion in air at 170° C. When struck by a hard substance, it gives off numerous sparks. With boiling water hydroxide of uranium is obtained. It is readily soluble in the majority of mineral acids and in certain organic acids to form the corresponding salts, the best known of which are uranium nitrate and uranium acetate, used as reagents.

Separation of uranium from ores containing it is usually effected by a wet method. The ore, after being ground, is treated in a hot state with hydrochloric acid in earthenware receptacles. The solution, which contains uranium, is filtered and treated with barium chloride and sulphuric acid in order to precipitate radium and barium in the form of insoluble sulphates. The uranium precipitated with other rare metals, by the addition of iron filings to the liquid is separated by boiling the precipitate in water. There is thus obtained a hydrous oxide in the form of flakes which can be separated off without difficulty.

At Joachimsthal the ore is roasted to eliminate sulphur and arsenic. The mixture of oxides obtained is melted in an electric furnace with a given quantity of carbon. This enables the copper, lead, iron and nickel to be separated in the metallic state, and furnishes as a supplementary product slag containing the lower oxides of uranium and other rare metals (carnotite, molybdenum). The first group of metals is extracted from the mass and the slags are again heated in the same furnace in the presence of carbon. The oxides obtained are thus transformed into carbides which are treated with water in order to separate the uranium carbide, which latter alone enters into the reaction. The hydroxide, after being dried and calcined, is transformed into ferrousuranium by heating in a crucible, or into metallic uranium by aluminothermic processes. It is also obtained at the present time by electrolytic methods.

Uranium has only recently been used in industry to give greater hardness and resistance in tempering steel and to replace tungsten in special varieties of steel.

Uranium is radioactive and is related to radium and helium. When an ore contains uranium it also possesses a definite proportion of radium. The degree of radioactivity therefore furnishes an indication of the contents in radium and uranium.

Salts of uranium are highly florescent. Certain of them serve in dyeing silk; the oxide is employed in the preparation of a yellow glass with green fluorescence which renders visible objects under ultra-violet rays.

In 1854 Leconte issued a publication demonstrating that poisoning by uranium gives rise to glycosuria. According to Kobert, uranium is the most poisonous of the rare metals. Paul Govaerts (1928) has made a study of extravasations which appear during acute uranium poisoning, and Eitel has developed a sensitive process for detecting uranium and localising it in the poisoned animal system. Eitel has succeeded in affirming that in the case of fatal poisoning, all the organs with the exception of the kidneys are unaffected by uranium.

MacNider (1927), Mauriac and his students (1927-28) and Garnier, Schummann and Marek (1929) have studied the toxicity of uranium nitrate, and by injecting subcutaneously a dose of 3 mg. per kilogram caused nephritis, usually fatal in rabbits. With a dose of 1-2 mg. per kilogram it has caused albuminuria always of considerable extent which lasted for eight days. Similar observations have been made by Chittenden, Hutchison and Lambert, Fischer and Hartwich. Worochilsky has produced experimentally, first of all glycosuria, then albuminuria and gastro-enteritis. Death has occurred in doses varying from 1/2 to 2 mg. per kilogram. MacNider recorded and studied lesions of the liver (1927).

Studies of the effect of uranium salts on the human system are very rare;
in 1925 De Laet and Meurice published their observations dealing with four adult workers, two of whom had worked eight hours per day with uranium salts for about twenty months, the other two having been engaged on the same work for fourteen and seventeen months respectively. Only one of these workers suffered after a period of six months from intense purpura of both legs. Analysis of the blood and urine, however, gave positive results in the case of the four workers: reduction of leucocytes, especially in the case of the two handling insoluble salts (contact with the skin and mucous membranes), considerable diminution in the number of red corpuscles (anisocytosis and poikilocytosis), especially in the case of the workers handling the soluble salts.

No glycosuria was noted, but, on the other hand, a certain diminution in the urinary elimination of nitrated salts and a strong increase in the chlorides. Leucopaenia persisted, though to a less marked extent, in the case of three of the workers, two years after they had been completely removed from work involving manipulation of uranium. De Laet and Meurice hold the view that uranium enters the blood stream and is at least partially eliminated by the urine.

Resuming their experiments with rabbits, Garnier and Marek (1931) discovered that by means of acquired tolerance they could bring the animals to withstand daily doses of 10 mg. per kilogram of uranium nitrate, or a dose very much greater than the dose usually considered fatal. Nevertheless, the animal though apparently not showing signs of injury suffered from loss of weight and from albuminuria and glycosuria without hyperglycaemia. Before death the animal showed signs of nervous derangement (loss of equilibrium and paresia of the limbs) and succumbed at the end of three to four months without developing hypernitraemia. The autopsy showed death to have been due to complex lesions: incipient renal and hepatic sclerosis, derangements of the nervous system, atrophy of the optic nerves. It was therefore concluded that cancer can hardly be exclusively attributed to dust inhalation. Moreover, it is still, at present impossible to state with certainty the true cause of the cancerous growth (Pircham and Sikl). (See also article "Radium and Radioactive Substances").

For detecting and localising uranium in the animal system, Eitel transformed the compound present in the cinders obtained by calcination of the organs into a uranyl compound, which with a Hanauer analysis lamp gives a characteristic greenish yellow florescence. (For hygiene and legislation, see article "Radium and Radioactive Substances").

**BIBLIOGRAPHY**

***
Vanadium

French and German: Vanadium. — Italian and Spanish: Vonadio.

In 1802, Del Rio reported that he had discovered “a new metallic substance”, which he called “panchrome” or “eritone”, on account of the reddish colour of its salts under the action of acids or of heat, but it was only later that Berzelius provided definite information regarding the properties of this element, which he designated “vanadium”.

Vanadium (symbol V) has not so far been found in a pure state. On this account very little is known regarding the physical properties of the pure metal. Vanadium possesses a strong chemical affinity for oxygen, nitrogen and carbon, and combines with extraordinary facility with other metals. It is almost acid-resistant, and burns with violent projection of sparks.

Vanadium is extensively distributed throughout the earth, though very few deposits are sufficiently extensive to justify extraction. The most important ores are: vanadinite (chlorovanadanate of lead, with about 17 per cent. of vanadic acid), roscoelite (silicate of vanadium and aluminium, with 28.5 per cent. of vanadic acid), carnotite (double vanadate of uranyl and of hydrate of potassium), vanadium sulphide from Peru, with 39.84 per cent. of sulphide, etc.

Vanadic acid may also be extracted by treating basic slag.

In the metallic state it is obtained by bringing to red heat chloride of vanadium in a current of hydrogen or in a less pure state, but in crystals by bringing to red heat in an electric furnace vanadic acid mixed with carbon in a current of hydrogen.

Almost pure vanadium may be obtained by the aluminothermic process, or by the Goldschmidt “thermite” reaction.

Since the metal in a pure state is of no interest whatsoever from the technical point of view, and since on the other hand its preparation is extremely difficult, mention will be confined to the direct manufacture of alloys, and especially of ferrovanadium and other vanadium compounds.

Vanadium is chiefly of considerable importance in the steel industry, this fact being based on its faculty for augmenting the resistance and other important mechanical properties of steel, such as hardness, capacity of resistance to shocks and blows, as well as elasticity.

Though used in lesser quantities, the pentoxide of vanadium (V₂O₅) is used as a developer in photography, and the chloride, as well as the trioxide of vanadium (V₂O₃) as mordants in printing. Another important product is metaammoniate of ammonium (NH₄VO₃), utilised in dyeing with diamond black. Brought to red heat, metaammoniate gives off pentoxide of vanadium.

Vanadium compounds may, in strong doses, prove toxic, and vanadate of ammonium and vanadic dioxide or vanadium pentoxide are particularly toxic.

Vanadate of ammonium is at present largely used in the preparation of blue inks. The habit of putting inky fingers in the mouth may represent a source of danger. Ballotta (1931) has stated that these inks contain 0.005 grm. of vanadate per cub. cm. and 0.003388 of the dioxide.

Animal experiment has revealed the fact that vanadate acts on the vasomotor and respiratory systems: somnolence, clonic contractions preceding coma, have been noted, and at the autopsy intense hyperaemia of the lungs, the intestine and the kidneys.

In experimental poisoning of a more or less serious character, the mucous membrane of the eyes, nose and stomach becomes covered with a greenish coating containing vanadium.
The action of the pentoxide during 20 to 25 minutes in a dose of 0.5 mg. per litre kills an animal in forty minutes. With a dose of 5 mg. per litre during five minutes it is fatal in one hour.

The risk of chronic occupational poisoning is represented by inhalation of pentoxide of vanadium dust during its use in the manufacture of vanadium steel, as a catalyst in dyeing, and for the preparation of vanadium compounds. Poisoning in the case of human beings is manifested (Dutton) by irritation of the mucous membrane of the nose, throat, and conjunctivae; by more or less grave digestive disturbances and derangement of the kidneys (hemorrhagic nephritis); nervous troubles (trembling, headaches, psychic derangement, and even blindness due to neuro-retinis).

Good general ventilation, supplemented where necessary by localised ventilating devices, should be installed in all workrooms where vanadium compounds are handled.

The use of adequate respiratory apparatus in the case of workers specially exposed to dust from this product is to be recommended.

Varnishes and Lacquers
(Manufacture of)

French: Fabrication des vernis et laques.
— German: Lack- und Firnisfabrikation.
— Italian: Fabbriche di lacche e vernici.
— Spanish: Fabricación de varnices y lacas.

TECHNICAL DATA

The preparation of lacquers and thick varnishes depends on the drying property of certain vegetable oils derived from wood, hemp, poppy, walnut, sunflower seed, soja seed, maize, cotton seed and French turnip, and, in particular, of linseed oil. The latter is subjected to partial oxidation to increase and quicken its drying power, which is done by heating it, between 150 and 320° C., in boilers heated by steam of superheated air, often in the presence of certain oxides or salts such as litharge, minium, metallic oxides of manganese, borates of manganese and of lead, resinites and oleates of lead, of manganese and of cobalt. If the heating is carried out at a moderate temperature, liquid oils, "weak varnishes", are obtained; at higher temperatures, medium, strong, or boiled oils are obtained.

"Blown" oils are manufactured by letting heated oil fall in very fine droplets in a glass cylinder whilst a counter current of oil and ozonised air is injected. These oils are very little used.

"Thick varnishes" are prepared by dissolving melted resin in boiled oils, or by adding, during the heating of the oil, at the same time as the metallic compounds, colouring bodies and melted resin. When the mixture is cooled the necessary diluents are added as required.

The composition of varnishes varies with the nature of the solvent, of the dissolved substances, and with their use. According to the solvent, varnishes are classified as alcohol varnishes or lacquer varnishes; turpentine varnishes; oil or thick varnishes; and various varnishes, made with ether, chloroform, acetone, amyl acetate, carbon disulphide, tar, and bitumen.

By the word "lacquer" is meant the resin which flows from the buds of various trees of the West Indies punctured by Coccus laccas or, when punctured by another insect, Carreria Larrea, from the buds of the Acaca Gryti Gray and of the Larrea Mexicana Mod., yielding American gum lacquer. Japanese lacquer is a milky juice which is obtained by tapping the Rhus vernicifera D.C. and Japanese anacardiaceae (Urushi-no-ki). By filtering crude lacquer under pressure, purified lacquer is obtained which is sticky and of a deep brown colour. This lacquer contains 60-85 per cent. of urushic acid or "Laccol" or "Urushiol", which is a mixture of several substances, one man, while the German word "Firnis" corresponds with the French "huile de lin cuite" and the English "boiled linseed oil" or "boiled oil".

What in French is called "vernis" and in English "varnish" is called "laque" in German.
of which is toxic, and 10-30 per cent. of water, with traces of gummiferous materials and an oxidizer.

In a broader sense, there are included under the term "lacquers", solutions of resins in drying or volatile solvents, which, after application and drying, leave a thin pellicle of the dissolved substance. This word is similarly applied to solutions of other appropriate bodies, which are not resins, such as asphalt, artificial asphalt, artificial resin, nitro- and acetyl-cellulose. Each lacquer is composed of an organic colouring material, attached firmly to some substance which acts as a base or foundation, and is generally a mineral. The colouring material may be of animal, vegetable or synthetic origin. It is attached to the base by mechanical absorption or by chemical reaction; it dissolves in a suitable liquid, i.e. a solvent.

Resins are substances with a somewhat complex and rarely constant composition; they are found in excre- tory products from several trees, or in the fossil state as amber, Dammar copal and Kauri copal, and, more
rarely, in products of animal secretion, as musk and castor. Nowadays, artificial resins are much used; they are prepared by treating natural resins or by dry distillation of certain substances, or by resinification of several organic substances. Synthetic resins should be mentioned, they resemble natural resins, and are obtained by condensation of a phenol with an aldehyde, e.g. bakelite and formolite.

Under the name of copals are understood resins which come from plants of species and families varying according to their country of origin. Copals are distinguished by their source, whether from Africa, Asia, Australia or America, by their properties, whether hard, semi-hard or soft, and by their colours, whether white, yellow or red. Oil of copal is obtained as a by-product during the distillation of copal above 300° C.

Colophane is a residue from turpentine, after the extraction of the oil of turpentine (see that article).

Gum-lacquer, which is put on the market in sticks, grains, lumps or scales, is used for the manufacture of sealing wax, glues, alcohol varnishes, lithographic inks, insulating materials, polishing materials, as a dressing for decorative work, and in the construction of gramophones.

Among other resins should be mentioned acroid resin, which is used in the manufacture of varnishes resistant to light, of resinous soaps or of sealing wax; Dammar resin; benzoin; Elemi; Mastic resin; Dragon's blood; Styrax or Storax, a thick, grey, resinous mass consisting of a mixture of the ethers of cymic acid and resins and obtained by heat and pressure from the internal bark of Liquidambar Orientalis Mill.; sandarac resin, which is found as small yellow grains and is used to manufacture varnishes, glues and dull varnishes used in photography; coumaron resin, which has in days gone by played an important part as a cheap substitution product for colophane and is prepared from solutions of sulphuric acid used for the purification of heavy tar oils.

Artificial resins, soluble in benzene and miscible in oil colours, are used nowadays as varnishes.

Phenols, formaldehyde, vinic acid or other organic oxy-acids are used to manufacture "Lakkaine", a product similar to gum lacquer and soluble in alcohol, ether, acetone, and soda-lye. With other acids or salts, possessing a chlorhydrine acid reaction, other products can be manufactured, such as "Novolak", "Abalak" and "Sibolit".

The use of o-cresol, in place of phenol, gives metakaline (Bayer), isol ine and bucheronium. Substitutes for gum lacquer are obtained with phenols and formaldehyde by the addition of alpha-naphthylamine and by further treatment with oxidising bodies in order to obtain resisting power on exposure to air.

In the manufacture of boiled oils and varnishes, oil of a Chinese wood — oil of Tung — is often added; and there are used as diluents, in place of turpentine, which is costly, pine oil or residues from the manufacture of pine oil, light and heavy oils of camphor, benzene, solvent naphtha, chlorated benzenes, hydrocarbons of the fatty series, but, especially, heavy benzene, sangajol, white spirit, and, less often, light benzene. Spraying oil-varnishes are obtained by the addition of wood oil which dries rapidly.

With regard to the thick varnishes already discussed, the protective pellicle which is obtained is the result of the oxidation and the polymerisation of the oils which combine with the resins in the state of fine division, forming a shining and entirely smooth surface.

The addition to varnishes of this class of volatile solvents, first causes a dilution and it is only afterwards that the above-mentioned changes occur in the constituents of the varnishes. These varnishes are named "volatile varnishes."

Bitumen varnishes, natural or artificial, are solutions of this substance and resins in linseed oil and in one or more diluents. Some varnishes of this group dry in the air, while others must be put into a stove.

The solvents used for alcohol varnishes are denatured alcohol, amyl alcohol, amyl acetate, and acetone. Benzene and petrol are used as adjuvants. Alcohol varnishes, without covering colours, are merely solutions of resins in alcohol solvents. In the same way polishing varnishes are composed of a solution of gum lacquer, wax, turpentine and an alcohol.

Mention must be made of cellulose varnishes, which are volatile varnishes having as a base nitro- or acetyl-cellulose in place of a resin. The solvents used are chiefly acetone, amyl acetate and methyl alcohol, and, as additional products, benzene, toluene, amyl alcohol, chlorated hydrocarbons, ethers and glycol ethers.

The importance attained by the use of these varnishes has obliged the chemical industry to find a large quantity of solvents and diluents, which are often sold in commerce under
fancy names. Moreover, mixtures of these products are often sold without any indication of their composition.

Glycol ethers combine the solvent powers of alcohol and ether, and are used chiefly for the preparation of Zapon lacquers or Cellon. They are often diluted with butyl alcohol and benzene. It would take too long to enumerate here all the products used as solvents of nitro- and acetyl-cellulose (see article "Solvents").

The plasticity of varnishes used in the leather, artificial leather, and film industries, is obtained by means of plasticizing products, among which it is sufficient to mention phosphate of tricresyl and of triphenyl, and the phthalates of methyl, ethyl and butyl. Technical methods still involve utilisation of products to be feared on account of the dangers which they present; mention may be made of tetrachlorehthane, and di- and epi-chlorhydrine.

**Sources of Dangers**

Sources of danger arise principally from the inflammability of the oils, and fumes given off during the melting of the resins or the distillation of the oils; from the risk of splashing by hot oils in the case of workers employed at the cauldrons; from fumes of solvents and diluents, which are readily inflammable and mostly poisonous; as well as from fumes given off during the various operations. Among these last may be mentioned acrolein (see that article) which is rightly feared on account of its irritant action. Furly fixes as a minimum dose which may be endured 70 cm. per cub. metre of air; but even in this weak strength it causes marked signs of irritation.

Risks of poisoning during the preparation of varnishes are not so great as during their use, especially if they are applied by means of sprayers. The reason of this is very simple: during the manufacture of varnishes every precaution is taken to prevent the volatilisation of the solvents and diluents. Instances of damage, chiefly to the skin, from the use of lacquers and varnishes are extremely numerous, and it is impossible to give a complete list of these.

The fact must also be emphasised that the composition of varnishes is very varied; the subject is confused by much genuine and illusory practical experience; and, in practice, a good deal of secrecy is maintained.

The different constituents of varnishes may, under certain circumstances, react one upon another in an unforeseen manner, and cause formation of equally unexpected poisonous substances. But the manufacture of varnishes is becoming more and more scientific, and at present the use of very complicated compounds is avoided; it seems by the suitable mixing with less solvents, to ensure with an equal certainty varnish-mixtures for the various purposes as required.

**Pathology**

Barnes in 1931 described a dermatitis among workers employed in the preparation of linseed oil, which he attributed to impurities existing in the oil cake, and also to personal idiosyncrasy.

Vokonu in 1928 also described a dermatitis due to linseed oil; it was bilateral, with itching, situated on the forearms, and was followed by a papulous eruption and scabs.

The reports of the medical inspectors of Great Britain and Germany record several cases of dermatitis due to lacquers and varnishes, particularly to the synthetic varnishes — nitro-cellulose and bakelite. Attention is rightly drawn to the risk of using nitro-cellulose varnishes for domestic purposes.

Zapon lacquers cause not only skin affections, which are quite frequent in the industries producing or using these lacquers, but also irritation of the visible mucous membranes, headaches, and passing disorders of the liver, which becomes enlarged and painful on pressure, with jaundice and urbinuria. This train of symptoms may be attributed to the presence of tetrachlorehthane, as in the case of Ohnesorge (1930), among hatters. In cases of poisoning observed among the workmen in a pencil factory, there was conjunctivitis, headaches, vertigo, weakness, cough, dermatitis, and congestion of the face, a train of symptoms which may be attributed to the presence of methyl alcohol and amyl acetate.

In 1931 Rouset had an opportunity for studying for a whole year skin affections among workmen at a large factory. These affections presented an extraordinary polymorphism, and were situated on the exposed parts. The onset was sudden, with intense, but transient, subjective signs. Mildness was an almost constant feature. The eruption was generally papulous, very bright red, non-prurigenous and lasted twenty-four to forty-eight hours. Sometimes, the passing erythema showed papular or vesico-papular appearances. Rouset attributed these skin condi-
tions to the effect of wood vinegar, with acetone and methyl alcohol, and of benzene, especially during their evaporation. Although there was certainly an individual cutaneous susceptibility which played its part, the use of these diluents for cleansing the skin was chiefly to blame.

The production of Tonkin lacquers causes among the natives severe dermatitis, with conjunctivitis and keratits.

Darier in 1928 described a temporary eruption of a simple kind among lacquer workers. The vogue of the game of Mah-Jong caused eruptions among players, due to contact with the lacquer covering "authentic" boxes of Mah-Jong. These cutaneous affections, which are well known in China, are due to the presence of Rhus vernix, which is used in the preparation of the varnish and causes a dermatitis characterised by urticaria and arthralgias or by an exanthemous, papulovesicular eruption with oedema and itching.

**HYGIENE**

The old technique for boiling oils, which is still used by many manufacturers, is as follows: linseed oil is put into a cauldron of iron, cast iron or copper, set in a block of masonry and heated at its lower part by flames or hot gases which come from a furnace. The cauldron is equipped with an overflow and a cover which is controlled by means of a cable or a chain. The cauldron is usually surmounted by a movable exhaust hood, connected to a system of ducts, which lead to a ventilating fan by which the gases and fumes are caught up and driven into a condensation apparatus. The non-condensable portions of these gases pass under the bars of a coke furnace kept at red heat. In other systems, a fine spray of water under pressure is directed into the system of ducts. The spray absorbs the gases and fumes and also acts as an ejector. In this way the use of a ventilator fan is eliminated.

The modern method is to carry out the boiling at a very high temperature, say 320° C.; it produces oils with very good drying properties ("Stand-oilies"). Boiling in vacuo, or in an atmosphere of an inert gas, has been tried, but without success. On the other hand, it has been successful with utilisation of carbonic dioxide. By this method it is possible to eliminate many of the disadvantages arising from the old method which affected the neighbourhood and the health of the workers.

The cauldron is made from a single piece, without soldering, and the gas, when introduced under pressure, causes a suitable agitation of the boiling oil. The apparatus is supplied with a condenser for the volatile condensable products, which are, however, small in amount. The heating is by gas-coke, or gas, or heavy oil.

Other kinds of apparatus possess an overflow for the oil which may run over during the boiling. The oil which has overflowed is returned to the cauldron by means of the pressure of carbonic dioxide.

By these methods boiling can be done at high temperatures without any fear of the oils becoming deep in colour.

The manufacture of varnishes with a copal or resinous base, with the addition of linseed oil and solvents, is carried out in an apparatus in which the products can be manipulated by means of pumps and carbonic dioxide under pressure. The volatile condensable products are condensed by a special refrigerant; what escapes is caught and condensed by spraying with water. The non-condensable gases are passed into a special oil furnace, where they are burnt.

In a similar apparatus, but provided with a mechanical stirrer, the boiling of oils is done at a low temperature, 200-220° C., with or without incorporation with metallic bases. In this case, also the fumes given off are condensed.

As regards solvents, some apparatuses only effect an imperfect condensation of the fumes; others, by an improved system of agitation, eliminate most of the condensable products. The best solution is provided by arrangements which make it possible for the residuary gases to be burnt. The recovery of volatile solvents — very important from the point of view of economy — which are found in the form of fumes in the air or in the gases can be effected by condensation, by compression, by adsorption or by absorption.

Nowadays an apparatus exists which makes it possible to determine the limits of the explosion of solvents at ordinary temperatures in a satisfactory manner. Solvents with a base of alcohol or of ethers can be concentrated much more than those with a base of hydrocarbons before becoming explosive. Mixtures of alcohols and ethers distilling above 150° C. do not explode at ordinary temperatures; on the other hand, when they contain a certain proportion of hydrocarbons they rapidly become explosive.
By ventilation the limits of explosion can be controlled considerably. Thus modern apparatus eliminates the disadvantages of the old methods almost entirely: danger from spontaneous combustion of the oil, and of the fumes generated; danger of fire; disagreeable smells; serious burns for the workers; and irritation of the mucous membranes by the fumes and especially by acrolein.

The manufacture of thick varnishes, whether it includes the boiling of oils or not, and the boiling of oils in any way whatever, are in some countries, e.g. Belgium, France and Italy, classified in the first category of unhealthy and offensive trades. This classification requires the adoption of the following measures: (i) the work must be carried on at a distance from dwellings, on account of the disgusting and irritating odours and of the dangers from fire and explosion due to melting resins and boiling oils, the vapourisation of liquid hydrocarbons, etc. (ii) workshops must be constructed of light, non-inflammable materials; (iii) tanks of inflammable liquids must be more than 10 metres from the furnaces or heating for the plant, and surrounded by a watertight fire-resisting casing, capable of receiving, if required, the whole of the liquids.

Operations which are liable to give off disagreeable fumes must be carried out in closed apparatus. The dispersion into the outside air of disagreeable emanations and furnace fumes cannot reach the furnaces. The manufacture of solid driers by melting, and pouring of resines or linoleates must be prohibited. In case of a break in the apparatus, burning liquid must be prevented from spreading outside the workshops or reaching the tanks. Fire-extinguishing apparatus must be always at hand, and the workmen must be trained in their use. Risk of fire can be reduced by suitable storage and manipulation of solvents and nitrocellulose; and by close supervision of such electrical equipment as motors and lighting, of machinery, of fans which create danger from static electricity, of the heating, of tools, and of the tidiness of the factory by avoiding accumulations of greasy rags. The exit of workers in case of danger must be rendered easy.

The importance of thorough ventilation of the workshops must be emphasised, as likewise that of installing electric lighting provided with efficient protection against the production of sparks, especially where the solvents are stored, and of the provision of a sufficiently high chimney reaching from 20 to 30 metres. The addition of volatile solvents to melted resins should only be done when the contents of the cauldron are sufficiently cool. Diluents should be used with a high boiling point, so that when they are added to the hot oils and varnishes there does not occur too great a loss by the formation of fumes. The mixing shop should be provided with efficient exhaust ventilation so that the inflammable fumes cannot reach the furnaces.

The fumes and vapours which occur in varnish works are: (a) volatile products which come from the partial decomposition of resins and oils while melting or boiling; (b) fumes from the furnaces; and (c) vapours from solvents.

Transfer of these products into an incinerating apparatus involves an enormous expense for the industry and a definite loss of volatile products which can be recovered.

It is much better to eliminate these products by the use of condensation and by causing them to pass through an alkaline solution. The air of the workshops is aspirated and passed through a condenser which is a long metal tube, where it gives up products of high boiling point. Any fumes which remain over must be removed by absorption in an alkaline solution (Perry-Webster system).

The individual protection of workers calls for attention. Care should be taken that the working clothes are not soiled by oil, varnish or solvents, as that constitutes a danger to the men in case of fire. The usual measures of personal hygiene must be adopted.

See also the Memorandum on risks from accidents and injuries due to cellulose solutions and on the measures to be adopted to prevent these, issued by the English Factory Department in 1928.

LEGISLATION

Women are excluded from varnish works in Argentina. In Belgium, young persons under sixteen years are excluded from boiling linseed oil on a large scale, from varnish factories, and from applying varnishes hot. In Spain, boys under sixteen years and women under twenty-one years are excluded from using varnish with a base of rubber, which would expose them to the action of fumes of carbon bisulphide, benzine and hydrocarbons.

Existing legislation has dealt particularly with factories for varnishes and lacquers which have a base of lead compounds. As regards the other varnishes and lacquers, the measures laid down for the chemical industry, hydrocarbons, etc., are valid (see those articles).

Dermatitis and eczemas caused by varnishes and lacquers are subject to com-
pulmonary notification in the Netherlands. Injuries caused by acetate of cellulose varnishes used in aeronautical work are compensated in Great Britain; injuries due to the preparation and manipulation of varnishes, glazes, mastics or dyes containing lead compounds are compensated in Belgium, France and Italy (see, with regard to this, article 'Painting'). As regards the other solvents, see article "Solvents" and those relating to various products used as solvents or diluents.

Ventilation

Ventilation is essentially a technical problem, having for its object not only provision for the renewal of the air in workrooms, but also for rendering atmospheric conditions in them as perfect as possible.

The problem is to effect on the one hand the removal of vitiated air arising either from occupation or the carrying on of industrial processes in workrooms, and, on the other, to replace the air removed by fresh air conforming to requirements of chemical purity, temperature, humidity and movement.

Physiological investigations in recent years (see article "Air of the Workrooms") have made it clear that, apart from the problems created in certain industries by poisonous fumes and by toxic or irritant dusts, the general effects of bad ventilation are due primarily not to any chemical vitiation, but to overheating and stagnation of the air and the effects of such overheated stagnant air upon the rate of heat loss from the surface of the body. The fundamental object of ventilation (except where toxic dusts and fumes are dealt with) is to remove the warm air heated by the oxidations of the human body and to replace it by cool, but not cold, air of moderate, but not excessive, humidity and in moderate, but not excessive, motion.

The first step in securing good atmospheric conditions is therefore systematic observation of the temperature. No schoolroom, no factory workroom, no office, no living room, should be considered as furnished, and fit for human occupation, without a thermometer. Furthermore, a thermometer is of no value without someone to read it; therefore it should be the definite duty of the foreman in the shop to note the temperature at fixed intervals. The regular reading of the thermometer is the first essential in the control of air conditions; and whenever the temperature exceeds 20° C. something should be done to remedy the situation.

Where an unduly high temperature exists, the first thing to be looked to in considering its cause is the question of artificial heat sources. It is very frequently the case that overheating is due, not at all to lack of ventilation, but merely to the fact that radiators or registers are pouring too much heat into the room. Anyone who has an opportunity to study a wide variety of ventilation problems will recall numerous factory workrooms, for example, in which the radiation is turned on full force in October and left turned on till May, with no reference whatever to atmospheric conditions. It is obviously impossible then to consider ventilation intelligently without considering heating as well. There are three methods of heating rooms which are in common use: (1) direct heating effected by radiators or other heat sources within the room itself; (2) indirect heating, effected by supplying to the room air which has been previously heated elsewhere as by a furnace or a plenum-ventilation plant; (3) direct-indirect heating, a combination of the other two in which the heat of the room is partly supplied by warm air entering it and partly by local radiators.

Either direct or indirect systems of heating can be controlled by automatic thermostats. These are devices in which the differential expansion of two suitable metals controls radiator valves or dampers in the air ducts. When in good working order such thermostatic systems are highly efficient. In a certain mechanically ventilated school in New York City, for example, where the thermostats were carefully adjusted, 143 different observations of the room air showed 124 records between 18° and 21° C., with 3 below 18° and only 3 above 22° C. On the other hand it must be recognised that thermostatic systems very easily get out of order. When the same school cited above was visited a few years later its temperature control was found to have become so imperfect that the experiments contemplated had to be transferred to another building.

It is obvious that even where automatic temperature apparatus is installed its operation must be checked up by thermometer readings; and where no such devices are provided frequent attention must be given to radiators and registers.
in order to see that they are not doing harm rather than good.

When a number of people are crowded together in a schoolroom or an office a new problem arises, distinct from that of the control of artificial heat sources — the problem of getting rid of the heat produced by the vital processes of the body. The average human being gives off about 100 calories of heat per hour. An occupied room will therefore become progressively warmer all the time (except in very cold weather when heat losses through walls and ceiling are extreme). The primary objective of ventilation is to compensate this bodily heat production; and there are two general ways of doing this, by natural conditions is greater the greater is the difference in temperature. A chimney likewise acts similarly even when there is no fire.

In these circumstances use is made of the natural openings as inlets for air and the chimney as an outlet.

Sometimes violent draughts may be created by opening doors and windows; but this method, which can only be done in small premises and during intervals of work, presents numerous objections (imperfection of the ventilation, insufficient result, chilling in winter; introduction of dust in summer, etc.).

or gravity ventilation and by artificial or fan ventilation.

1. NATURAL VENTILATION

Circulation of air is always taking place between the inside and outside of a room through openings, the interstices of doors, windows, thicknesses of walls more or less impermeable. It is noteworthy that this natural ventilation is so much the more efficient, the greater the difference in temperature is between the two. Wind acts in the same way, and its action under cer-

The simplest method of ventilation is seen in the window which, if adequately arranged, is very useful for the purpose. Cold air travels downwards to where it is warm, so that it suffices, for example, to open the windows on the first floor on the sunny side and on the ground floor on the opposite side in order to secure a thorough ventilation of the place. On a single floor good results are obtained by openings in the lower part of the windows on the shady side and at the top on the sunny side.

Effort has been made to solve the
problem by making use of various special openings placed in the panes of glass of the windows.

In these instances the chimney usually serves as the outlet. But all sorts of ventilating vents (Tobin’s tubes, etc.) are found. Outlets are also provided by ventilators in the roof, lanterns, hoods with exhausts, chimneys connected with the ceiling, etc. Shafts connected up to exhausts or chimneys are also used. In order to prevent reflux of air when the direction of the wind changes, movable revolving cowl, the action of which is well known, are affixed to the extremity of the chimney or lantern.

This ventilation, to be efficient, must be arranged in such a way that the ventilating shafts are properly placed. The air should be made to arrive in summer at the level of the floor, and in winter at the level of the head or higher, unless special means for handling the incoming air have been provided. The outlets for air should be in an opposite position, and all the openings should be provided with means for closing and regulating them: blinds, shutters, Venetian blinds, etc. The openings at the outlet at the level of the roof should be protected either by a fixed arrangement or by some form of revolving cowl moving with the direction of the wind: with the object of preventing the return of air into the ducts, and to assist the action of the wind as an aspirating force. These installations work even with a difference of temperature of 5° C., but the output is improved by artificial heatings at the inlets and gas rings in the outlet shaft, etc.; this can double or even increase the output by five times.

Where it is a question of the removal of heavy gases and fumes recourse must be had to powerful suction which is often disagreeable and even dangerous for the persons employed. Further, under the roof or close to the walls vertical dead ends may form when the gases may go round in a circle without being removed, and where sometimes the ventilation takes on a reverse direction.

Effort has been made to reduce to a minimum this excess of pressure by the combination of a fan with a kind of ejector (“induced draught”), and by using — as a means of getting rid of the gases — conical diverging diffuser. But this apparatus has its drawbacks; and consequently for some years another method has been adopted (Channard-Etoile) which obviates altogether louvres and flues, ensures a good draught at all times and requires no attention. This is simply a cylindrical cowl closed entirely at its upper surface and communicating with the outer air by seven vertical openings demarcated by projecting paddles and constituting the channels of outlet for the escape of the gases to the outside and inversely preventing the passage of gaseous currents which might try to enter from the outside air into the chimney. The ratio of the resistances offered to the passage of the gases as they go out and come in is of the order of 10 (for the gases trying to enter) to 1 (gases going out).

This apparatus, which is made in sheet iron, cement or fireclay, or other acid-resisting material, can be applied as easily to roofs entirely of glass as to chimneys or to exhaust shafts over hearths or boilers. The slightest breath of wind sets the ventilation going without any trouble; the strongest draughts do not interfere with its action, nor do the sudden starts of the slightest back draught. This form of natural positive ventilation without mechanical parts is used widely in factories for the removal of steam, hot air, poisonous gases and air thick with dust, etc.

It would seem, however, that the simple system of horizontal wafters (Knappen system), used in recent years, is not open to most of the criticisms directed against natural ventilation.

Exhaustive experiments conducted by the New York State Commission on Ventilation in America have led to the conclusion that the best system of ventilation for the average schoolroom is a system of modified window-gravity ventilation; and this system is likely to prove entirely adequate for the small factory workroom unless special heat sources, such as annealing ovens, forges, etc., are present and unless the processes of work lead to the liberation of objectionable fumes and dusts.

The system in question involves three essential elements: (a) the admission of air at the windows over slanting window panes so placed as to deflect the incoming air upward and to mix it gradually with the air of the room; (b) the placing of radiators beneath the windows so as to temper this incoming air; and (c) the provision of a gravity exhaust duct to remove heated air from near the ceiling.

In order that the window-supply gravity-exhaust system may operate most successfully it should include the following provisions:

(a) Radiators must be located beneath the windows and extend for the full width of the windows from which the air supply is to be derived. These radiators, being much larger than
those customarily installed in ordinary plenum systems, should be either automatically controlled by intermediate acting thermostats or equipped with fractional or modulating hand-controlled valves, placed at the top of the supply end of the radiator. Even when automatic control is included it is best to supplement it by the provision of hand control as well; and standard metal radiator shields are desirable to protect those nearest the radiators from excessive heat.

(b) Deflecting boards of some satisfactory type should be placed at the bottom of the windows. Devices which include small box-like openings, and devices which involve the use of filtering screens of various types are undesirable. A plane glass deflector one foot high is fairly satisfactory, but the best results may be obtained by the use of curved vane deflectors which secure the most equable distribution of the air.

(c) In order to avoid certain practical difficulties it is recommended that windows should be so constructed as to open easily from the bottom, and that window shades should be firmly attached to the window frame, the best arrangement being that which includes two shades anchored midway between top and bottom, one to be pulled upward and the other downward, these shades being so guided by cords and pulleys as to avoid the shaking of the screens by the incoming air flow.

(d) Exhaust ducts having a total area of not less than 0.75 sq. m. for a room of 450 cu. m. capacity containing some fifty persons should be provided on the wall opposite the windows. These exhaust openings should be conveniently dampered so that their area may be adjusted to varying weather conditions. The exhaust ducts should be carried up through the interior of the building so as to avoid chilling and the tendency to back drafts should be further reduced by placing an aspirating cowl on the opening at the roof and perhaps by placing heating coils in the exhaust duct.

Such a system of window-gravity ventilation, in a workroom of the type described, will effect an air change of 30-50 cu. m. per person per hour and will keep the carbon dioxide content of air generally below 8-10 parts per 10,000, an entirely satisfactory result in the light of modern knowledge.
2. Artificial or Fan Ventilation

In large workrooms, (containing more than fifty employees) and in workrooms where the heat produced by the human body is supplemented by the influence of special heat sources, window-gravity ventilation will generally not suffice and recourse must be had to a system of forced or fan ventilation which may be of three principal types:

(a) exhaust ventilation: air is drawn from a room by appropriate fans, the renewal of air taking place automatically from natural openings or from inlets suitably placed at distant points;

(b) pressure system of ventilation: the air is driven into the workroom by means of fans and a system of pipes provided with openings; the air escapes through special openings or through doors and windows;

(c) mixed ventilation: a combination of the two systems.

Whatever be the system adopted, two other questions of the first importance arise: choice as to the air to be introduced into the room and its distribution.

The air should be as pure as possible, freed from dust and germs and toxic or unpleasant gases and vapours. In some cases the filtration of the air before its entrance into the workroom may have to be effected. The air should be drawn from a certain height, by means of ducts outside the zone where the prevalent winds might contaminate it. In summer, if necessary, the air should be freshened and in winter warmed beforehand, in order to keep the atmosphere within as good limits of temperature as possible.

Distribution should be such as to allow the air to enter and reach the workers in a pure state, without setting up unpleasant draughts. If the incoming air is cooler than that of the room, it should be brought in at a low level and be removed above. Warmed air should be introduced at a higher level. It is known that air as it cools tends to fall; this is why outlets should be at the floor level. It is advantageous to multiply the points at which air enters and contaminated air goes out.

The common arrangement of placing a propeller (helicoidal) fan in one wall and on the other another extracting fan of the same capacity is not altogether satisfactory, because experience has shown that, unless the air is well stirred up, a direct draught is set up between the two fans and the air in the lower portions of the room is not at all, or only slightly, renewed. The workers, too, placed in the line of the draught are too often inconvenienced and liable to take a chill.

A. Exhaust ventilation is the procedure generally adopted because it is the most direct, the simplest, the cheapest to install, the easiest to maintain, while being at the same time very fairly efficient. The most efficacious method is to arrange for thorough ventilation by means of fans placed on one side of the room and inlets on the opposite one. When the workroom is very large the fans can be placed on both sides, the air inlets being in the centre. The main advantage of this arrangement is that a minimum force is needed to ensure the mixing and movement of air.

The necessary exhaust draught is provided by mechanical means: air pumps, piston machines, etc., are now replaced by fans which have many advantages, furnishing as they do unlimited quantities of air; they are controlled easily; allow of changes in the physical qualities of the air as regards temperature, humidity, etc.

Generally helicoidal propelled fans working at low pressure are used (Backmann ventilating fans). Although the types vary very much, according to the forms given to the blades, they have nevertheless characters in common. They are made up of inclined blades, each being a portion of the thread of a screw. The blades mounted on an axis are either belt-driven or are set in motion by a motor. The direction of movement is from left to right, and the air drawn from the belt-driven side is discharged on the other side of the fan. When this acts on a closed room it commences to extract a certain quantity of air, so that the remaining air is under a negative pressure as compared with the external air. In these circumstances, especially when the revolutions of the fan are numerous, as much as 8-10 mm. of vacuum is reached — a limit which should not be exceeded.

Some details on this subject may not be out of place: the shape and position of the blades of the fans are calculated so as to yield a maximum output. Each fan has further, in relation to its construction, a more or less determined limit of variation in velocity for its maximum output, the yield varying directly with the velocity. The output of a given type of fan, making a prescribed number of revolutions and running under suitable conditions of air circulation, is proportional to the velocity and the cube of the diameter.
of the fan according to the formula $C = K \times D^3 \times N$, where $K$ is a constant, $D$ the diameter of the fan, $N$ the speed of revolution per minute, and $C$ the output per minute. The value of $K$ varies with the make and in particular with the inclination of the blades. Practically it oscillates round the figure 0.6. The number of blades is usually six, sometimes eight, but never more.

The fan only works correctly against a slight resistance, allowing of a minimum expenditure of energy. Naturally the output diminishes as the resistance increases. The conditions for successful working are:

(1) Plenty of air in the room where the fan is placed, and several correspondingly large air inlets.

(2) Arrival of fresh air at the point of aspiration. If the fan is placed at a level higher than that at which the exhaust is required, a hood must be placed round the fan sufficient in size not to interfere with its proper working.

(3) If the fan is placed in a corner of the room, a duct should be placed along the opposite side with openings increasing in size the further they are from the fan, so that the air drawn in at each opening should be as nearly constant as possible. The duct in this case should have a diameter equal to that of the area of the blades of the fan, and should have smooth and straight walls.

(4) Free discharge for the air. If this is made into a chimney, it should have a cover as a protection against the rain, placed high enough and wide enough to prevent blocking it up. If the discharge is made into a duct, the diameter of this duct should be greater than that of the fan. If the fan is placed at an angle of 45° to the duct, the junction should be curved so as to avoid friction and increased resistance to the discharge. (See also article "Dusts, Fumes and Smoke".)

(5) The fan should have protection against the wind. It should be placed at the side opposite to the prevailing winds; sometimes the outlets are sheltered so as to make the removal of vitiated air more successful.

(6) A sufficient speed of the fan should be maintained, having relation naturally to the work demanded of the fan. The speed should be meticulously

---

Fig. 195. — Ventilating piping in the packing department. (Hoshi Pharmaceutical Co., Ltd., Osaki, Japan.)
regulated, because if it is more than 83 m. per minute, even with air reasonably warmed, either before or on its entry, disagreeable draughts are felt near any openings. If, however, the air entry is arranged at a point above the heads of the workpeople, and if it is sufficiently warmed, a higher speed than that mentioned can be borne. The total minimum surface area of the inlets should be three times the disc area of the fans. If the latter have a greater speed, this minimum must be correspondingly increased.

Finally it should be remembered that the power of a fan varies as the cube of the velocity. Better results, therefore, are obtained by maintaining a moderate velocity from several fans to ensure the amount of air necessary. No fan, however, ought to run at a velocity lower than that of its limit of maximum yield. According to Walker the consumption in h.p. is given by the formula:

\[ Q^2 = 0.0000115 - \frac{h.p.}{D^4} \]

where \( Q \) is the output in volume per second (1/60° of C; see preceding formula) and \( D \) the diameter in cm. The power necessary to ventilate a room of 30,000 cu. m. with six changes of air an hour per week (say 180,000 cu. m.) is less than one h.p.

B. The second system is *pressure ventilation*, that by exhaust draught being insufficient to ensure very great changes of air. This system enables the air in a workroom to be diverted to selected points, distribution being effected by suitable piping.

Pressure ventilation is a suitable method of distribution of fresh air to places where work is carried on at high temperatures (glass furnaces, casting, etc.). It is suitable also for ventilating underground or other premises which, owing to their situation or surroundings, are difficult to ventilate by exhaust.

The types of fans used are extremely numerous; but those mostly employed to-day are high-pressure centrifugal fans. They consist of vanes mounted on a circular frame often assuming the form of a cone like the turbine. The whole turns around an axis in the direction of the concavity of the vanes and is enclosed in a metallic envelope with an opening of large diameter on one side, situated concentrically to the axis called the “eye”. On the other side is the frame supporting the envelope and axis of the turbine. The fan is belt driven, worked by a pulley, or set in motion directly by a motor. The air enters at the eye and is driven out on the opposite side, having been forced against the periphery by the vanes, and is thus driven into the room or along the piping.

According to Boulin and Leclerc de Puligny a fan with vanes 0.60 m. in diameter sets up a negative pressure of 40 to 300 mm. with from 900 to 2,500 revolutions a minute. The output increases proportionately from 640 to 1,700 litres.

The ventilation of large workrooms is carried out under an average pressure of 7.5 cm., the pressure corresponding with the output of a given fan. It is, however, not possible to lay down any simple law for these types of fans as can be done for low-pressure volume fans. Every change in velocity modifies the pressure in the system. Further, the fan can be connected up to main and branch ducts and to installations having different resistances to the air movements.

For a constant resistance the following laws hold:

- The volume discharged by a fan is proportional to the angular velocity, or rather to the circumferential velocity, that is, to the number of revolutions;
- The pressure produced is proportional to the square of the angular velocity;
- The power taken at the brake is proportional to the cube of the velocity.

In practice, use of fans with low pressure and ducts of large diameter is to be recommended, for it would be a waste of useful energy to displace large quantities of air for general ventilation by means of great velocities and piping of small section.

The pressure system increases, although only slightly, the pressure in the room ventilated; and this causes the imprisoned air to escape at all possible openings that can be found. Consequently to ensure good circulation of air it is indispensable to provide suitable outlets arranged on the same lines as those for exhaust ventilation.

*Plenum* ventilation is often combined with air washing or artificial humidification. In such a system the incoming air is first heated to a moderate degree (10° to 21° C. depending on various conditions) by passing through *tempering coils*, which are lines of steam piping like those in an ordinary radiator, but so constructed as to pre-
sent the largest possible surface to the rapidly moving air. From the tempering coils the warmed air passes through a spray chamber or humidifier. This is a chamber filled with a fine mist of water produced by some form of spray discharge, and at its outlet end the air passes between a series of overlapping eliminator plates or baffles which change its direction suddenly many times. Contact with these baffle plates removes the excess of moisture which drains off from the eliminator to a collecting pan below. Three things occur in the spray chamber, when it operates success-

fully. The air is humidified nearly to the point of saturation. It is cooled by the loss of the amount of heat required to transform the water taken up from the liquid to the gaseous form (2° to 5° C. in summer time), and it is washed free from a portion of its suspended dust particles.

Finally, on leaving the spray chamber the air passes through a second set of heating coils, where its temperature is brought up to the final point desired, ranging from perhaps 15° C. where the removal of the heat produced in an auditorium is necessary to 65° C. where a large amount of indirect heating must be accomplished.

The temperature of the air delivered by the fan may be regulated automatically by thermostats controlling either sections of the heating coils or dampers which admit a varying proportion of by-passed air, not exposed to the heating coils at all. The humidity of the air delivered can be regulated by controlling the relative temperatures of the tempering and the final heating coils, since the air passing the humidifier is supposed to be saturated at the temperature at which it leaves the spray chamber, and its

final humidity will obviously depend on the increase in temperature to which it is subjected after this point.

From the fan chamber, the tempered air is delivered to the various parts of the building by a system of ducts carried up, through, or along the walls. It may be pointed out that many systems of fan ventilation in actual use fail to give satisfactory results because the ducts are so imperfectly proportioned as to distribute the air unevenly between the different parts of the building. The problem of the proper proportioning of air ducts

---

**Fig. 196.** Ventilating piping in a chemical laboratory. (Hoshi Pharmaceutical Co., Ltd., Osaki, Japan.)
is by no means a simple one, as emphasised particularly by the studies presented in the Second Report of the British Departmental Committee on the Ventilation of Factories and Workshops (1907). It is important that individual duct dampers should be provided so that the air supply to each room can be independently governed; and by somewhat elaborate but wholly practical systems of double or individual duct ventilation even the temperatures of each room can be separately controlled to meet varying conditions of weather and occupancy. Where air is delivered to a large factory workroom by a long duct running along the ceiling it is common practice to construct the duct with a tapering form, becoming gradually smaller from the inlet to the outlet end. Recent studies have shown that a uniform straight duct is likely to give quite as good results; but the section of the main duct should in any case be some 20 per cent, in excess of the sum of all subsequent branch ducts. It is most essential that branches departing from the main duct be slanted forward in the direction of the main current so that the air will not be subjected to a change in direction of more than 30°.

Even with a well thought out system a great loss in efficiency results from eddies at the point where the air flow is changed, particularly with the branch ducts and at the level of the openings placed at intervals along the sides of the pipes. Adequate arrangements allow of remedying this inconvenience. Cleaning of the piping, it should be remembered, should be done at openings specially arranged at suitable points.

By this system the air, as has been said, is led generally to the points of distribution along cylindrical metal pipes placed above the heads of the workpeople; but the discharge points should be placed so as not to cause draughts striking directly on the persons employed. On the other hand the air ought not to be made to enter too close to the ground, as this would raise the dust and dirt and might cause trouble of another kind.

The linear velocity of air maintained in systems of fan ventilation will usually vary from 400 to 700 m. per minute in the main duct near the fan. As the air passes through horizontal branch ducts and vertical stacks its velocity is gradually reduced and at room inlets it is usually between 100 and 300 m. per minute. It is desirable that it should not exceed 100 m. per minute at such points in order to avoid unpleasant draughts. If, then, it is desired to provide an air supply of 1 cu. m. per person per minute the inlet registers in any room should have a total area equal to 0.01 sq. m. per capita.

C. The third system finally is only a combination of both the exhaust and pressure systems. In this case exhaust fans are used in conjunction with centrifugal ones. The first are installed in relation to the air inlets so as to ensure complete ventilation of the room with such movement of air as is necessary for the position at which the work has to be done. In large sheds even it is possible with a good system of ventilation to avoid stagnant pockets of air. Installations of locally applied ventilation are, therefore, desirable at times in addition to general ventilation.

Where special heat sources, such as forges, melting pots, annealing ovens and the like are present, and where toxic fumes are generated, it is essential to install special local exhaust ventilation, sufficiently powerful to remove the toxic or otherwise harmful substances at the point where they are produced. In such cases the sources of the heat or fumes should be equipped with hoods connected by ducts with exhaust fans which, if properly designed and operated, often prove highly efficient. It is, above all, in connection with grinding and polishing wheels and similar dust-producing devices that the principle of local exhaust ventilation finds its most general application. The chief conditions essential to the success of an exhaust system for the removal of dust from grinding and polishing wheels are four in number: the design of the hoods themselves, so that the point where the dust is generated may be covered as completely as possible without interfering with the work, and as closely as possible so that a full suction velocity may be maintained; the arrangement of the suction draft so that it may operate with, and not against, the centrifugal force which throws the dust particles from the wheel; the elimination of all obstacles between the hood and the main exhaust duct which may decrease the velocity of suction; and the maintenance of an adequate suction head in the main exhaust duct itself.

Observations made by Greenburg show that such systems of special exhaust ventilation may keep the air of a grinding shop almost as free from dust as the atmosphere of an ordinary room. In one typical workshop, with forty-nine polishing wheels more or less constantly in operation the dust
content of the air was kept down to 8,000 particles per cubic metre with the exhaust system in operation, while when the velocity of the exhaust fan was reduced the count rose to 30,000 particles.

Modern research and experiment have tended to reverse the views held up to now. These were during the last forty years that the optimal conditions of a good system of ventilation were intense renewal with a very low velocity of the air close to the occupants (plenum system). To-day, according to the reports presented to the second Congress on heating and ventilation (Paris, 1925), the view is held, especial-

ly in towns where the air which is drawn in is likely to be dirty, that circulation in a closed circuit, treating the air, in its passage through the premises, so as to rid it of mineral or organic dust by washing and freeing it of smells and micro-organisms by filtration (ozonization) offers the best conditions.

An average renewal of 50 cu. m. per head per hour would involve a considerable expenditure in fuel. Effort is made to economise by first applying a partial recirculation of the air. The experiments of Larson (1916) show that, with a temperature of 19.5° C. and a relative humidity of 60 per cent. 20 parts per 10,000 of carbonic acid are found, and an economy equal to 40-50 per cent. in fuel is effected.

It is not necessary to cite here the accounts of General Morin (1869) according to whom 30 cu. m. of air per head per hour, replacing 15 cu. m. in a textile factory in France, reduced the daily absenteeism from sickness from 10-12 to 3-4, and increased production by 6 per cent., nor need there be quoted in detail the results of the enquiry by the Inspector of Factories, Williams, of Manchester, after the coming into force of the Cotton Cloth Fac-

Fig. 197. — Ventilation and humidification in a weaving shed (by cooling in summer and warming the air in winter). (Installed by Kestner and Neu of Lille.)

ories Regulations limiting the maximum proportion of carbonic acid gas allowed (diminution in sickness rate, increase in wages, better quality of production, etc.). It is well, however, to recall the data collected by the British Minister of Munitions during the war: good ventilation increases output by about 12 per cent.; output falls off in summer by about 3 per cent., even if the workroom is well ventilated; by 10.4 and even 13.4 per cent. if it is badly ventilated. In Italy Loriga obtained the opinion of a glass manufacturer who assured him that, by the installa-
tion of a good system of ventilation over the glass works, he had obtained a constant output all the year round. Finally, the Hamilton Watch Company of America has stated that with a good system of ventilation the personnel was able to produce in a nine-hour day what formerly they did in a ten-hour day.

**Heating the Air**

The air requires to be warmed when it is taken from outside in winter or when heating is necessary on technical grounds. The inlets should be arranged behind the heating apparatus (several factories utilise the furnaces or boilers for driving machinery), or are surrounded by either steam pipes at low pressures or by hot water pipes from contact with which the air becomes heated to the desired temperature. The heating system with low pressure steam pipes would seem to be the best, the heating surfaces not being so great as with the hot water pipe system. Whatever be the means used, they must be such that, apart from the action of the fans, warm air tends naturally to come into rooms to be ventilated and not to go out by the openings intended to act as air inlets. When it is a question of plenum ventilation, the same arrangement is made (batteries of pipes or radiators) placed in the main duct not far from the fan.

**Freshening the Air**

In the course of a warm season for certain operations done close to where there is a high temperature (glass works, foundries, etc.), it becomes necessary to freshen the incoming air. This is effected by making the air pass through subterranean channels where it is cooled. Or a diminution in the temperature of the air can be obtained by means of water either by contact or evaporation.

The question of humidification of the air is without doubt of the utmost importance. This problem confronts every manager of a textile factory, as well as every manager of a works in which it is necessary to avoid all drying by the atmosphere. Therefore humidification and ventilation should be combined, and not infrequently with heating also. The object sought is to maintain a hygrometric state sufficient for carrying out the process which is as little harmful as possible to the health of the workpeople, while at the same time renewing the air to be breathed.

Textile fibres are hygroscopic and work more easily if kept in an atmosphere the temperature and humidity of which are suitable. For long it has been known that certain regions favoured by a moderate temperature and a humidity sufficiently marked in degree enable counts to be spun finer than can be spun in other districts. Hence the necessity in other regions of humidifying the atmosphere artificially.

The first humidifying apparatus consisted of moist surfaces utilising natural evaporation (vats or troughs in which hot or cold water circulated) cascades or travelling bands of cloth moistened by water of different temperatures and placed in or near a draught. Subsequently recourse was had to artificial evaporating apparatus, various forms of humidifiers, etc. The first encouraging attempts at humidification and ventilation date from 1899-1900. But the problem of humidification is rapidly converted into a more complex problem: that of freshening. There is no need, as is brought out in the article on "Air—Hot and Humid", to try to maintain in spinning and weaving sheds a relative degree of humidity without fresh air, on the ground that draughts would be injurious to the technical process. Years ago, in their construction and technical arrangement, effort was made to avoid all contact with the external air; the spinning rooms were placed in the centre of the building, surrounded by other work-rooms; the roofs were of double glass; there was no removal of the air, etc., which entailed serious injury to the health of the persons who were compelled to occupy the rooms. This was the time when a "draught" was synonymous with "fresh air".

Modern installations, on the contrary, are based on the principle of introducing moist air instead of removing the warm air to the outside and of placing the shed under a positive pressure instead of a negative. Freshening the air is thus strictly linked up with ventilation and humidification. The apparatus that may be used to attain the object desired depends on incorporating water with the pure air by prolonged contact of the liquid with the gas, or by pulverising or intricate mixing, or by humidification obtained separately from ventilation. Of such apparatus there are three distinct forms: (a) the saturators which humidify and refresh, making use of air that has been prepared beforehand in chambers or special apparatus. The air carries with it the quantity of water corresponding with its degree of saturation; (b) the vaporisers in which the second completion is effected in the shed because the air draws with it, in the form of a mist, atoms of water which thus evaporate a second time; (c) the saturators in which the air is prepared in the shed and not in special chambers; the ventilation accompanies and assists in the evaporation of the water, and this work is effected in distinct apparatus.

The installation of the humidifying and ventilating plant ought to be taken into consideration at the time the factory is built. The air prepared in a special chamber is distributed through the rooms by means of special pipes placed in the thickness of the ceiling. In principle this installation should comprise a high pres-
sure fan of large capacity capable of supplying the quantity of pure air necessary (naturally the diameter would be calculated according to cubic capacity of the rooms to be ventilated); batteries of steam radiators for heating the air driven in by the fan (in winter for example); a humidifying chamber in which the air is charged with water vapour by contact with jets for pulverising the water arranged in the manner of baffle plates; a system of piping to distribute the humidified air through the rooms.

As has been seen above certain systems do not comprise distributing pipes.

All these systems, it should be remembered, create fairly considerable variations of temperature and humidity in different parts of the rooms, and produce draughts. This is why the installation of a humidifying ventilation system demands very careful study beforehand, and a perfect application of technical principles. Naturally the experts must decide the variations in method they introduce based on these simple data.

When, on the contrary, it is a question of premises already built and where nothing has been arranged for, special plant can be used including generally a pressure pump, pulverising jets and piping for bringing into the room the humidified air (atomisers).

The installation ought to assure a quantity of water in excess of that required to absorb all the calories given off in the shed. What happens is that a quantity of raw material goes into the shed where it undergoes one or more operations and is warmed or chilled according as the temperature of the room in question is higher or lower than that of the room in which the material has been previously treated. A quantity of heat can then be absorbed or given out; all this must be borne in mind in making the calculations.

The hygroscopic capacity of the material, its weight (kilograms per hour) must also be considered. The greater the less affinity of the textile material for water can be fairly well estimated by the amount which is taken up in conditioning as, for example, 8½ per cent. for cotton, 12 per cent. for linen and hemp, 18½ per cent. for combed wool, 17 for carded wool, 11 for silk, etc. Tables enable determinations to be made for calculating the quantity of water absorbed by a given textile placed in an atmosphere containing a given degree of humidity. Experts to-day can calculate exactly the renewal of air necessary, as well as the quantity of water which it is necessary to evaporate to obtain a given hygroscopic state and a given amount of air to be introduced.

The most important factors in the calculation are the maximum degree of humidity which the textile work can stand, the maximum temperature which can be allowed in the air of the room, the outside temperature and humidity in relation to the results to be obtained.

Details are given in the articles on textiles (cotton, wool, flax, etc.). So far as temperature is concerned it is admitted that the optimum is reached, with an outside shade temperature to the North and at 2 p.m., when at least 28° C. is recorded and a relative humidity of 45-50 per cent.

The technical expert is provided with formulas for calculating installations such as atomisers, saturators and vaporisers.

Neu gives in the following table the data for each type of installation according to the quantity of water to be evaporated and of air to be introduced to absorb 100,000 calories in a room in the inside of which it is desired to maintain a temperature of 28°C. and a relative humidity of 60 per cent., when the outside air is between 28° and 45° per cent.:

These data permit of the following conclusions: "When an installation of atomisers is in question, the higher the state of humidity which can be maintained the less will be the number of changes of air required to maintain a temperature of 28°C. It will be sufficient to continue evaporation of the same quantity of water in the shed by passing a certain amount of air from the inside of the room into the apparatus. If the change of air is not limited, this type of plant will allow renewal to be obtained which will be dependent on the state of humidity, and the temperature of the room will fall making it possible to reach 24° to 25°C. with a relative humidity of 90 per cent., that of the external air standing at from 28° C. to 50 per cent. In the case of vaporisers similarly less air is needed to maintain a temperature of 28°C. with a relative humidity of 90 per cent. (Neu). On the other hand, when the air in the workshop is too humid and the steam and mist which form interfere with work being carried on and so affect output (see
the article "Air: Hot and Humid"), it is absolutely necessary to ensure desiccation of the air. For this object processes by means of hygroscopic substances (such as chloride of lime, magnesia, etc.) can only be effective in quite small rooms. In practice recourse is had to the following three methods:

(a) increase in the temperature of the surrounding air;
(b) removal of the steam by exhaust ventilation;
(c) ventilation with warm air.

(For details see article, "Air: Hot and Humid.")

CONTROL OF VENTILATION

Naturally it is right and useful to be able at any moment to control the general or local ventilation, if the objects in view are to be adequately attained.

The purity of the air can be determined by suitable analyses of the carbonic acid gas, the gases, the dusts, the temperature and humidity, etc. (See the articles, "Air: Diminished Pressure", "Air: Testing in Workshops", "Air: Hot and Humid", etc.)

The velocity of the air can be measured by anemometers or by the katathermometer.

The formulas established by L. Hill for his kata are the following:

(a) For velocities equal to or above 1 m. per second:

\[ v = \left( \frac{H - 0.13}{0.47} \right)^5 \]

(b) For velocities equal to or below 1 m. per second:

\[ v = \left( \frac{H - 0.20}{0.40} \right)^2 \]

where \( H \) is the loss in heat in milli-calories per second and per c.c., and \( \theta \) the difference between 36.5\(^\circ\) C. and the temperature of the room in degrees Centigrade.

The pressure of the air exhausted or driven in can be determined by manometers or suitable pneumometers (Krell and Prandtl apparatus, for instance).

When the room is ventilated mechanically, the standards of ventilation can be estimated by the output of the fan by means of the anemometer, which gives the average velocity of the draught at the point where the air enters or where it is exhausted.

Technical experts have determined certain objective standards (under the name of "constants") which are sometimes laid down in regulations.

Besides chemical constants (oxygen, carbonic acid gas percentage) there are physical constants to be thought of: temperature, humidity, cubic capacity of the rooms; rate of air renewal (the minimum standard would seem to be six changes per hour for sedentary workers, to be raised to ten for more active workers); velocity of circulation of the air (15 cm. to 1 m. for sedentary workers, 1 to 1.75 m. for semi-active, 1.75 to 5 m. per second for active work).

Biological standards must also be borne in mind in their bearing on the various sensations affecting the air of a room: the feeling of freshness, smell, closeness, etc. These various sensations, however, do not, by themselves, permit of a determination of the efficiency of a system of ventilation.

The ultimate basis on which physical and chemical standards of ventilation can be laid down must rest on the physiological results recorded.

LEGISLATION

Vocational Guidance and Selection

The problem of vocational guidance and selection has occupied thoughtful men from the most remote times. Even in Plato's Republic, Socrates puts the question: "Should each person carry on, for all the others, the trade for which he is fitted; for example, should the husbandman provide the food of four persons, or should he, without considering others, devote a quarter of his time to seeking his food, and the remainder to building his house, and making his boots and clothing? It seems to me that the first method would be of the greater advantage to him." In this same dialogue it is said that things are done "better and more easily when a man only does work adapted to his capacity and at a time agreeable to him." In another dialogue, "Laws", the necessity for specialisation in requisite production is recognised, and it is there stated that "no ironworker works in wood; that no worker in wood is under the orders of workers of iron; and that each practises a single trade from which he derives his living". The idea of fitness perfected by specialisation is expressed by Xenophon in a somewhat uncertain manner when he states that "an individual whose work is confined to a speciality should of necessity excel in it".

In the Middle Ages the question of vocational guidance was considered from the doctor's point of view by Paul Zacchia, who studied carefully the aptitudes necessary for service as a monk.

In more recent times Pascal recognised that "the choice of an occupation is the most important thing in life", and Diderot added that "the man who is entirely fitted to his occupation, if he has genius, ought to be a prodigy; if he has not genius, unremitting application will raise him above mediocrity". Ramazzini also, in his classic work, has not neglected the medical aspect of vocational guidance.

It was not, however, until recent times, when mechanisation of industry has carried division of labour to an extreme degree, that the question of fitness and of the choice of a vocation has once more been forced upon attention and has demanded study by modern scientific means.

Vocational guidance of workers in industry has for its aim to recommend a vocation or a definite occupation to a man who possesses the necessary
fitness for the said vocation or the said occupation; on the other hand, vocational selection seeks, for a given occupation, the man possessing the fitness which makes him capable of carrying it on with success.

In 1906, in a short report submitted to the First Congress of Occupational Diseases, at Milan, De Giovanni dealt with the relations between these diseases and the personality of the worker, emphasising that the study of the human body, from the point of view of its structure, shape and functions, shows repeatedly great variety in types of structure and individual physiological variations. Hence arises the varying power of resistance shown by individuals to the same work and to various kinds of injuries which the work in question may cause. Preventive medicine should furnish advice to operatives as to the quality and quantity of work in relation to individual fitness, and should also show them how to increase as much as possible their output and prolong their working life. In fact, a great advance will be accomplished when the knowledge obtained suffices to fix, on a scientific basis, the criteria for determining the physical type of worker suited for any given occupation. De Giovanni says that only morphological, rather than anthropological, criteria can provide an adequate idea of how the functions of physiological correlation occur in an individual who is to be placed on a given kind of work.

There must then be considered procedure which, in the case of guidance, is applied in the interest of the worker and the factory; in the case of selection in the interest of the factory because, in the first place, what happens to workmen whose aptitudes do not fulfil the demands of the business is not taken into account. The employer arranges the work of selection so as to exclude the weak and inefficient, without concerning himself with the extent of this weakness or inefficiency. There are, however, experts who consider that after having satisfied the requirements of industry, which, at achieving increase of output, selection also contributes “to the happiness and success of the individual worker” (J. S. Rowntree).

Whether it is a case of guidance or selection, advantage is obvious as much for the management of the works, in reducing the number of useless workers and diminishing labour turnover or changes in the personnel of the works, as for the wage earner, who, from the fact that he is placed in a vocation for which he is well suited, finds his work to his taste and effects it with greater success.

In large concerns, where the posts are numerous and varied, vocational selection coincides, to some extent, with vocational guidance. Although confined to a limited sphere, it endeavours to satisfy, as far as possible, the needs of the working-class community. According to the National Industrial Conference Board, in 255 large American factories which have practised selection of their personnel for some years, no complaints are reported, beyond objections raised by individuals whose occupational fitness was below the average, either through disease or physical infirmity. But even for such persons, experience has shown that, placed in work which suits their physical condition, they may become useful and contented workers, representing a profit rather than a reduction in the output of the factory.

The importance of physical condition in relation to the output of work has been emphasised in the case of vocations calling not only for muscular efforts or for considerable bodily resistance, but also for psychological fitness. In the case of salesmen, for example, height and weight, according to H. A. Richmond, should be in proportion to their capacity for work.

Petrazzani and Patrizi, between 1907 and 1909, considered independently of each other the expediency of an examination into vocational aptitude in the selection of motor-drivers. This was the starting point for the numerous studies which have subsequently contributed to progress in this domain.

Selection is also regarded as a factor in the prevention of accidents, especially in countries where legislation makes the employer responsible for injuries sustained by the worker, or in the case of industries in which the work is particularly dangerous, such as railways and aviation.

The importance of personal aptitude in the production of accidents has been dwelt upon by a number of authors. Thus, for example, Stephenson found that diminution in the number of accidents sustained by apprentices did not depend solely on the degree of skill attained by the workers in proportion to their practice at their occupation, but also, in large part, on their innate manual dexterity. The figures showing the comparison between the frequency of accidents among competent and incompetent beginners were as 1 is to 1$\frac{1}{2}$, whilst they became as 1 is to 3$\frac{1}{4}$ for those two categories respectively at the end of their apprenticeship. This study showed that cer-
tain dispositions or aptitudes cannot be developed or perfected by exercise, and that it is necessary to select workers carefully before allowing them to engage in occupations for which they are not sufficiently suited.

By analysing some important figures on accidents to railwaymen, E. Schmidt found that 78.8 per cent. of cases occur to persons who have had previous accidents. This authority, like Pen, has emphasised that there is a predisposition to accidents which must be taken into account, especially in the case of work which is associated with risk.

This predisposition has also been studied by Eric Farmer and E. J. Chambers among sixty-four apprentices and forty workwomen. They noted the number of accidents which happened to these persons over a fairly long period, and included even insignificant wounds which required only a slight dressing. The results did not show any correlation between intelligence and a predisposition to accidents. On the contrary, accidents were found to be clearly associated with disordered or insufficient sensory-motor functions of kinesthetic co-ordination, or with temperamental derangement.

On the other hand, the same authorities were able to show a correlation between a predisposition to accidents and the individual's output capacity. This capacity was lower than the average in individuals placed on work for which they were unsuited; and these workers also sustained a larger number of accidents. These individuals had given less satisfactory results when submitted to an examination made by means of qualifying tests.

Vocational guidance and selection require a careful examination of the physical and mental constitution of each prospective worker, as well as an analysis of the vocation. In the first place, collaboration between the psychologist and the doctor is required. The psychologist, in the person of the school-master; who in reality is only a practitioner of psychology, must seek out psychological aptitudes; hence arises collaboration between the school and those interested in vocational guidance.

For physiological aptitudes, recourse must be had to the doctor, who is alone able to understand the functioning of the human body; and his habit of thinking biologically must be brought into play.

Efforts have sometimes been made to distinguish between the psychologist and the doctor, but at the present time such discussion is quite useless. Incomprehension of the pathological condition by the physiologist has also been claimed. In the present-day state of knowledge this is also a futile attitude, for physiology and pathology are interwoven, and it is impossible to understand one without the other.

Thus participation of the doctor in the work of occupational guidance is indispensable. But it is not provided for in the same way in all countries; only those of certain importance industrially — and in these chiefly a few large centres — have organised this collaboration and attained practical results.

The doctor, usually the school doctor, is generally called on to exercise his skill in the guidance offices, working in association with the employment exchange, where the vocational guidance expert centralises the information supplied by the school, the employment exchange and the doctor.

NATIONAL OFFICES FOR VOCATIONAL GUIDANCE

In Austria, the Vocational Guidance Office of Vienna has organised a medical service on systematic lines. The doctor gives his opinion for or against such or such occupation, gives advice as to hygiene, and directs the weak and sick to the public health offices and welfare centres for apprentices. Good organisation of the medical service has succeeded in attracting the attention of employers, and in several trades employers compel their young workers to pass a physical examination at the time of their engagement.

In Belgium, the Vocational Office of the Brussels district has every young man and young woman who desires advice on the choice of a vocation first of all medically examined and the result entered on a sheet drawn up by the medical officer of the Office (O. Decroly and A. Nyns).

In Czechoslovakia, the central office of the Vocational Guidance Organisation at Prague recommends a medical consultation at the time of choosing a vocation.

In France, collaboration between the employment exchange and the doctor exists, for in most of the Vocational Guidance Offices * the great majority of children are submitted to a careful medical examination; although attempts are still confined almost entirely to negative vocational guidance, yet there and there pathologic examination is beginning to be accorded to the fact that there are two kinds of contraindications: those which are absolute and those which are relative. The latter are susceptible of improvement, though this will only be attained by a better organisation of physical education, or the creation of centres for vocational re-education (Fontègne). The Lyons Office for Vocational Guidance and Employment has

---

* Vocational Guidance Offices refer to the national or regional organizations responsible for providing guidance to the unemployed and assisting them in finding suitable employment.
have examined them from the viewpoint of choosing a vocation.

In Spain, the Vocational Office of Barcelona also attaches great importance to a medical examination for young persons who seek advice on the choice of an occupation.

In Switzerland, there is no general rule for collaboration with the doctor. Such collaboration is however at the present time very well organised at Berne, where the school doctor enters upon the guidance sheet the findings made during the examination of the scholars, there being a compulsory examination for all children during the final school year.

In the United States, collaboration with the doctor is comparatively limited, the employment exchange not making a direct appeal for his intervention. However, a committee of paediatricians and specialists in industrial hygiene, set up by the Children's Bureau, has formulated a number of recommendations regarding the question of fitness for work and the need for it to be dealt with by a medical officer nominated for this purpose.

In addition to these vocational guidance offices, a doctor may be called on to collaborate in the work of committees for vocational guidance. Up to the present, France is the only country where there exists such a national committee, a scientific section of which is "charged specially with the study of problems of a medical nature, physiological, psychological and hygienic, having a bearing on vocational guidance". On behalf of this committee Drs. Lauffer and G. Paul-Boncour furnished a report dealing with the type of vocational guidance sheet desirable (see Appendix to this article).

In some countries collaboration of the doctor in vocational guidance is laid down by law: France (Decree of 26 September, 1922), Germany (Order of the Federal Employment Exchange of 12 May 1923, etc.).

THE PRACTICE OF SELECTION

Measures have been taken in several countries to ensure a systematic method for vocational selection.

In France, a medical selection examination, such as is in force in several public and private concerns, is made a rule on the great railway systems. Some companies entrust this examination to medical specialists. In civil aviation, selection is very careful; particular importance is attached to a general medical examination, without, however, neglecting the special tests. The General Transport Company for the Paris district has the use of a private laboratory controlled by the municipal authorities, which is also intended for the examination of taxi and tram drivers; but the examination is confined to psychomotor reactions, and is in no way medical.

In Germany, it is practised in a large number of industrial firms and in the
transport industry. On the State Railways (Deutsche Reichsbahn) the method of selection was applied in the case of 13,000 apprentices in the repair workshops during the period 1921-1923. In the Berlin trams concern, the management have the employees examined as to their fitness for various duties. In 1926 requests were made by 267 large private concerns for the services of the offices of vocational selection. In all these cases particular attention was given to mental capacity, while a physiological examination, properly so called, when it did take place, was only carried out in a summary manner and as a preliminary.

In Great Britain, vocational selection sheets are in use in a very limited number of industries, and very often have only been elaborated in an empirical manner (E. L. Collis). This gap is to some extent filled by the work of the National Institute of Industrial Psychology of London, where attention is directed, among other matters, to the question of selection.

In Italy, selection is practised in some of the large public concerns, such as the State Railways and the trams, in which the employees are examined medically before engagement, in a manner calculated to ascertain whether they possess the capabilities required to perform a definite kind of work. As regards private industries, medical collaboration is provided for in the methods of selection in use.

In the United States, according to figures published in 1926 by the National Industrial Conference Board concerning industrial undertakings which submit their workers to a medical selection examination, the number of those refused work was negligible in the large works which afforded considerable opportunities of placing. On the other hand these refusals increased in undertakings characterised by advanced specialisation. The causes of refusal were chiefly the following: tuberculosis, venereal diseases, hernia, heart disease, monocular blindness, amputation of limbs, mental weakness, defective hearing, specific varicocele and hydrocele, infectious or contagious diseases, diseases of the kidneys, rheumatism, arteriosclerosis, chronic alcoholism and drug addiction.

A medical examination for the purpose of vocational guidance or occupational selection differs in no way from a general clinical examination. It is characterised solely by its object, and attention is directed to the fitness of an individual for a definite occupation or vocation. For this purpose the doctor should base his opinion on facts furnished by an analysis of the occupation.

The elaboration of an analysis of this kind consists in deciding on the different physical and psychological qualities required for carrying on with success the vocation under consideration. In this work it is of first importance to avoid increasing without limit the number of qualifications required, and to know how to distinguish between the essential and the accessory; every vocation presents a number of difficulties which are surmountable by any normal individual, whilst it is characterised by special difficulties which need special qualifications to overcome them. These latter are the difficulties which the technician, who knows the occupation, should have in view when he is drawing up a list of the essential qualities required (Bolt).

Satisfactory vocational monographs exist only for a very limited number of occupations, and agreement of views on this subject is entirely lacking. Divergencies of opinion abound directly any question is raised of the relative value of qualifications, and of the required degree of accomplishment or proficiency in regard to these (Bolt).

Whilst, for clinical observation, it suffices to follow a general procedure, it is otherwise when choice of an occupation is at stake. As a matter of fact, a description valid for one district may be without value for another, for the processes and characteristics of the same occupation may vary with place and circumstance. Hence the necessity for the local technician and the works doctor to supply particulars relating to the particular aspects of the occupations in the district from the point of view of the human factor. General principles can only be laid down, once for all, by taking as a starting point the element which remains invariable, namely, the human factor.

In England, the National Institute of Industrial Psychology, which supplies industries with vocational monographs on scientific lines, has studied vocation in the workshop, and has given detailed analysis of the mental and physical qualities which are required, chiefly: accuracy and rapidity of movement, attention to details, resistance to distraction and monotony, and accurate judgment of distances, shapes and colours.

In Germany, a bibliography of vocational monographs, which is relatively complete, has been published by the Bureau of Vocational Guidance of the Employment Exchange of the State of Saxe-Anhalt, in collaboration with the Federal Labour Office of the Reich.

In the United States, the large industries have, for some years, introduced into their programme of scientific organisation of labour the elaboration of vocational monographs ("job specification"), in which quite an important part is devoted to such physiological aptitudes as maxi-
mal limits and qualities preferred as regards age, sex, colour, height, weight, length of the limbs, power of lifting, power of grasp, lung capacity, vision, hearing and the degree of infirmity tolerated.

THE DOCTOR’S TASK

The general principles of vocational guidance, according to Fürst, should take into account the following considerations: (a) the general constitutional examination; (b) the examination of the systems of the body; and (c) the sensory organs.

(a) The General Constitutional Examination

Proportions of the body and anomalies in structure: relation between the length and breadth of the body. When this relation corresponds to the age of the individual, the latter will be regarded as biologically correct (Kaup’s law of body proportions). The relation “weight/height” being at a given age the same for individuals of different height, if there is a variation it can be deduced that some anomaly exists in the constitution. Considerable variations call for a thorough examination of the internal organs. The vital index — the relation between weight as numerator and height multiplied by the circumference as denominator — is based on a similar principle.

The general aspect of the individual must be taken into account. In fact, diseases of the thyroid due to excess of functioning (hyperthyroidism) are indicated by a tendency to acceleration of the pulse, with cardiac excitability and by exaggerated sensitivity to heat; such individuals should not, therefore, be advised to take up a vocation which exposes them to high temperatures. The thymic constitution, with hypertrophy of the thymus and of the lymphatic tissue, is characterised by an abnormal reaction to external influences such as electric currents; it constitutes a predisposition to death by electrocution; therefore persons with a thymic constitution are advised not to take up the career of electrician. Arthritis, or a predisposition to rheumatism, gout and renal affections, are contra-indications for occupations involving danger from cold. The asthenic type signifies a disposition to cardiac and pulmonary affections, and a dusty or sedentary occupation should not be recommended for such persons.

Some anomalies of growth, without organic disease properly so called, may be combated by such moderate stimulation of growth as mechanical work in the factory; whereas strong stimulation, such as the occupation of builder, blacksmith or butcher, would only aggravate the condition. Occupations which exert a bad influence on growth are those of harnen, hairdressers and tailors, occupations in the printing trade, and work requiring close attention.

(b) The Examination of the Systems of the Body

1. Osseous system. — (i) Vertebral column. Any predisposition to deformity of the vertebral column may be aggravated in the following occupations: office work, tailoring, work requiring great accuracy, and carpentry when working with the plane, if, in the periods of rest, adequate precautions are not taken. Considerable malformation accompanying general and habitual debility contra-indicates an occupation requiring general effort, such as carrying loads. The urine should be analysed when there is lordosis at standing occupations.

(ii) The thorax. — Slight rachitic malformations tend to disappear during the exercise of most occupations. More accentuated malformations are contra-indications to difficult work. Special attitudes may have an unfavourable effect on the development of the thorax; such are those adopted by tailors, workers on close work, like watchmaking and engraving, shoe-makers, carpenters and hairdressers.

(iii) Lower limbs. — Pronounced deformities of the lower limbs and flat foot constitute a hindrance to standing and walking occupations.

2. Respiratory system. — Obstruction to nasal breathing is a contra-indication for all dusty occupations. A history of chest trouble in the family or the individual is important, and calls for a radiological examination. If active tuberculosis is suspected, all hard work must be discouraged, and, if possible, there should be a period of recuperation before entering any occupation. Cases of marked tuberculosis with expectoration, even without bacilli, should be excluded from food industries and from workshops where dust is given off, or where a number of persons are at work. Slightly built individuals

1 Handwörterbuch der Arbeitswissenschaft, article "Berufs-Beratung (ärztliche)", Halle, 1927.
should be directed to open-air occupations and kept under medical supervision.

Asthmatic subjects should be dissuaded from the entering the occupation of glass blower, or from a musical career where wind instruments are concerned.

3. Circulatory system. — (i) Organic lesions are contra-indications for all occupations requiring muscular effort; in these cases sedentary and commercial occupations and most of the technical ones with close work are to be recommended.

(ii) The irritable heart, with Basedow's vasomotor disturbances, renders individuals unfit for occupations entailing great effort; on the other hand, work requiring little effort has generally a favourable effect. Night work, the alcohol and drink industries, and occupations exposing to high temperatures must be avoided.

(iii) Anaemic persons should be advised against hazardous occupations, with exposure to lead and deleterious gases or fumes; they should not work in dark workshops.

4. Abdominal and digestive organs. — Predisposition to gastric affections is a contra-indication to continuous work. Predisposition to dental caries is a contra-indication for the occupations of baker, confectioner and miller. Tendency to habitual constipation excludes from occupations which cause a compression of the abdominal organs. General asthenia, a tendency to enteroposition, hernia or cryptorchidia exclude occupations demanding great effort; renal disease is a contra-indication to work in the open air, due to cold.

5. Nervous system. — The general constitution ¹ must be taken into consideraion, including the torpid type with psychopathy or debility, the asthenic with depressed constitution or nervous excitability; microcephalus or hydrocephalus with debility; the stigmata of degeneration in the face and ears, or congenital malformations.

Psychopathic subjects and irascible and weak-willed persons should be detected, not so much with a view to deciding the kind of occupation they should follow, as on account of the necessity of supervision. Epilepsy is a contra-indication for the occupations of Slater, locomotive engine driver, chauffeur, erecter of machinery or cook.

6. Skin. — Chronic affections on the uncovered parts are a contra-indication for occupations concerned with food or in workshops where the personnel is numerous. Sweating of the hands excludes from fine work; dryness of the skin and a tendency to rhagades excludes from occupations where chemical agents are used. Here the general constitution is of importance.

(c) The Sensory Organs

1. Vision. — Stereoscopic vision is of such value that persons with vision in only one eye must be excluded from fine work as engravers or goldsmiths, and from the occupations of Slater, tinsmith and chauffeur.

² Fende insists on the importance of constitution in vocational guidance which he calls "biotypologic". The knowledge of this biotypology of the worker has for its object the recording of physical and psychic aptitudes, and of the capabilities and deficiencies of the individual in relation to standard efficiency, so that he may be employed in work which suits him best; the noting of morbid tendencies and constitutional weaknesses which may lead to diseases and accidents; the collecting for each individual of facts which may later on be useful for settling any medico-legal question which may arise in case of sickness or accident.

In addition to a human type physically and psychically normal, with a balanced character, Fende has described at least four abnormal types characterised by a want of balance in use of positions of the body, originating functions which create the tendency to definite diseases or accidents. Two of these types are characterised by excess of development of the length, compared with the breadth, of the body...
An examination of the best eye — the one most used — should be made. Sense of light: hemeralopia is a drawback to photographers, drivers and chauffeurs.

Sense of colours: minute examination is needed for the occupation of engine-driver, decorator or photographer. The seriousness of defects of refraction should be estimated according to the possibility of correcting them by spectacles.

Marked myopia excludes from needlework; a tendency to chronic conjunctivitis excludes from dusty occupations or those with a high temperature.

Visual acuity: at least two-thirds for each eye is required for all such fine work as that of opticians, watchmakers, goldsmiths, dentists, turners, printers, engine-drivers and postmen; two-thirds for moulders, sculptors, saddlers, shoemakers, fitters, chauffeurs, and chimney-sweeps, and at least two-thirds in one eye and one-third in the other for blacksmiths, tanners, bookbinders, bakers and agricultural workers.

2. Hearing. — Hereditary predisposition to otosclerosis is a contra-indication to such very noisy occupations as the iron trade, boiler-making, railway work, telephone work and the textile industry.

Chronic affections of the middle ear and affections of the rhinopharynx are contra-indications to occupations in which there is a risk of exposure to cold.

Central perforations of the drum are prejudicial for sailors, fishermen, teachers of swimming, and in some chemical industries.

Perfect hearing is required for the occupations of engine-driver, post office official, gamekeeper, forester, lorry-driver, as well as for commercial and administrative posts in which intercourse is required.

Vestibular examination is necessary in occupations which require a well-developed sense of equilibrium.

It may be added that Chajes collected in 1928, in the form of detailed tables, the hazards which are associated with various occupations, as well as the aptitudes which are required, and the contra-indications which must be considered, in the practice of rational vocational guidance.

APPENDIX

I. — MEDICAL SHEET FOR VOCATIONAL GUIDANCE PROPOSED BY DRS. LAUFER AND PAUL-BONCOUR AT THE NATIONAL COMMISSION OF VOCATIONAL GUIDANCE OF PARIS (DECEMBER 1926)

Date of examination:
Surname and Christian name of child:
Date of birth:
Address:
In Paris since:
Vocation desired:
Hereditary history:
Father (nationality and state of health):
Mother (nationality and state of health, pregnancy, confinement):
Collateral history:

Personal history:

Hygienic conditions of home:

Personal hygiene:

Medical examination

Height standing:
Height sitting:
Weight:
Type: facies, aesthenic, musculature, obesity or wasting.

Born at term? weight at birth? Infancy: walked at? talked at? Afflictions or illnesses: childhood: afflictions or illnesses; history of tuberculosis (glands, suppurations, fistula, pleurisy, haemoptysis). Ventilation and exposure to sun; humidity; crowding. Food; sleep; drink; use of tobacco; habits of cleanliness; sports; various excesses; former, recent or existing contact with infectious cases, and the duration of such contact.

Complementary examination

Relation of weight to height.
Puberty: onset, notation of development, condition of hairiness, menstruation.

Skin and scalp: sweating of hands and feet, eruptions or tendency to, sensitiveness.

Peripheral glands: cervical, at angle of jaw, submaxillary, axillary, inguinal.

The mouth:

Teeth and gums: state of dentition, state of gums.

Rhino-pharynx: coryzas (frequency); epistaxis (frequency); nasal permeability, complete or incomplete; state of pharynx, frequency of pharyngitis; tonsils; adenoids.

Larynx: affections; weakness.

Thorax and shoulder girdle: configuration; venous network; deformities.

Lungs, pleura and hila: affections; weaknesses; respiratory insufficiency; dyspnoea, signs of enlarged bronchial glands.

Heart and pericardium: affections; palpitations; arrhythmia.

Peripheral vessels: pulse; varicose veins or tendency to; disorders of the circulation of extremities.

Abdominal walls: musculature; abdomen fat, flat, hard; state of inguinal rings; hernias, deep abdominal palpitation.

Stomach: appetite; digestion; disorders of dyspeptic origin; vertigo, headaches, nonchalance, irritability, etc.

Intestines: intestinal affections; haemorrhoids.

Liver: hepatic disorders.

Osseous system and joints: bad attitudes; malformations, softness of bones.

Vertebral column: other affections.

Lims: shape of the hand; deformities or anomalies of the upper limbs; deformities or anomalies of the lower limbs; flat feet or tendency to; joints; joint joints.

Nervous system: various affections and nervous disorders; easy ejection; disorders of movement (paralysis), contracture, atrophy, trembling, agitation, tics onychophagia, spasms; sensibility (tendency to neuralgias and headaches); other affections.

Psychic disorders: emotional; very closely connected with organic changes; psychic and character anomalies.

Genito-urinary system; testicular ectopia; incontinence and disorders of micition; analysis of urine.

Thyroid and glands of internal secretion; hyperthyroidism.

Vision of each eye separately and binocularly; affections of the eye annexes; acuity and errors of refraction; colour blindness; the visual field. *

Hearing of each ear; the external ear, the middle ear, the internal ear.

Acuity:

Other peculiarities.

II. — TYPE OF A MEDICAL SELECTION SHEET

<table>

Watch and Clock Makers

The watch and clock making industry has for its object the manufacture of mechanical apparatus of all kinds for measuring time.

The different kinds of work that are met with in the watch and clock industry are the following: foundry work, including rolling, cutting out, pressing and machine hammering; washing, degreasing, and pickling separate pieces, especially those intended for electro-plating; electro-plating, chrome-plating, lacquering with zapon, enamelling, countertracing, soldering, application of luminous paint; stone and glass work. Then comes an extensive field of work requiring great accuracy: adjusting, regulating, finishing and mounting.

The work may be carried on in workshops attached to large shops, and also in small shops which very often confine themselves to repair work.

The watch and clock industry tends more and more to concentrate the manufacture in the same works, instead of passing the watch from workshop to workshop. However, a large number of independent factories exist which are occupied in making separate pieces, such as hands, escapements and cases.

A large number of factories where chronometers are made — especially in countries which specialise in this industry — are equipped with workshops which can be regarded as models of their kind. But, just as often, work is carried on in some of the small shops, or in workrooms behind large shops, or, what is more common, at home; then it is under less favourable hygienic conditions. In fact, in Switzerland work is now very rarely done at home, and this custom tends to decrease more and more.

A watch and clock maker does his work in a sitting position with the head and upper part of the body bent forward; thus he is exposed to the evil of compression of the thorax and abdominal organs. Hence arises frequency of disorders of digestion which are increased by the absence of exercise in the open air.

Sources of Danger

Several injurious factors must be mentioned: dust is one, although it only arises in small quantities coming from filing or grinding such materials as gold, silver, steel, copper and brass. Dust may also arise from materials used in enamelling.

As regards gases, carbon monoxide must be noted, arising from foundry or blowpipe work, and also nitrous gases from pickling.

The preparation of separate pieces for plating, whether with gold, silver, nickel, or chromium, which includes the removal of grease and pickling, exposes the workmen to the action of hot and concentrated caustic alkalis, giving rise to eczemas and burns; to the action of nitrous fumes in pickling; of soda and soap during the washing of watch cases; and of trichlorethylene when the new method for washing cases and bodies is used. Although this operation may be done in closed apparatus, cases of poisoning have been observed, caused either by the faulty manipulation of the apparatus, or by the premature opening of the washing compartment, or during cleaning of the apparatus. Even with perfect management a slight escape of trichlorethylene fumes always occurs when the washing compartment is opened and the washed pieces are taken out (Steiner).

Electro-plating processes may cause exposure to the poisonous action of cyanides used in appreciable quantities in the preparation of baths for gold and silver plating. During hot gold plating fumes of cyanogen and hydrocyanic acid are given off, which should be removed by means of a good exhaust.

Chromium plating, which is coming to be used more and more in the watch and clock industry, is done by means of a solution of chromic acid at about 30 per cent. strength, used hot; the solution is very caustic and poisonous and easily causes eczemas and indolent ulcers. Irritant fumes are given off
from the baths; it is, therefore, necessary to provide a good exhaust.

Enamelling is being replaced more and more by "lacquering" (danger from resins, solvents, etc.).

The application to metal dial-plates of a kind of lacquer known as zapon, which is a solution of nitrocellulose in acetate of amy!l, is effected by means of sprays in front of an exhaust opening if the workshop is well arranged.

The lacquer is dissolved in vessels containing acetate of amy!l.

Painting with luminous paint sometimes causes in sensitive women an irritation of the skin of the fingers and even eczema.

It cannot be claimed that the list of occupational hazards in this industry is complete, owing to the great complexity of the industry, which is extremely specialised. In addition, a good deal of work is done at home, making it difficult to detect the injuries caused by it. Further, a large number of the factories or workshops are small concerns, and by no means lend themselves to the systematic application of prophylactic measures.

STATISTICS

Statistics relating to sickness among watch and clock makers are out of date and not very numerous. In 1896 at Frankfort-on-Maine out of 106 watch and clock makers and mechanics there were 71.3 sick, of whom 33.2 were incapacitated for work. At Vienna also the sickness rate was quite high, especially for the age-groups 21-25 years and 41-50 years. The highest figures were those due to tuberculosis and influenza.

According to the figures of the Local Sickness Office at Leipzig, the total number of days of sickness was not very high, whilst tuberculosis and forms of rheumatism were responsible for quite high figures. Nervous diseases were below the normal.

The English death-rate figures for 1921-1923 also show rates below the average. Respiratory diseases show very low figures, whilst suicide is fairly common.

PATHOLOGY

The occupational pathology of watch and clock makers is not very important. There exists a belief that the most characteristic disease of watch and clock makers is myopia, promoted by the bent position of the head during work. But the researches of specialists have not entirely confirmed this opinion. As a matter of fact, Cohn came to the conclusion that the watch and clock makers of Breslau, whom he carefully examined, were not more liable than persons belonging to other occupations where work demands close application. Whilst it is true that he found myopia in 9.7 per cent. of watch and clock makers, 4 per cent. of them were already myopes before joining the trade.

In this connection it should be remarked that myopes who can easily do fine work without any particular eyestrain readily choose the occupation of watch and clock maker. That this number of myopes is comparatively small — Emmert and Dor have found a proportion of 18 per cent. among printers — is explained by the fact that watch and clock makers constantly use for their fine and delicate work a magnifying lens applied to one eye, generally the right. In this way they avoid partly efforts of accommodation and efforts of convergence, especially when the worker can adopt the habit of keeping the other eye open. Lawrentieff, however found that the use of the magnifying lens encourages strabismus.

It is obvious that if the lighting of the workplace is not arranged according to correct principles, and if the worker has to adopt or has already adopted the bad habit of concentrating light on to the article worked upon by means of a globe of water, then in these cases eye-fatigue and even eyestrain may be found. Cohn has found this eyestrain in 10 per cent. of workmen examined.

In 1853 Delthil noted cramp of the right hand in a painter of watch dials, as soon as this workman took hold of the brush; and Cohn has given a very good description of spasm of the orbicularis muscle in watch and clock makers. This spasm would appear whenever the worker wanted to put a magnifying lens applied to one eye, and delicate work a magnifying lens applied to one eye, generally the right. In this way they avoid partly efforts of accommodation and efforts of convergence, especially when the worker can adopt the habit of keeping the other eye open. Lawrentieff, however found that the use of the magnifying lens encourages strabismus.

Further, a large number of the factories or workshops are small concerns, and by no means lend themselves to the systematic application of prophylactic measures.

It is obvious that if the lighting of the workplace is not arranged according to correct principles, and if the worker has to adopt or has already adopted the bad habit of concentrating light on to the article worked upon by means of a globe of water, then in these cases eye-fatigue and even eyestrain may be found. Cohn has found this eyestrain in 10 per cent. of workmen examined.

This spasm would appear whenever the worker wanted to put a magnifying lens, which he constantly used at his work, to his right eye.

Numerous cases of dermatitis (eczema), due to the use of lacquers, were recorded in 1930. For lesions caused by paint applied to dials to render them luminous, see article "Radium and Radio-active Substances".

According to Oppenheim and Neugebauer, watch makers who open watch cases by means of the right thumbnail have a short, hard nail twice as thick as the nails of other fingers. Finally, wounds of the fingers are to be noted, due to work at furnaces, or with milling and filing tools or presses; and also foreign bodies in the eyes due to dust particles of metal coming from lathes, milling machines and polishing wheels. However, hygienic measures for
the removal of dust are applied in most factories, and reduce these troubles to a minimum.

**Legislation**

Watch and clock makers’ workshops should satisfy the most exacting conditions of hygiene, and in particular those relating to ventilation and lighting, natural or artificial. Governments have sometimes wished to fix a minimum standard of lighting for watch and clock making; thus, for example, the Lighting Commission of the United States requires an average lighting of from 100 to 150 lux, with 50 as a minimum. The regulations made by the different American States — Pennsylvania, New Jersey, Oregon, Massachusetts and Wisconsin — have, in fact, adopted these standards. The English Departmental Committee on the lighting of workshops and factories recommends 30 lux for such fine work as manufacture and repair in the watch and clock trade, and 50 lux for very fine hand work.

Occupational cramp among watch and clock makers is compulsorily notifiable in the Netherlands.

**Welding, Autogenous**

(Blowpipe Welding and Cutting, Electric Welding)

The object of autogenous welding is the permanent attachment of two pieces of the same metal by fusion or by softening the edges of contact by means of the local application of a powerful heat source with or without addition of metal of the same nature.

Whilst technically it is possible to include welding by forged iron, by soft steel, or by smelting broken or defective pieces (by reheating these in a mould by means of molten metal) under the designation “autogenous welding”, it must be remembered that the habit has arisen of applying this designation more especially to blowpipe welding, electric welding and aluminothermy.

**Technical Data**

Blowpipe welding is resorted to in many operations of metallic construction and repair, and in processes of refilling or building up where lack of material occurs, etc.

In the blowpipe oxygen serves as the combustion agent, and acetylene (oxy-acetylene blowpipe), hydrogen (oxy-hydric blowpipe) or lighting gas as the combustible. Methane, water gas (for certain special processes of manufacture), “blue” gas, oil gas, ethylene, benzene fumes or benzene, petrol and tetraline are also used. Similarly, compressed air is sometimes used instead of oxygen.

Acetylene, the flame of which attains a temperature of 3,600° C., is usually produced on the spot as required by starting from carbide of calcium, but gaseous acetylene (compressed or liquefied) is also used. At present liquid acetylene is kept in steel bottles containing about 30 litres filled with a porous substance containing acetone, or else is compressed at a pressure of about 15 atm. The porous substance prevents the formation of a vacuum in the bottle in which the acetylene might accumulate and give rise to explosion (see article “Acetylene”).

Hydrogen is obtained either by electrolysis or by starting from water gas by means of fractionated liquefaction and distillation. Lately it has been manufactured by starting from water gas and steam, causing these to pass over a contact mass of iron carried to a temperature of about 500° C., and with separation of the carbon dioxide likewise formed at the same time. The hydrogen is stored in steel bottles, where it is compressed to 150 atm., and thereafter placed on the market. Hydrogen given off as a by-product of certain chemical operations or prepared by means of zinc or hydrochloric or sulphuric acid is also used.

Oxygen is produced either by electrolysis or by liquefaction, starting with water, and is compressed to 150 atm. in steel bottles.

Electrolytic oxygen prepared by the Schmidt process contains, according to research engaged in by Bossard and Haeuptli, hydrogen in such large amounts that it produces a detonating mixture. It can however be obtained almost pure when made to pass through a special furnace constructed for this purpose.

Gas oil (Gas oil), obtained by starting with the gases from coke furnaces, is a mixture of ethane and ethylene, plus about 20 per cent. of acetylene.

The apparatus used for welding is the blowpipe, which receives the two gases used from small short pipes opening into the middle of the blowpipe in a mixing chamber. In front
WELDING, AUTOGENOUS

of this is situated an aperture with interchangeable jets.

When acetylene and oxygen are used, or lighting gas and oxygen, blowpipes with an injector are required, into which the oxygen is transmitted, at very high pressure, by means of an opening in the form of an injector, the second gas being aspirated at a weak pressure or without pressure and becoming mixed with the former.

In welding, the metallic parts joined are first of all prepared by planing, correction of faults and bevelling of edges, thereafter being placed in position and maintained there by screwing or other means (use of electromagnets). The two parts are thereafter heated by blowpipe, commencing at one end and continuing until the metal melts. When dealing with large articles, the point of contact is first, with metal, fine strips of the metal in question being used, one end of which is maintained in the zone of fusion, the liquid metal being then caused to fall in drops at the required points.

In autogenous welding with aluminium, the use at the same time of an agent of fusion capable of decomposing of the aluminium oxide formed is necessary.

Besides welding there is the process of rapid cutting with the oxyhydric or oxyacetylene blowpipe of iron and steel and more recently of cast iron.

Metal is brought to red heat with the point of the flame reaching the temperature of combustion of iron (1550°C.); the supply of hydrogen or acetylene is then cut off, leaving only a jet of pure oxygen under pressure. By successive alternation of this jet the required cutting operation is effected. In practice the same apparatus serves the two purposes, unifing the heating blowpipe and the cutting jet (oxygen), the two jets being either placed opposite each other or concentric. The blowpipe may be operated by a mechanical plant worked by hand or by a motor.

In cutting under water the jet of the blowpipe is covered with a bell, into which compressed air is driven at a pressure slightly superior to that at the working post. Before diving the diver lights the blowpipe, regulates the air pressure and then dives with the apparatus lit. Special lighters situated on the apparatus enable the diver to relight the blowpipe under water if it should be extinguished, without his being obliged to come up to the surface.

In cutting under water it is possible to use apparatus burning liquid combustibles (benzole, benzene, alcohol and benzole mixture).

Electric welding is effected in the same manner as arc welding or welding by means of resistance.

In arc welding the fusion of the metal may be obtained in various ways. The welding apparatus may be constituted by an arc lamp with inclined carbons and automatic regulation (Zenever process). The arc is directed downwards by means of an electro-magnet and the metal to be melted is placed in contact with the arc. This process has met with renewed popularity with the introduction of the hydrogen arc.

Usually the arc passes between the article to be welded, which constitutes an electrode, and an electrode made of carbon (Bernadas process) or a metallic electrode constituted for electro-magnet (process of Slavianoff) intended for building up. "Hydrogen arc" welding is based on the principle that electric discharge in an atmosphere of hydrogen makes it possible to attain a much more considerable temperature than in any other atmosphere and one which permits of the melting of all metals and even of quartz. The apparatus used is composed of two tungsten electrodes at an angle of about 60° and of a tube directed in accordance with their bisecting line, by which hydrogen or mixtures of hydrogen and nitrogen, lighting gas, water gas, etc., are supplied.

Welding by metallic electrodes may be applied for the same purposes as blowpipe welding and is of superior efficiency for renewal of worn pieces or for correcting defects in the dressing of castings. Electric welding is very much resorted to in metallic construction where it replaces with advantage riveting, notably in naval construction.

Welding by resistance (end to end welding; welding of points; continuous welding) is used for welding large articles. The articles to be welded are introduced into the secondary circuit of a transformer, through which a current of weak voltage and strong intensity is passed, thus raising the parts to be united to the required temperature and bringing them into close contact with one another. Usually these operations are effected in semi-automatic or completely automatic machines.

Finally, aluminothermy, consisting of the use of thermit, is resorted to in engineering, but only for urgent repairs or for certain types of work.
Thermit consists of a mixture of powdered aluminium oxide and iron oxide, which is placed in a special funnel packed round the fracture to be welded. Combustion gives off such great heat that the melted iron flows into the mould surrounding the pieces to be welded (welding of rails).

**Sources of Risk**

One of the risks connected with this work — and the one which is certainly the greatest encountered by welders and cutters — is that represented by burns.

These affect the naked parts of the body and especially the eyes, and are caused by flames of the burners, splashes of molten metal, ignition of gas escapes, rags or greased-soaked clothing under the action of the oxygen or are due to ignition and explosion of copper jets and pressure-reducing valves (formation of acetylde of copper with acetylene, super-pressure), etc.

Special mention should be made of *explosions* which may occur: explosion of bottles, formation of detonating mixtures in the burners as a result of defective regulation, etc. Explosions may be produced during welding or cutting of empty receptacles which have contained volatile products (benzene, benzol, etc.) or acids (notably sulphuric acid, in which case explosion occurs as the result of the action of the acid on the metal, or of fulminating gas).

Cases of poisoning may be caused by impurities contained in the gases used to form the point of the flame: arsenurried hydrogen where the hydrogen has been prepared from zinc and arseniferous acid; sulphurretted hydrogen, phosphoretted hydrogen or impurities in the acetylene (cases recorded by Brezina, 1920). The latter may contain phosphoretted hydrogen amounting to 0.04 per cent., which content represents not only danger for the workers but is also harmful as regards the mechanical properties of the welding material. When impure acetylene burns in an acetylene Bunsen burner, free phosphoretted hydrogen is present in the point of the flame and throughout the whole flame, disappearing only completely at its periphery. In the case of the oxyacetylene blowpipe, combustion of hydrogen phosphide occurs differently, the transformation into phosphoric dioxide is more complete and more rapid, and the quantity of free phosphoretted hydrogen becomes greater the nearer it is to the point of the flame. As in autogenous welding the point of the flame only is used, previous purification of the gas becomes essential.

In course of welding or cutting of lead, brass, brightened, zinc or articles containing these metals, cases of poisoning may also occur due to liberation of metallic fumes. Danger is generally to be anticipated in connection with lead or zinc fumes liberated during cutting of old zinc or old iron which has been previously painted with minium or lead colours, etc.

Dismantling of ships by blowpipe constitutes in this connection an important source of lead poisoning and of brass fever. In Germany, cases which occurred were so numerous that safety measures were imposed by a Circular dated 26 June 1923. In the United States, of 221 workers in the naval dockyard of Philadelphia, 112 cases of lead poisoning occurred between 1924 and 1925. In Great Britain, 131 cases occurred in 1924, one of which was fatal, and 121 cases between 1925 and 1929. In the U.S.S.R., 30 out of 56 welders in the naval dockyard of Leningrad presented signs of lead absorption, 5 signs of suspected lead poisoning and 7 of slight lead poisoning; 34 out of 70 in another dockyard suffered from lead poisoning. In a general manner, 75 per cent. of the cases of poisoning which occurred affected workers engaged entirely on board ship; 50 per cent. affected those who worked mainly on board and 25 per cent. those who worked on the quays (Silber, 1927).

These cases of poisoning are at times favoured in their development by particular working conditions, e.g., in enclosed apparatus, where gases of combustion, or those liberated by the residues of substances contained in the apparatus or by the metal, may occasion very serious injuries. In these cases the heat of the flame causes volatilisation of the residues still adhering to the sides of the receptacle, even in very small quantities and even after the receptacle has been cleaned and although the product in itself is not toxic. In fact, experience shows that in enclosed spaces the fumes liberated exercise such a serious effect on the respiratory system of the worker that though his work is subject to repeated interruptions he may at times be exposed to fatal risk (Fischer). Thus, for example, grey cast iron contains 3 to 4 per cent. of carbon in the form of graphite capable of combining with the oxygen of the blowpipe and producing carbon monoxide. This gas has often been the cause of fatal poisoning amongst welders (Holtzmann, 1928; Hegel, 1929; Schwartz,
Without imparting the luminous sensation, the invisible infrared rays, or calorific rays, are comprised between 760 and 1,500 μ (infra-red rays) and upwards to 50,000 μ. Whilst the former pass through the cornea, the crystalline lens and the anterior chamber in a weakened state and reach the retina without imparting the luminous sensation, the latter become absorbed by the anterior chamber, the conjunctiva and the cornea.

More important still is the series of the shortest invisible radiations, the ultra-violet rays with chemical action, whence their designation "chemical rays". They are comprised between 400 and 315 μ and even below. Those from 400 to 375 μ possess a triple action, producing partly and chiefly fluorescence of the crystalline lens and partly fluorescence likewise of the retina, while a third part probably arrive without undergoing change at the photo-sensitive elements of the retina.

The harmful action of the ultra-violet rays was referred to in 1904 by Hertel, and in 1908 Schanz and Stockhausen, as a result of experiment, formed the conclusion that these rays produced inflammation of the anterior part of the eye known in extreme forms under the names of "electric ophtalmia" and "snow blindness". They also exert, however, an action on the more deeply seated parts of the eye, producing notably intense fluorescence of the crystalline lens which, owing to its capacity for transforming invisible radiations of short wave length into visible rays, protects the retina. They are said further to constitute a cause of injuries of the choroid.

In electric welding the eye should be protected against the action of ultra-violet and infra-red rays and against...
glare. Though the temperature of the electric arc is estimated at 3,000 to 6,000°C, and gives a glaring white light, the calorific radiation during the action of the arc is so weak that at a distance of a metre the temperature only rises 2° C. in ten minutes. This elevation of temperature is due to the action of molten metal rather than to that of the arc. On the other hand, however, the ultra-violet rays have an intensity one hundred times greater than in the case of autogenous welding (Galanin).

According to this author, the intensity of radiant energy varies from 0.25 to 6.8 small calories per minute and per sq. cm. in autogenous welding, and from 0.25 to 13.7 small calories in electric welding. Demidowitch (in 1930), on the other hand, only met with values amounting to 7.2 small calories.

When the eyes are protected by a screen or by suitable glasses, control of the blowpipe and of welding operations demands a visual effort of some importance which it is necessary to take into account.

Holstein (1930) draws attention to the fact that electric welding is capable also of damage to the genital functions (alteration of the testicular tissue), but he adds that the existence of these troubles has not so far been clearly proved. He recalls finally danger due to the fact that the electric spark in passing through the air causes formation of nitric acid, and that welding may liberate acrolein fumes.

The temperature of the workplace may be relatively high where workrooms are badly ventilated, and still more so when the work is effected in enclosed spaces (boilers, piping, etc.), and where ventilation is difficult to install. Deutschmeister (1936) found temperatures reaching 35° C. in a boiler. It is obvious that the sensation of discomfort is all the greater since it is essential that the worker's face is kept close to the blowpipe. It may be said that the welder often works in a sort of individual nitch closed by a screen for protecting him against injury likely to be caused by the apparatus used by his fellow-workers. This method possesses, however, the inconvenience of offering obstacles to adequate ventilation of each working place.

The working posture may also constitute a source of injury or discomfort: often the worker is obliged to assume a cramped position, bent during 75 per cent. of the working shift (Demidowitch). Other postures are equally uncomfortable, the worker having to remain for hours on his side, with his back in a sitting posture, kneeling, etc. (Deutschmeister).

Mention should also be made of cutting under water, where the working posture is also very trying, since the worker has to exert a powerful effort in applying the blowpipe to the surfaces to be cut, usually encountering whilst doing so resistance from the current of water.

In conclusion, reference should be made to noise due to the blowpipe, especially where gas is used, or to other operations effected simultaneously in the workrooms.

**PATHOLOGY**

Apart from injuries due to burns and explosions, ocular injuries are the most frequent. According to Toulant (1925), ophthalmia due to autogenous welding is rare where the workers' eyes are protected by dark glasses, but may occur as a result of excessive susceptibility of the eyes or as a result of inadequate protection.

The acute form, constituting a type of kerato-conjunctivitis, is characterised by desquamation of the corneal epithelium. It presents the same symptoms as actinic ophthalmia (Toulant). Hirschberg (1898), Cruellitz (1906) and Snell (1909) have described an acute and painful ocular trouble caused by the electric arc, accompanied by watering of the eyes, photophobia, inflammation of the eyelids, with injury of the conjunctiva, the cornea and the retina. Apfelbach (1914) has recorded fifty cases which showed similar symptoms and more rarely forms of keratitis, retinitis, permanent pigmentary changes of the retina, and scotomas.

According to Bridge, the acute symptoms of electric ophthalmia generally appear four to eight hours after exposure, the duration of which may be counted in seconds ("a flash"). The duration of acute symptoms is dependent on the duration of exposure and the intensity of the arc. In general it does not exceed twenty-four to forty-eight hours, but ocular pain is very acute and almost insupportable during five to six hours. Swelling of the skin, a dry and harassing cough, and conjunctival irritation may last even for ten hours. The blinding sensation produced by the glare of molten metal lasts several days, during which time the worker is not able to fix or distinguish things and has the sensation of a black veil in front of his eyes.

Undoubtedly individual susceptibility plays a highly important role, and the symptom complex, being determined by the individual constitution, may vary very greatly. There is a certain rela-
tion, not however constant, between the phenomena produced and the intensity, the dimensions, the distance of the light source, and the duration of exposure of the eye to the action of the light. There are even known cases of ophthalmia affecting workers who have passed at a distance of 10 metres from an electric welding post, and who have only come in contact with the radiations indirectly or sidewise, so to speak.

Individuals whose nervous system is to some extent affected may also suffer from asthenopia, even in the case of very slight action of a lamp of medium intensity. Such individuals may even suffer from most serious nervous symptoms, attaining hysterical traumatism.

In conclusion, the various symptoms involved may be grouped under three classes: vascular or inflammatory injuries (injuries to the eyelids and the conjunctivae); functional injuries (dazzling, asthenopia, diminished sight, etc.) of a sensitive motor or secretory type, photophobia, pain in the eyeball, blepharospasm, derangement of the function of the extrinsic muscles of the eye, watering of the eyes, etc.).

Bridge has not met with the permanent injuries or cases of cataract mentioned by certain authorities. Apprentices are said to be more affected than experienced workers, probably due to the fact that they are less expert at employing means of protection.

The chronic form is characterised by diffuse scleritis (Toulant), owing to the combined action of luminous and calorific radiations.

According to Tacchini, this form is said to occur amongst workers engaged on autogenous welding with the oxy-acetylene flame after a few days' work, and is characterised by a sensation of fatigue, tension of the eyeballs, which are painful under pressure, and simultaneously by a sensation of dryness of the cornea and conjunctivae. The edges of the lids are red, and covered, especially at night, by a viscous secretion. The conjunctivae of the eyelids are inflamed, and the blood vessels very congested. In certain cases there is a perikeratic circle with injury of the iris. During work the fibres of sphincter pupillae are subjected to intense effort, hence marked myosis. After a certain time, exposure to light remaining the same, the myosis becomes less marked. At this moment more serious troubles set in. The retina, receiving less effective protection from the iris, suffers from the abnormal stimulation to which it is subjected, and shows persistent symptoms such as indistinct vision of objects, sensation of fatigue on regarding a light source, heaviness and headache, with a feeling of tension, at times attacks of intense headache, fatigue, nausea and vomiting. Ophthalmoscopic examination reveals a slight degree of injection of the papillary and retinal blood vessels. Cessation of work causes these symptoms to disappear, but the former resistance capacity of the visual sense is diminished, for a spell of blowpipe work is liable to cause immediate recurrence.

On the uncovered parts of the skin the ultra-violet rays of the electric arc exert a pigmentary action which may, in certain cases, develop into slight burning or intense "sunburn".

Amongst general troubles, there should be mentioned brassfounders' fever, due to the fumes of zinc liberated by welding zinced tin (Brezina), anorexia, frequent fits of vomiting during the night, symptoms triggered by a sensation of heat (Adler-Herzmark), and even pulmonary oedema (Kissinger, 1929).

The small quantities of nitrogen monoxide which are released from the elements of the arc, as well as particularly unfavourable condition (confined working space, bad ventilation, etc.) have been known to cause in six to ten hours serious phenomena among workers, characterised by breathing difficulties, spitting of blood and, even in the more serious cases after a period of apparent improvement, death in twenty-four to fifty hours. The inhalation of ammonia has been used as an antidote against nitrous fumes, bottles containing carbonate of ammonia being distributed to the workers.

**Hygiene**

Safety measures should be applied with a view to protecting the workers against the risks of explosion, burns and danger from the electric current. These measures are described in detail in most of the regulations issued in the various countries.

Workrooms should be well lighted and ventilated, with a view to preventing combustion gases, fumes and smoke liberated during welding from vitiating the atmosphere. Gas from the hearths utilised for preliminary heating of the articles to be welded should be captured and directed outside. In the production of hydrogen, zinc and sulphuric acid free from traces of arsenic and phosphorus should be used, and acetylene should be com-
plectly freed from impurities such as sulphuretted and phosphoretted hydrogen. Adequate precautions should be adopted where toxic or dangerous products are used (benzene, etc.), or in view of their possible content of carbon monoxide or methane. Work should be carried out in the open when it is not possible to provide adequate ventilation.

All welding or cutting of boilers or similar receptacles in which the presence of the flame may give rise to explosion of gaseous mixtures should only be engaged in subsequent to thorough cleaning and elimination of such gases by ventilation, neutralisation or filling with water. Closed receptacles should be pierced with care in a water-jet. Those which have contained toxic products should also receive thoright cleaning. Where mixing receptacles are handled, the lid as well as the stirring mechanism should be removed wherever possible.

Workers engaged on welding and cutting of closed receptacles should be provided with adequate air renewal from time to time. Combustion gases should be withdrawn by a powerful exhaust ventilator in a continuous manner by means of air outlets placed as near as possible to the bottom of the receptacle.

As regards work effected in the open (dismantling of ships), the workers should be so placed that the gases and fumes removed by the natural air current are withdrawn in the opposite direction.

Protection against burns due to flames or sparks should be provided by incombustible, or at least fireproof, garments, aprons, as well as by boots and gloves of leather or asbestos.

Welders should be provided with respiratory apparatus for protection against eventual poisoning where ventilation is inadequate. When compressed air is used, masks should be worn unless filtered compressed air is provided.

The face and eyes should be protected by means of screens and glasses. This protection is often assured by apparatus fitted to the blowpipe or to an electrode, or by screens held in the worker's hand. These means of protection may again, in imitation of certain types proposed for use against splashings and projections, take the form of casques fitted to the head, or even to the face. Protective appliances of this kind enable glasses to be changed in accordance with varying conditions of work. For further reference to glasses, see article "Goggles".

In practice, the problem demanding solution is as follows: how is it possible to arrest the passage of ultra-violet rays coming from the artificial light source?

It is essential in the first place to insist that the same means of protection should not be applied in regard to all eyes, since the factor "eye" takes precedence of the factor "glasses". It is, however, certain that cheap types of glasses are rarely satisfactory, and that it would be advisable to support the proposal made by the autogenous welding associations of introducing a "certificate of guarantee" for the glasses to be used.

The question of the most useful colour of glasses for protecting the eyes of welders is still under discussion. For greater detail on this subject, reference should be made to special studies on this question. Here mention will be confined to the fact that all green, red, yellow, amber, greenish yellow, or smoked glasses offer protection against ultra-violet rays for the eyes of workers engaged in autogenous welding. Yellow or greenish yellow glass possesses a maximum power of absorption against ultra-violet rays and red glass against infra-red rays. Green is said to possess a total power of absorption for ultra-violet rays and an almost total (95 per cent.) power of absorption for infra-red rays.

The glasses should be unbreakable, and should be replaced as soon as they have become darkened by spotting due to particles of metal projected. The glasses should be closed at the sides with a view to protecting the eyes against metallic splashings and reflected rays, which may affect the eye from a lateral direction. They should be well jointed at the bridge, and at the level of the glass should have a dead space sufficing to ensure good ventilation.

All glasses with parts made of material capable of becoming dirty and giving rise to infection should be eliminated. Glasses should be strictly confined to personal use, as cases of trachoma have in fact been known to be transmitted by glasses (Tacchini). The worker should besides receive adequate protection from injury likely to be caused by apparatus operated by his comrades. In certain workrooms each welder is surrounded by large screens, or works in an individual cabin closed on three sides, painted in a dark colour to absorb the light, the fourth side being closed by a black curtain. This method, however, presents the disadvantage of demanding
good ventilation, which it is difficult to obtain in practice.

Important progress has been made by the introduction of new technical methods involving the use of automatic welding apparatus. The processes are carried out in closed cabins provided with coloured glasses through which the workers are able to follow and regulate the work.

A permanent International Commission on Acetylene and Autogenous Welding deals at its periodical meetings with the various problems encountered in this industry, and the French Central Office has published a leaflet concerning the following preventive measures: compulsory obligation for proprietors of autogenous welding plant to place at the disposal of their workers an ointment for slight burns, as well as dressings necessary for first-aid or for treatment of burns with a view to avoiding inflammation; compulsory obligation for workers engaged in brass-welding or welding of other alloys containing copper to consume, during work or after work, milk to which a little bromide of potassium has been added, the quantity or dose being prescribed by a doctor consulted on this subject.

Preventive measures against the risk of poisoning by toxic fumes, especially lead and zinc fumes:

The attention of workers should be drawn to the precautions to be taken by means of tracts, lectures, posters, etc.

Arc welding is work which demands great attention, coolness and accuracy. The Belgian prevention associations have published leaflets containing a list of the precautions to be taken. Those adopted by the Belgian Association only are given here:

1. Never engage in welding without a screen or helmet. Test the glasses to see whether they are in good working condition and have them replaced if they show the least defect; no direct light should be able to traverse the edges of the glasses.

2. During work the wearing of shoes instead of boots is prohibited unless leggings are worn with them. The wearing of celluloid collars is likewise prohibited.

3. As a protection against sparks the special clothing and leather gloves with cuffs provided should be worn.

4. When removing slag with a hammer special glasses with clear glass should be worn.

5. Care should be taken to see that the working post is well isolated on all sides by fixed or movable screens before commencing work, in order to avoid inconvenience to workers in the immediate neighbourhood.

Legislation

Measures of protection for women and children as well as hygienic measures to be observed are mostly included in those dealing with safety.

In the U.S.S.R. an Order of 13 August 1930 enforces medical examination of welders prior to engagement for autogenous welding.

Compulsory notification is required in France for ocular affections caused by industrial heat and light sources. Conjunctivitis, optic neuritis and retinitis, ulcers of the cornea and conjunctive and poisoning by zinc oxide occurring during welding operations and autogenous cutting are subject to compulsory notification in the Netherlands.

Compensation for injury due to very intense light (foundry workers, sheet-iron workers) or to ultra-violet rays is provided in Bulgaria; for diseases due to radiant energy when the latter is particularly powerful in Finland; for forms of dermatitis and ocular injuries due to light and radiant heat in Mexico and Sweden; for conjunctivitis and retinitis in Manitoba; for injuries due to the constant action of radiant energy of great intensity (retinitis affecting metallurgical workers) in the U.S.S.R.; for conjunctivitis and other affections of the eyes caused by manipulation of substances at high temperatures in Japan. Legislation also provides for compensation in cases of poisoning due to welded metals (see each article).

Welfare Workers

In most countries the origin of the appointment of welfare workers may be sought in the need felt by employers for providing their workers with someone capable of giving first-aid treatment in the absence of a doctor in cases of illness or accident. This tendency has been further strengthened by legislation in those countries where the employer has been rendered responsible for all accidents occurring to workers in course of their work as well as the sequelae of these — incapacity for work, invalidity — current experience having proved that immediate and well-applied treatment in such cases greatly diminishes the extent of loss occasioned both to the worker and to his employer.

It is at present difficult to furnish a precise definition of a factory welfare worker. It is obvious, however, that the tasks to be performed by this type of social worker cannot be entrusted to anyone lacking the requisite experience and training.

The occupation of welfare superintendent is generally considered as a female employment, and choice of staff is mostly influenced by the need for appointing women with maternal instincts and sufficient sensibility to fit them for a profession which demands a certain amount both of charity and devotion. It is probably with this idea in mind that one authority has stated that it seems impossible that a man could fulfil this function (L. Schmidt-Kehl). These qualities, however, ought to be accompanied by aptitude of an intellectual order and adequate training, for the days are past when employers were content with persons sufficiently willing but lacking in special training and skill (F. Swift-Wright).

Usually the employer requires that the welfare assistant should aid the factory surgeon in an intelligent manner and be of useful assistance to the heads of departments, the sanitary engineer and the administrative branch (statistics), or, in short, should co-operate actively with all branches of the factory. In addition to this the welfare supervisor is required to co-operate with public health officials.

Throughout all the functions which she exercises, the welfare worker must bear in mind her role as collaborator of the employer, and friend and comrade of the worker, and must never regard her task as that of a detective (F. Swift-Wright).

There is no fixed scheme of duties in accordance with which the welfare worker can organise her work. She must be able to adapt herself to conditions and to enter wholeheartedly into the life of the factory and that of the workers. She will be able to accomplish this by acquainting herself with the working conditions, the living conditions, the preferences and the needs of the workers, by making every effort to establish sympathetic contact with the staff, in sharing both the joys and sorrows of the workers. It is in this way only that confidence can be established and that the welfare worker may fulfill adequately the role which she is intended to fulfill, namely, that of an enlightened and wise helper, earnestly interested in the lot of the workers. Because of the fact that the life of the factory is constantly subject to change, it is eminently necessary that she should possess a marked faculty for adaptation to circumstances and a spirit of initiative, prompt to act in unforeseen circumstances (L. Schmidt-Kehl).

The welfare worker, still very often in the pioneer stage, will find that her field of action has no limit short of a thoroughly well-organised establishment. Most frequently, especially in a factory of secondary importance, such organisation is lacking, and the welfare worker is then left to her own devices as the one and only individual interested in hygienic and social conditions and industrial relations. The only limits to her activities are those imposed by the ideas of her employer or by her own strength, until she is able to determine the scope of her task and to establish its natural limits (F. Schmidt-Kehl).

It is nevertheless possible to enumerate amongst the numerous duties of the welfare worker a certain number
of clearly defined tasks. She must pay frequent and thorough visits to the workrooms in order to become acquainted at all moments with the situation of the workers as regards health and safety. She must enter into close contact with supervisors and foremen in order to receive notice of all details relative to defects in the technical or subsidiary plant to which their attention has been called in course of daily practice. She ought at the same time to interest herself in suggested improvements which they may make.

The welfare worker must, again, develop an interest in the moral attitude of the male and female employees, devoting quite special attention to the young persons of either sex. She ought to devote attention to their conduct in the workshop as well as in the canteens, club rooms, etc., always striving to gain their confidence by means of friendly advice and well-considered and impartial intervention, imposing at the same time her authority, without, however, any tendency to abuse such authority. The type of discipline which she will thus strive to establish will be modelled on the type of discipline peculiar to family life, and not that of the barracks-room.

In the ambulance room of the factory the welfare worker, in the absence of a nurse, should render useful service to the doctor. In the absence of the latter she may replace him in so far as the limits of her knowledge permit; first-aid in urgent cases, always, however, applying to a medical man for matters beyond the range of her capacity. It is further the duty of the welfare worker to inform the members of a worker's family in the case of accident or illness occurring during presence at the factory. She should act as a liaison agent and where necessary fulfil all requisite formalities required of workers by the sickness funds, institutes of hygiene and social prophylaxis, medical specialists, hospitals, sanatoria, etc.

The welfare worker must make a careful record of all her observations on a card index or other register, which represents ultimately the source of information which enables her to supply the doctor or the management with regular and accurate information as to cases.

It is highly desirable that the welfare worker should intervene during engagement of workers. She must get into touch with new arrivals, see their medical entry certificates and become acquainted with their personal situation and social conditions. More intimate contact will of necessity be established later, contact on which the welfare worker will be obliged to rely whenever an occasion occurs for bringing to bear her influence on the psychology of the worker.

Another point at which the activities of this agent may render useful service is during transfer of workers from one workshop to another, since in such circumstances information of a psycho-physiological order, which the welfare worker is in a position to supply, ought to be taken into consideration. This makes it possible to maintain or even to increase the efficiency of a transferred worker by entrusting him with a type of work adapted to his strength. Since decisions of this kind depend on heads of workshops and foremen, the welfare worker should make every effort to render intelligible to them any suggestions which she deems it useful to make, avoiding, of course, at the same time any tendency to encroach tactlessly on the sphere of influence of these representatives of the management.

Data relative to the personal and social conditions of workers in possession of the welfare worker will enable her to impose her views as regards equitable measures of procedure relative to dismissal of workers. She may also intervene in favour of retention of those workers who have families dependent on them, or, where it is essential to effect a reduction of staff, for instance, urge the dismissal of a woman worker who has children to look after and whose husband earns a wage sufficient to maintain the family. Similar intervention relative to family circumstances will likewise be useful whenever the management or committees in the establishment are engaged in making decisions relative to the granting of aid to indigent workers.

Another task not infrequently entrusted to the welfare worker is that of supervising the domestic economy of the establishment: directing the work of charwomen and cleaners; advising the kitchen and canteen management; dealing with the lay-out of the factories, etc. By such tasks, especially in small factories, the welfare worker eventually succeeds in creating for herself a sphere of influence which finally facilitates intervention in every sphere in which the enlightened advice of an energetic woman may make itself felt.

Very often she is also requested to collaborate in organising a factory library, lectures and all other recreative or educational activities connected with the worker's life.
Apart from these activities effected in the factory, the welfare worker is also required to visit the workers in their homes. This side of her work is of such importance as to make it impossible to conceive of a real factory welfare worker ignorant of the conditions of family life of the workers under her charge (L. Schmidt-Kehl). During these visits the welfare worker has an opportunity of getting acquainted with the conditions of the workers. She will further by this means manage to win their entire confidence, a confidence which the worker does not in general accord unless he is very sure that the interest shown in him is not limited entirely to his activity in the factory, where he very often suffers from a sense of overshadowing of his personality, and feels himself to be nothing more than a cog in the machinery employed.

Whether it is a question of treating a patient, or helping a woman during childbirth, or looking after an infant, or again of measures of industrial and social hygiene and prophylaxis (family tuberculosis), the welfare worker will not lack opportunities for rendering herself useful and exerting a most favorable influence. She must, however, avoid all tendency to become dictatorial and likewise observe scrupulously as one of her most sacred duties professional secrecy as regards every fact learned outside the factory without the consent of the worker. As regards compulsory notifications imposed by law, it is the task of the welfare worker to explain to the individual affected the social necessities which govern her action. It is by such methods of explanatory comment that she will be enabled at each moment to effect a highly useful task of social education.

**Material and Moral Conditions**

In most countries the welfare worker is appointed by the employer. This fact does not, however, imply that she should in any way be hampered in her activities, since this would be contrary to the interests of the employer, to whose advantage it is to improve the material and moral condition of his workers. It must, however, be admitted that the employer's attitude towards the activity of the welfare worker varies greatly from one factory to another. Though the majority of employers regard welfare workers as officials of obvious utility, others are still inclined to judge their work as a type of pure philanthropy. In all cases one condition is absolutely indispensable in regard to their activities and that is that they should enjoy the confidence of the employer, who must not regard them merely as agents to whom he transfers a part of his authority, but rather as persons called upon to fulfill a social function.

A proposal has been made to make factory welfare workers State officials but to do so would be to create a barrier between the welfare worker and the employer, since the latter would be inclined to consider her as an intrusion in his establishment and to oppose her frequently and even at times unwittingly in a spirit of passive resistance, thereby rendering ineffective all useful collaboration.

It is also of importance that a spirit of comradeship should be established between the welfare worker and the workers. Only too often workers are inclined to regard the welfare worker as an agent of the management and to interpret every attempt at social service due to the initiative of the latter as a piece of decorative philanthropy intended to mask a desire for profit (Abbe). It is up to the welfare worker herself, thanks to her qualities, her tact and her devotion to dissipate this atmosphere of mistrust and establish the cordial relations which are indispensable to a fruitful social effort.

At present the welfare worker is encountered as a general rule in all large industrial undertakings. In certain instances, in view of the multiple activities to be fulfilled, it is even the case that in larger establishments the activities accomplished in smaller factories by a single individual may have to be entrusted to a group of welfare workers. Many factories have adopted a system by which one welfare supervisor is appointed to direct the activities of nurses, first-aid workers and welfare workers engaged in social services, visiting nurses, etc.

The institution of welfare workers is encountered in its most highly developed form in the United States. An investigation carried out by the National Industrial Conference Board (1925), covering 501 establishments, shows these to have at their disposal 773 doctors within call, 152 male and 688 female certificated nurses, whilst 252 of the factories possess private facilities for visits to the workers' homes. Information relative to the work of nurses deals further with 499 establishments, classified in accordance with the size of their staff. From the table reproduced below, it is seen that the institution of nursing services is more frequent as the factories become larger...
and employ a greater number of workers, being very general in establishments employing 1,000 wage earners and upwards.

1 One of these is a male nurse

According to an enquiry carried out by L. Tattershall (1930), 1,006 industrial and commercial establishments, employing a total of 1,946,554 workers, had 2,022 welfare workers, including 189 men and 1,833 women. The men were engaged generally in establishments where difficult work was effected or where very few women workers were employed (iron and steel industry). The staff of these social service departments is practically permanent, 4 per cent. only being employed for periods of broken time. More than three-fourths of the welfare workers worked under a doctor and more than 50 per cent. of the establishments employed welfare workers inside the factories and also for the purpose of visiting the workers' homes. In three-fifths of the establishments providing for visits to the workers' homes treatment was given to workers and their families.

In Great Britain the number of "social workers" has been estimated at about 1,000.

In Italy, according to the Ministry of Labour (1923), the facts relative to persons employed on work corresponding to that of the factory welfare worker are as follows: 673 establishments, not including those in Venetia (Venezia Giulia), with 321,194 workers gave employment to 341 male and 118 female nurses for first-aid work. The General Industrial Confederation summarises as follows the duties entrusted to individuals engaged in social service in factories: sending workers and members of their families to medical institutions (hospitals, sanatoria, etc.); sending workers or members of their families to specialists for examination or surgical treatment or radiographic examination, etc.; sending pregnant women to maternity institutions, etc.; sending adults and children to holiday camps (sea, mountains, etc.); furnishing advice as regards taxes, pensions and similar matters and obtaining for workers certificates delivered by public authorities, etc.; in short, intervening where necessary between the workers and all civil and military authorities, undertaking for them correspondence with foreign consulates, giving them advice as regards aspects of social legislation and assistance in problems of a moral or legal order, etc.

In Germany in 1925 the number of factory welfare workers (Fabrikpflegerinnen) amounted to 110, 84 of these being in Prussia, 9 in Wurttemberg, 7 in Bavaria and 6 in Saxony. In most cases there was only one welfare worker to each establishment, but in those of a certain importance this number was increased up to ten in the case of a Berlin factory. On the other hand, several small establishments were found to have grouped themselves together to employ in common one welfare supervisor, an example of this being the case of fourteen factories in Rhineland.

Whilst in the United States it is chiefly the metallurgical and engineering industries which occupy the greatest number of welfare workers, in Germany, as in Italy, it is the textile industries which head the list, followed by the metallurgical trades.

In general, it has not been found that it is those factories which employ the greatest number of women workers which engage welfare workers. In Germany, out of a total of 96 welfare workers, 58 worked in establishments which employed more male than female workers. As regards the proportion between the number of welfare workers and the total number of workers employed, it was found that the greater the number of workers em-
ployed the greater also was the number entrusted to the care of a single welfare worker (cf. American statistics in the above table).

It is interesting to note that in Germany it has been found that the number of occasions on which male workers have sought advice from the welfare worker is less than that on which advice has been sought by women workers (L. Schmidt-Kehl).

**Professional Training**

One condition essential to the satisfactory fulfilment of the functions of factory welfare workers is good professional training. The data available show that schools attended in the various cases have been fairly varied. Thus, 38 welfare workers out of 93 came from a women's college of social studies. Of these 38, 7 had in addition attended a special course for factory nurses. Two had worked for several years as ordinary nurses and only one had attended a normal school of domestic economy. Without entering further into detail, it is seen from these facts that the professional training of welfare workers is fairly heterogenous.

Though welfare workers have for the most part only followed an ordinary course of nursing, it is nevertheless of first importance that courses of this kind should be completed by further training relative to social work and social institutions.

At the present time the existing preparatory institutes for welfare workers or factory superintendents may be considered as satisfactory centres of occupational training. Their curriculum offers students the possibility of acquiring on which advice has been sought a knowledge of nursing, political and social economy and industrial legislation. It comprises further instruction relative to public and private educational institutions, to social insurance and welfare, to individual and collective hygiene, care of the sick or wounded, care of children, as well as lessons in practical psychology in its application to social life, a knowledge of statistics, classification of data, organisation and enquiries and office technique, etc. A curriculum of this kind enables future welfare workers and factory nurses to acquire during their training a fairly accurate idea of the work which they are called upon to effect during their career.

The duration of study is about two years, the second year being devoted to specialisation (welfare, child care, social insurance, etc.). The curriculum of the training centres (in Belgium, France, Great Britain, etc.) comprises generally the following subjects: occupational deontology, domestic economy, elements of technology, accident prevention, first-aid, individual and industrial hygiene, elements of industrial accountancy, keeping of records and card indexing, industrial and social legislation, social economy (industrial organisation, wages, etc.), etc.

In certain centres the students are obliged to serve an apprenticeship, which comprises the time spent as a worker in the factory and a further period of three months in an institution for factory welfare or as factory superintendent, as well as visits to a certain number of industrial establishments and welfare and insurance establishments.

In other countries where training centres do not exist, special courses of varying duration have been organised. Thus in Italy "health visitors," or factories, whose duties are similar to those of factory welfare workers, receive a course of instruction lasting three months and organised by the Central Medical Committee of the National Social Insurance Fund.

In conclusion, in order that the welfare worker may be enabled to maintain her intellectual equipment and her sense of professional duty at a high level, it is essential that efforts be made in the direction of continuing her education with a view to preventing moral slackness and the effects of automatic routine, in the case of the isolated welfare worker, removed from her cultural surroundings and often too exposed to influences of a detrimental environment, in the midst of which she must needs maintain her status. This objective might best be realised by the organisation of periodical courses of instruction, by reading of a professional periodical and especially by the existence of a professional organisation facilitating discussion of technical problems and providing a defence of the moral and material interests of the whole group of factory welfare workers.

WHITE LEAD

White Lead

CHEMISTRY

White lead is a basic carbonate or hydrocarbonate of lead, of which the composition is not always the same, but can be represented by the formula 2 CO₂Pb₂+Pb(OH)₂ (corresponding to 86.32 per cent. of lead oxide (PbO), 11.36 per cent. of carbon dioxide and 2.32 per cent. of water). Carbonate of lead is found in nature in the form of cerussite (PbCO₃) and hydrocerussite, of which the formula is that given above.

White lead takes the form of a white, amorphous, heavy, insipid powder, insoluble in water and soluble in dilute nitric and acetic acids.

White lead blackens readily under the influence of hydrogen sulphide (present sometimes in the air) in consequence of conversion of the carbonate into black sulphide of lead. This constitutes, together with its toxicity, one of its principal disadvantages.

The qualities most appreciated in white lead are its great covering power and the perfect emulsion it makes in suspension resulting in the skin produced on the drying of the oil. Further, white lead is a dryer; and mixed with other pigments does not spoil the tint.

The commercial value of white lead varies according to the process of manufacture. Two principal kinds are placed on the market — soft white lead, ground with much water and then dried, and hard, i.e. white lead deprived of its moisture which can then contain acetate of lead. White lead is often mixed with white substances of less value, such as barium sulphate, gypsum, zinc oxide, lead sulphate, Kao'n, silica, chalk, etc.

Certain commercial mixtures have distinctive names, such as flake white, light white (blanc léger), white lead, Krems white, Venetian white (white lead and barium sulphate in equal parts), Hamburg (1 of white lead to 2 of barium sulphate), Dutch (1 of white lead and 3-4 of barium sulphate), etc. "Silver" white, obtained by precipitation a solution of lead acetate with sodium carbonate, is only employed for artistic painting. Pattison's white lead is only a basic chloride of lead prepared by mixing a boiling solution of chloride of lead with an equal quantity of saturated lime water.

METHODS OF MANUFACTURE AND THEIR HYGIENE

Of the numerous processes of manufacture of white lead only the most important will be described, grouped according as they start from metallic lead or lead in solution. It must be noted that though the methods of treatment and the apparatus used differ in different factories, this is rather of technical than of hygienic importance.

(a) Dutch or Stack Process

Metallic lead is subjected to the action of air charged with acetic acid vapour; tribasic lead acetate is formed which, under the influence of carbon dioxide given off by fermenting manure, becomes converted into white lead. This process comprises the following operations:

1. Melting and Casting of Lead. — The melting of the lead ingots takes place in pots placed in a reverberatory furnace and continually stirred. The metal is run into iron moulds, slightly inclined, and divided into 2 or 3 compartments by longitudinal walls. Thin strips about a metre in length are thus obtained.

Formerly strips rolled into spirals were used. These are now replaced by grids obtained by moulding. All these preliminary operations are now carried out mechanically: from the melting pot to the cutting of the lead strips or moulding of the grids. These latter fall as they are made on an endless chain which drops them on to a trolley.

Dangers. — Continual stirring of the lead during melting exposes the workmen to considerable heat and to the fumes which escape even if the ventilating hoods over the working doors draw well. Mechanical stirrers of simple construction, installed in certain factories, materially improve the conditions of work. Particles of lead which become detached from the strips and melting pots fall to the
ground and can easily get into the air, rendering it toxic. Removal of the dross from the surface of the lead during melting is also a source of danger.

**Hygiene.** — Melting should be done in a separate room and under a hood which, during casting, allows only of such an opening as is strictly necessary for the process; during all the other manipulations (re-melting the strips or grids) it should be completely closed. Workmen should have at their disposal means of limiting or hindering direct contact with the metal. Skimmings should be collected in a special air-tight receptacle or under water as in the case of slag.

2. **Carbonating the lead.** — This is carried out in stacks or in chambers built of masonry. A bed of horse dung or of tan of 30 to 40 cms. thickness is arranged for this purpose. Above are placed rows of earthenware pots containing a little dilute acetic acid or vinegar, or a mixture of vinegar and the yeast of beer. The perforated lead grids are placed on the pots. Where strips are used these are rolled into spirals and introduced into the pots, a rim preventing them reaching the bottom and so coming into contact with the acid. The whole is covered with boards, on the top of which exactly the same procedure is repeated several times.

One stack comprises numerous rows of pots and may contain 30 to 35,000 kgs. of lead and the proportion of lead converted into carbonate is from 40 per cent. to 60 per cent. After the lapse of 6 to 12 weeks, the perforated grids or strips are more or less completely changed into white lead. In this stage of the manufacture the risk of poisoning is great, as the work is carried out by hand and everything (implements, pots, dung, boards, grids, strips, etc.) is covered or contaminated with lead compounds.

**Hygiene.** — Organic matter should be chosen which does not give off unpleasant or injurious emanations. In Holland, as in Great Britain, for example, dung is replaced by tan; fermentation takes longer, but the white lead is a better white. The grids or strips and the dung should be removed without any dust, by watering as much as is necessary the grids (white beds) with a hosepipe and stand pipe installed in each stack. In watering the white beds, however, the white lead is not rendered sufficiently moist to prevent generation of dust when the workman, be he as careful as he can, lifts the corrosions to place them in a box.

3. **Screening or picking,** which consists in detaching the crusts of white lead from the lead which has remained unattacked, used to be done by hand with a wooden mallet. The operation is done now in an apparatus hermetically closed, sufficiently protecting the workman against the toxic dust given off during the operation.

**Hygiene.** — Picking and screening by hand should be prohibited. The picking should be done mechanically above troughs of water and under the action of pulverising machines (rollers) so arranged as to make the white lead fall into the vats. The closed apparatus should be provided with an effective exhaust and draught to prevent the lead dust escaping outside. The white lead, detached and ground, is carried into a bolting machine and eventually reaches a vat, while the grid passes to a special compartment. Grinding is done wet; simple guards protect the workmen from the splashes. The falling of white lead on the ground should be prevented as far as possible. Sieves should not be opened until all the dust has subsided, which can be facilitated, if necessary, by a jet of pulverised water or steam. If trolleys are not used corrosions should be carried in impermeable boxes avoiding any direct contact with the skin.

4. **Grinding, Drying, Crushing, etc.** — White lead is prepared in three forms: in flakes, in powder and ground in oil. Flake white lead is the direct product of the corrosion after passage through the rollers. White lead in powder is obtained by a series of highly dangerous operations, although closed automatic apparatus with effective exhaust is now used. These are grinding, sieving and packing or placing in sacks. Grinding the corrosions (wet) is effected in various ways notably by a series of horizontal mills disposed in stages (cascade system). The suspension of white lead passes successively from one mill to another with considerable splashing. The white lead, after it has left the mills, is placed in earthenware dishes which are loaded on to racks and introduced into the stoves or corridor driers. After drying, the contents of each dish are thrown down a covered-in shoot which carries them to a cylindrical grinder provided with a sifter or bolting machine; the white lead is passed through the barrel or sack fitted to the lower part of the shoot. All these operations are
carried out in apparatus hermetically closed and provided with an exhaust. The white lead in powder thus obtained is sold as such or ground in oil.

5. Grinding in Oil. — Incorporating the dry white lead in oil is done in a horizontal mixer, above which is an oil reservoir, the rate of discharge being regulated according to the desired density of the paint. The mass then passes through two cylindrical rolls and from there is transferred to barrels.

Actually, the majority of white lead works mix the pulp white lead directly with oil without previous drying and dry grinding.

Hygiene. — The following precautions should be observed: prohibition of entry into the stoves to take out the dishes before they have been properly ventilated and cooled. The stoves should have impermeable walls (smooth on the inside), and solid, even floors, capable of being easily cleaned either by water or vacuum. The Regulations of Great Britain require that every stove shall have one or more windows made to open and so placed as to admit of effectual through ventilation, that no dishes be placed on a rack more than 3 feet from the floor, and that no stove shall be entered for the purpose of drawing until the temperature has fallen to 70° F. or to a point not more than 10° F. above the temperature of the outside air.

Workmen employed in drawing the stoves ought not to be employed on more than two days a week. Generally speaking, all the processes, from removal of the corrosions to packing, are effected by mechanical means, as well as from one apparatus to another. Such apparatus should be installed in special rooms, and provided with metal air-tight covers; they should not be opened until all dust has subsided. If the bins in which the white lead is deposited can be emptied mechanically from the outside, entry inside should be prohibited. For grinding in oil in particular the following precautions should be observed: white lead in powder should be deposited in the hopper of the mixer in such a way as to prevent all escape of dust. The hopper should be surrounded by a hood connected with an exhaust maintaining a negative pressure inside. The mixing of dry white lead and oil and the preliminary grinding should be done in closed apparatus, from which the white lead in paste form should pass automatically to the cylindrical rolls. Packing also should be done in such a manner as to prevent the escape of dust.

German legislation, for example, prescribes that white lead shall not be pulvrised and mixed with oil except in pulp form, thus prohibiting mere moistening in these operations.

The working day for grinding and packing dry white lead should not exceed 5 to 6 hours, even if the workmen are employed in other departments for some part of the day.

Precautionary measures are necessary for avoiding the contamination of water in the subsoil (excepting public sewage) by liquids containing organic matter such as manure, or by waste water from the factory containing lead compounds in suspension or in solution.

(b) German Chamber Process

This consists in submitting metallic lead to the action of a mixture of air and acetic acid and carbon dioxide. White lead is obtained dry or wet. Although carried out in various ways, the process generally comprises the following operations:

1. Preparing the lead (little danger); melting it and running it into grids or long strips (see under (a) Dutch Process).

2. Carbonating the lead; transport into the oxidising chambers is effected by means of trolleys; the chambers are built of masonry divided into stages by a scaffolding of wooden beams supporting wooden laths on which to hang the strips of lead which are exposed simultaneously to the action of acetic acid vapour and carbon dioxide introduced from outside in special pipes. During this operation, which lasts from eight to ten weeks, the openings in the chamber (doors, windows, etc.) are hermetically closed and no one may enter. The white lead formed, which is deposited partly on the ground and remains partly suspended to the laths projecting from the scaffolding, is washed by means of a stream of water directed on the laths to cause it to fall down. The laths are then thrown to the ground and the whole is again well watered. The white lead suspension then runs into a tank at the side of the oxidising chamber, being driven there by a strong stream of water and shovels.

Hygiene. — The walls of the chambers should be constructed of smooth and impermeable material, and the latter should be provided with water
supply and hosepipe; the whole of the internal contents before and after the introduction of the materials should be kept moist. Entry should not be made till after complete cooling and thorough ventilation (which however must not proceed so far as to dry the white lead). Detachment of the white lead from the laths, beams, walls, etc., should, if possible, be effected by a powerful stream of water. The white lead in the chamber should be removed either by a stream of water or, in the wet state, by trolley (it should be noted, however, that the white lead does not absorb water well and that it is almost impossible to deprive the chamber of all dust and not find small quantities of dry white lead on the uprights of the frames). By thus using removal by water all manual work is avoided; metallic debris, which may get into the vat, is easily separated by difference in density or by screening.

Although the German system sensibly diminishes the danger of poisoning, all necessary precautions for the protection of the workers should be adopted. They should have suitable boots; night work in the chambers should be prohibited; duration of work in filling and emptying should be limited to a maximum of six hours daily, with a rest of one hour after each spell of two hours’ work.

3. Washing, Grinding, Crushing, etc. — The suspension of white lead, treated with water in special washers, passes into vats provided with strainers where it loses a great part of its water; what remains is next removed by means of filter presses. The succeeding operations are the same as in the Dutch process.

Hygiene. — The measures to be observed are in general the same as those already indicated. The white lead should be conveyed to the washbecks by mechanical means or by a stream of water. Workrooms should be built so that no dust or lead fumes can enter. Workrooms in which the processes of dry sieving, packing, etc., are done should be separated from others by impermeable walls, if these operations are done while the product is in a dry state. If the dust cannot be immediately and completely removed by exhaust draught, other effective means may have to be devised as a pit alarm (respirators, moist sponges, etc.). Lastly, hours of work may be shortened. We give below a brief summary of the other processes most commonly applied.

(c) The French Process Known as the Clichy Process

This uses, as the initial material, litharge (see that article) dissolved in acetic acid so as to form a solution of the basic acetate, which is then precipitated by carbon dioxide. The operation is carried through almost entirely in the same apparatus. Litharge in powder is introduced into a tarred wooden vat containing dilute cold acetic acid provided with a mechanical stirrer. After having been clarified by decantation, the liquid passes into a precipitating vat where, through a series of vertical tubes dipping into the liquid, the carbon dioxide previously washed is passed. The white lead is entirely precipitated in 12 hours, and the residual liquor, which contains neutral acetate of lead, is used to dissolve a fresh quantity of litharge. Subsequent processes are analogous to those of the Dutch process.

(d) The Wulze (or Carter or American) Process

This method is very quick and less unhealthy than the others, but it requires a larger number of workers. Basic acetate of lead is obtained by causing acetic acid and a little steam to act on metallic lead in a fine state of subdivision and in the presence of compressed air. The solution of basic acetate of lead thus produced is treated in a carbonator with carbon dioxide under pressure. The transformation of the acetate into carbonate takes only from two to three hours.

(e) The Austrian Process

This is a modification of the German process in which fine lead leaves folded in the middle are used together with a hot liquid fermented by means of inferior dry grapes or fruit must. The reaction takes five weeks. The white lead put on the market in the form of thimbles or tiny hats sometimes underwent a superficial polishing — very dangerous as it was done by hand and had naturally to be done dry.

(f) The Electrolytic Process

This is excellent from the hygienic point of view, but does not appear to have yielded sufficiently good results either from the point of view of quality (poor covering power) or from the economic point of view. Among the different ways in which this process is applied, the commonest is the electrolysis of a bath containing a
soluble salt (acetate or nitrate of soda or ammonium) with one anode constituted by a plate of lead. The lead is changed into a basic salt and the carbon dioxide given off precipitates the white lead.

(g) A Process Without Acetic Acid

This process consists in using finely divided lead, carbon dioxide, air and water.

The Milner and James processes are only modifications of those described above. Lastly, a fairly unhealthy process has been described in which the lead is melted and oxidised in a current of pulvcrised steam. The litharge thus obtained is spread out on a floor and sprinkled several times with acetic acid, being stirred at the same time. The whole is placed in stoves heated until deisiccation and the reaction is complete.

USES

White lead is certainly one of the substances with the widest technical use in industry. It should be observed that, if, on the one hand, less poisonous or harmless substitutes have taken its place in many industries (to the number of 18) enumerated by Layet, it is, on the other hand, now used in work where it was not used before.

White lead serves above all as a pigment, either for white colours or for other light tints. It is thus used in the following processes: manufacture of satined, damasked, glazed (coated) paper, cardboard or paper for cards (visiting cards, wallpaper, etc.); in pottery, ceramics, enamels, stained glass, etc. (see these articles); in the glazed leather and waxed cloth industries; in the lace trade; in the manufacture of carpets; in the chemical industry (lead compounds). White lead is further used in the dressing of stuffs, whitening unbleached lace, gloves and shoes; as a pouce for reproducing designs on materials; for the preparation of the white paste for setting pearls; for paints and cosmetics (used since Roman times and still to-day in certain oriental countries). Mention should be made of cases of poisoning of alimentary origin (burning wood painted with white lead in bakers' ovens).

The commonest and best known use of white lead is, however, certainly as a pigment for water or oil colours in house painting, painting of wagons, ships, wood and metal work, decoration, toys, etc.; as a lacquer and cement for jointing, piping, etc.

At one period the use of white lead was very extensive because of a "white fashion" not only in furniture, but also in articles of wear (shoes, sticks, etc.).

TOXICITY — CHANNELS OF ABSORPTION, ETC.

[See articles "Lead (Poisoning by)"] and "Occupational Poisonings"]

So far as white lead is concerned, few examples of fatal poisoning by a single dose can be adduced (sometimes it has been 25 grm, and sometimes 40 to 45 grmrn.). The toxic dose varies according to individual and accidental circumstances. There are cases in which much smaller doses of salts of lead have shown themselves poisonous.

Although authorities agree that white and red lead are the lead compounds which cause incomparably the largest number of cases of chronic plumbism, they do not state what is the minimal dose capable of inducing chronic lead poisoning. It is thought, however, that though this dose is very often difficult or impossible to determine, yet a minimal dose of 2 milligrammes absorbed daily would suffice to cause chronic poisoning (Legge and Goodby).

Numerous analyses of the air in white lead factories made by Lehmann (1921) proved that one cubic metre of air contains 0.2-4 mg. of lead, which in a working day of 8 hours would represent the inhalation of 0.4-16 mg. of lead (on the supposition that a workman breathes during this time 1 to 4 cubic metres of air). Certainly, some of the lead is deposited on the nasal mucous membrane and is eliminated by the handkerchief. Kranenburg (Netherlands) in 1914 found in different departments of white lead factories in 1 cm. of air the following amounts: Chambers during emptying, 8 mg.; during emptying wet, 4-8 mg.; the same when very wet, 0.6 mg.; during the filling of the chambers, 3-2 mg.; stoves during emptying, 1.2 mg.; during filling 1.5 mg.

Examining the faeces of 9 white lead workers exposed to a moderate amount of risk, Lehmann found (1921) lead to an extent varying from a minimum of 0.1 mg. to a maximum of 1.8 mg. (average 0.9 mg.). He considered that these quantities can be regarded as inoffensive.

STATISTICS

Though statistics as to incidence of lead poisoning among workpeople in white
lead works are very numerous, many of them unfortunately date back to a time when preventive measures hardly existed and methods were very different from those adopted in modern factories. Statutory requirements also have materially modified the conditions under which the work is done and the data available from factory inspectors’ reports generally vary very much according as to whether the date precedes or follows the date of the application of statutory regulations.

Austria. — Before regulations were enforced (1894-1900) the general morbidity of white lead workers showed very high rates (105.3, 138, 247 and even 376.3 per cent. of the workmen in a group of four factories), as well as morbidity from lead poisoning (19.3, 56.4, 90.5 and even 135.6 per 100 workmen; but after they came into force the rates fell to 14.5 per cent. for general morbidity (e.g. at Klagenfurt, 1914) and to 9.4 per cent. for lead poisoning.

France. — The following figures are taken from a personal enquiry by Audisteré (of Paris) on the personnel of a white lead and red lead factory, with about 127 workers (of whom 47 were employed on white and 21 on red lead). Of the 47 white lead workers, the duration of employment in 12 cases had been 1 year, in 15 from 1 to 5, in 2 from 5 to 10, in 11 from 11 to 20, and in 7 more than 20 years. Cases of sickness of every description (lead poisoning and others) reported during the period 1918 to 1920 were as follows:

<table>
<thead>
<tr>
<th>Year</th>
<th>Total working days</th>
<th>Total days of sickness</th>
<th>Ratio of days of sickness to days of work</th>
</tr>
</thead>
<tbody>
<tr>
<td>1918</td>
<td>34,320</td>
<td>2,530</td>
<td>12.4%</td>

<td>5.1%</td>
</tr>
</tbody>
</table>

In 1922 (Regulations applied in 1919), the cases of lead poisoning in white lead workers numbered 94 (out of 797 reported cases). For white lead (and red lead), the figures are: 1925, 125; 1926, 105; 1927, 37; 1928, 31, 1929, 25; 1930, 44.

Great Britain. — The reports of the Medical Inspector of Factories show the following cases of lead poisoning in the white lead (and red lead) industry for the years 1925 to 1932: 1925, 19 (1); 1926, 13 (1); 1927, 11 (1); 1928, 21 (1); 1929, 9 (1); 1930, 3 (1); 1931, 1 (1); 1932, 4 (1), figures in brackets being the fatal cases.

In a memorandum on industrial lead poisoning issued by the Factory Department of the Home Office (1921), the number of cases per 1,000 workers exposed to risk was approximately for the years 1911-1914 as follows:

<table>
<thead>
<tr>
<th>Industry</th>
<th>Approximate number of workers</th>
<th>Number of cases of lead poisoning per 1,000 persons employed</th>
</tr>
</thead>
<tbody>

</tbody>
</table>

It must however be remembered that, as in the case of white lead, diseases, the cases notified do not accurately reflect the situation, for without doubt there exist a certain number of cases latent or not recognised or omitted and therefore not included in the reports (quoted from memorandum).

Germany. — Statistics for the whole Empire cannot be given. In the factory inspector's reports information is given on the sanitary conditions of particular factories, which may serve as an indication.

In 1919 in a white lead factory in Prussia 37 cases of sickness per 100 workmen were reported (there were 10.9 cases in 1913) and 3.7 cases of lead poisoning per 100 workmen (2.7 per cent. in 1913).

In 1920 to 1921 Lehmann saw 400 workmen employed in 21 white lead works (of which 19 produced only white lead), and made the following clinical observations: no blue line in 53 per cent.; normal punctate basophilia in 24 per cent. and almost normal in the other 29—total 48 per cent.; haemoglobin normal in 64 per cent.; haematoporphyrine (in the urine) normal in 80 per cent.; strength of the extensors of the wrist normal in 56 per cent., and above it in 21 per cent.—total 79 per cent. The figures for morbidity in the German white lead industry per 100 workmen were as follows:

<table>
<thead>
<tr>
<th>Year</th>
<th>Total working days</th>
<th>Total days of sickness</th>
<th>Ratio of days of sickness to days of work</th>

1 See for example the statistics given by Geism: Thesi (Zurich, 1911), pp. 72 et seq.
factories before coming into force in 1914. Stricter regulations were enacted in 1920 (27 January).

Italy. — No information save the results of the enquiry in 1912 by Rubino relating to 17 of the 35 workers employed in the two white lead factories of Genoa.

Netherlands. — Enquiry in 1912 by the Medical Inspector of Factories showed that among 98 out of 110 workmen employed on the average in 4 white lead factories, 83 gave evidence of lead in the feces. In 1913, 31 cases of lead poisoning among the 385 workmen in 4 white lead works were reported and similarly, in 1914, 28 of the 54 reported cases of lead poisoning occurred in the same four factories. During the latter years, the whole of the personnel was examined, with the result that a blue line was found present in 54; tremor of the fingers in 88; in one case paralysis of the fingers of both hands: 13 had had lead colic. The turnover among the workers was very high. In 1912, for example, the white lead works with an average of 110 workers engaged 354 persons.

Of the 23 reported cases in 1915, 14 related to 13 white lead workers in the factories in question. Of the 27 examined, only 26 showed a blue line and 52 tremor of the fingers. In 1916, 7 of the 23 reported cases were white lead workers. Following on these enquiries, the inspectorate decided from 1 January 1917 to limit the daily hours of work to 8.

In 1917 the reported cases numbered only 11, of which four were employed in the four white lead works. The periodic examination of 127 workers showed 43 with a blue line, and tremor in 60. In 1918 only one case of lead poisoning affecting a white lead worker was reported. The factories were reduced to 3, and 77 of a total of 110 workers were examined. A blue line was found in 13 and tremor in 22. In 1919, examination of 58 men was made of whom 26 were employed before 1919 and the remainder only since 1 January. The turnover was still very high.

**Pathology — Diagnosis**

**Demonstration of Lead, etc.**

[See article "Lead Poisoning"]

**Hygiene**

In addition to the special hygienic measures described in the paragraphs concerning the manufacture of white lead, the hygienic and prophylactic measures applying to the industry as a whole are identical and may be summarized thus:

The rooms should be spacious, well ventilated, with direct and sufficient daylight; the machines should be installed on a definite plan. The floors should be impervious, smooth and solid, and maintained in good condition. Workrooms should be cleaned daily by a stream of water as soon as work has ceased for the day. All trolley lines and drains should be cleaned carefully every day at the end of the day's work.

The walls and woodwork, etc., and generally all places where lead dust can collect, should be washed every week. All dry cleaning should be prohibited. The German regulations, however, permit of vacuum cleaning, even by means of portable apparatus. The dust then collected should be disposed of in a place suitably chosen, so that its re-entry into the workroom or absorption by the workers is impossible.

The walls should be smooth, impervious and lime-washed at least twice a year, or if oil painted or covered with a washable material, they should be washed at least twice a year.

The furnaces, apparatus, pipes, trolleys and all the objects which the workmen are called on to manipulate should be cleaned whenever necessary and at least once every fortnight. The handles of the tools (spades, shovels) should be cleaned every day after work has ceased.

Smoking, chewing and taking snuff during work should be prohibited as well as the bringing of food or alcoholic drinks into the workrooms.

Workers who have to manipulate lead compounds should be instructed as to the dangers to health of lead and as to the precautions necessary for guarding against them. This instruction should be given to every workman by the appointed surgeon on first employment and repeated at the periodic examination. Work in a white lead factory does not demand an apprenticeship nor any special aptitude. This explains why the personnel increases rapidly at certain periods of the year (when orders are good) to diminish rapidly afterwards. This turnover, which is constant and well marked, is characteristic of the white lead industry.

The happy effect of alternation of work in the factory with that on allotments close to it has been repeatedly noted.

**Legislation**

**Employment of women and young persons.** — It should suffice to say that legislation in general prohibits the employment of women in processes in the manufacture of white lead and of lead colours. Thus, for example, Argentina, Australia, Belgium, Canada, Czechoslovakia, France, Germany, Great Britain, Japan, New Zealand, the Netherlands, Poland, South Africa, and Switzerland exclude women
and young persons from "all work exposing the persons employed to serious risk of poisoning."

The First General Conference of the International Labour Organisation of the League of Nations (Washington, 1919) recommends that in view of the danger involved to the function of maternity and to the health and well-being of the offspring, women and young persons under the age of eighteen years be excluded from employment on the manufacture of white lead and on cleaning workrooms where such work is effected.

It is further recommended that the employment of women and young persons under the age of eighteen years in processes involving the use of lead compounds be permitted only subject to the following conditions: locally applied exhaust ventilation, so as to remove dust and fumes at the point of origin; cleanliness of tools and workrooms; notification to Government authorities of all cases of lead poisoning and compensation therefore; periodic medical examination of the persons employed in such processes; provision of sufficient and suitable cloakroom, washing, and mess-room accommodation, and special protective clothing; prohibition of bringing food or drink into workrooms.

The Conference also recommends that in those industries where it is possible to substitute non-toxic substances for the soluble salts of lead, the use of the said soluble salts of lead should be vigorously controlled. All salts of lead containing more than 5 per cent. of their own weight in metallic lead in a 0.25 per cent. solution of hydrochloric acid are to be considered as soluble.

Legislation as to the age of young persons on admission varies from one country to another. Thus, for example, in Italy and in Japan lads under 15 years of age are excluded from white lead works, under 16 in Argentina, Belgium, Germany, Greece, Spain; under 18 in the British Empire and the Netherlands.

Young persons under 15 years of age are excluded from lead colour factories in the State of Delaware; under 16 in the States of Alabama, Arizona, California, Colorado, Connecticut, Florida, Illinois, Kentucky, Maryland, Missouri, Nevada, New Jersey, New York, North Dakota, Ohio, Oklahoma, Utah, Vermont, Wisconsin, Wyoming, in Germany and Belgium, Greece, and Argentina; under 18 in Great Britain, South Africa, Western Australia, New South Wales, Victoria, Tasmania, Norway, Poland; under 21 in Pennsylvania. Women under 18 are excluded from white lead factories in South Africa, in Greece and in the province of Quebec and under 21 in Italy (see article "Lead").

Special Legislation on White Lead Factories and Use of White Lead
(See also article "Painting Industry").

**Wine and Spirit Industry**

Wine is the product of the fermentation of grape-must, which, in its turn, is derived from crushed grapes. Must consists of a collection of substances dissolved in water squeezed straight from the grape. Water, then, is its principal constituent.
The composition of the must, and consequently of the wine which comes from it, varies in different countries according to the quality of the grapes and the process of its production. It will suffice here to speak of the kinds used in making ordinary table wines, in order to convey an exact idea of any strain arising from work connected with wines and musts.

During the fermentation of musts, which is carried out in large vessels, usually in vats, the sugar, or glucose, present in the must, is decomposed, and converted into alcohols which dissolve in the fermenting liquid, and also into carbonic anhydride, which for the most part escapes into the surrounding air.

If large amounts are liberated in closed, confined or badly ventilated premises, the personnel working at the vats is exposed to serious risk from poisoning, which may manifest itself as a slight indisposition with general discomfort, headaches, dizziness or a singing in the ears, or by more serious symptoms, such as fainting or even sudden death from suffocation.

The work entrusted to the cellarmen, following the maturing of the wine in the vats, commences with emptying the vats and putting the wine into barrels. In the meantime, while the first wine is in the cellars, it has to undergo another fermentation — the second, or slow, fermentation — still under the action of *Vini mycoderma*; this results in the formation of alcohol and carbon dioxide. The marc or residuum is then pressed in order to prepare the second wines.

Wines in barrels require special attention during the eventual alcoholic poisonisation arising from rackings off, clarifying and filtration. Finally, the wine passes from the barrels into such smaller receptacles as casks and bottles, ready for being placed on sale and for consumption.

This series of operations offers many opportunities for exposure of the personnel of the wine-cellars to industrial alcoholic poisoning. Although acute intoxication by ethyl alcohol in the case of drinkers is well recognised as a cause of accidental or habitual drunkenness, and although chronic indulgence in alcoholism is well known as a cause of disease; on the other hand, much less attention is devoted to the problem of acute or chronic occupational poisoning.

**Statistics**

Data relative to the hygienic and sanitary conditions of workers in this occupational category are not numerous (for mortality statistics, see article "Alcohol, Intoxication by ").

An article by Granjux on the state of health among workers in a factory where Bordeaux liqueurs were made was published in 1908. This expert was struck by the absence of cases of alcoholism among the workmen of the said factory, by the number of elderly people among the employees and by the small proportion of lost time. There was no weekly round of tasks as adopted by the Chartruese monks, but, instead, machinery had been so developed there as to allow the alcohol to be manipulated in closed vessels, and to prevent its evaporation in the workshops.

About a third of the staff were more than fifty years old, which is explained by a very humane idea adopted by the management: old workmen who are tired out, but not diseased, are put on work which gets increasingly easier. They too, when pensioned off, in proportion to those at work in the factory, was 6 per cent.; morbidity among the workers was also negligible, the percentage of days of absence having been only 2.18, a very low rate if there be taken into consideration the fact that two-thirds of the workers were women, and that the old workmen were kept on as long as they were capable of rendering any service whatsoever.

This state of things is accounted for by the use of machines, by selection of the factory hands and by the adoption of such measures for general health as spacious, well- aired and clean workshops, automatic or mechanical labour, and dining halls.

There should also be mentioned the steps taken by the management to assure the good health of its employees by setting up canteens in the workshops to protect the workmen against the attraction of the wine-merchant; by instituting a system by which the workman is provided with free drinks in exchange for coupons, of which they received a fixed number every week; by establishing houses in the country; by medical assistance with free choice of doctor; and by medical assistance during maternity and for working mothers.

Delaunay in 1924 also examined a certain number of Bordeaux cellarmen, without, however, finding among them any illness peculiar to their work. He holds that the principal influences conducive to unhealthiness are lack of air and light with humid conditions; but he considers that wine fumes and sulphurous emanations have practically no effect on the constitutions of cellarmen. Rheumatism, on the other hand, is frequent, but tuberculosis is exceptional.

This expert, as likewise Léon Meunier in 1928, has, on the other hand, referred to forms of illness peculiar to "wine-tasters", who have every day to taste 100, 150, 200 or even more samples. Tasting consists, first of all, in inhaling the aroma of the liquid under examination, whether wine, liqueur or alcohol, next in taking a mouth-
ful into the buccal cavity, where it is rolled round in contact with the taste bulbs, and then in spitting it out, so that the same process may be repeated on another sample. These tasters complain of marked fatigue, of a feeling of irritation in the throat and of stomach troubles, which affect novices the most, as after a time the worker grows accustomed to the process. These affections of the glanulard and motor activity of the stomach are of necessity reflex phenomena, because the taster never swallows the liquid.

Badham in 1924 studied the health conditions in certain wine-cellarSydney; he examined 63 workmen, among whom he found an undue incidence of lesions of the renal arteries. A case of pulmonary tuberculosis was attributed by Badham to insufficient ventilation in the wine-cellar where the man worked. Two cases of lead poisoning were caused by the use of a mixture of white lead and turpentine for the painting of the barrels. Analysis of the air established that the amount of carbonic acid present varied between 3.8 and 11.9 parts per 10,000 of air. But it is well known that workmen who are accustomed to live in such an atmosphere do not realise the unhealthy state of the atmosphere. Alcohol and ether vapours are given off whenever the liquid is being poured, whilst wine is being racked, from any winy mass collected in vessels, from wine which is often spilled on the ground, and from that which falls on the outside of bottles and casks. The evaporation of alcohol is also facilitated by the coming and going of the workers, and by the high temperature of the cellar.

PATHOLOGY

Alcohol can be absorbed even through the unbroken skin. But it is well known that the absorption of alcoholic vapours by the respiratory tracts after inhalation is both easy and rapid. Men who fill barrels and bottles with ordinary table wines standardised at from 10° to 14°, or choice wines which have a higher degree of alcohol, show acute symptoms of ordinary intoxication, which may be serious or even induce coma. There are on record several clinical observations of serious and acute intoxications from ethyl alcohol among wine-bottlers, working in close places, without these individuals having actually drunk a single drop of wine (Pieraccini). Intoxication due to swallowing, which would at least act as a help to inhaled alcohol, was ruled out on vomiting being induced artificially. The matter vomited did not contain traces of alcohol, although it was present in the urine.

Intoxication and drunkenness are found among cellarmen occupied in racking wines, and, most of all, among the bottlers. In short, alcoholic fumes are given off from the surface of the wine, and from the opening of the tap to the bottle; they form, especially if the stream is divided into secondary jets, a fine mist, on account of the wine striking against the neck of the bottle or the inner sur-

face of the funnel. The clash of wine and air causes the formation of a certain quantity of tiny droplets, which carry alcoholic fumes. In the same way, little bubbles of air escape from the mass of liquid, when it is being disturbed at the moment of racking, and particularly when sparkling wines are being racked. Yet this danger is less serious when bottling is carried out by mechanical or automatic devices.

Other substances, such as volatile ethers, which are present in wine may also cause occupational drunkenness.

Akin to acute intoxication, a form of chronic intoxication, of occupational origin, occurs amongst wine-makers. In the closed places where the preparation, storing and manipulation of wines take place, the atmosphere is continually full of alcoholic vapours and wine fusel oils. The smell soon warns strangers who come into these places by chance of the state of affairs. But it is well known that workmen who are accustomed to live in such an atmosphere do not realise the unhealthy state of the atmosphere. Alcohol and ether vapours are given off whenever the liquid is being poured, whilst wine is being racked, from any winy mass collected in vessels, from wine which is often spilled on the ground, and from that which falls on the outside of bottles and casks. The evaporation of alcohol is also facilitated by the coming and going of the workers, and by the high temperature of the cellar. Chronic occupational alcoholism may assume all the pathological forms characteristic of chronic indulgence in alcohol. Theoretically a difference should be recognised between the two forms of poisoning, on the supposition that inhaled alcohol acts principally on the nerve centres, which are more sensitive to the poison, although the alcohol reaches the different organs uniformly through the circulation; on the other hand, ingested alcohol not only causes lesions, through direct action on the pharynx, the oesophagus and the intestines, but is even able to attack the liver more seriously and more directly.

The chronic occupational form is dangerous also because it comes on in an insidious manner, and because it is generally combined with the form due to indulgence; hence the ingested and inhaled alcohol combine their injurious action. Nevertheless, an equal quantity being taken of each and absorbed for the same length of time, inhaled alcohol seems to act more vigorously than ingested alcohol, because the latter, if it is taken at ordinary
meal times, settles down to a certain extent with food, whereas inhaled alco-
hol gains access unaltered and rapidly, and can strike immediately — that is,
without first undergoing any chemical changes — at those vital organs which
are most richly supplied with blood, of which, of course, the brain stands
first.

This occupational alcoholism, description of which dates from Ramazzini1,
occurs, not only among cellarmen, but also among wine-tasters, agents and
wholesale merchants, and innkeepers who sell wine in small quantities by
the glass. Among these persons wine fumes, inhaled occupationally, may be
the forerunner of eventual alcoholism through ingestion.

The tannin present in the must and
the wine may also be a source of
trouble to the workers. Tannin, even
in a very dilute solution, exercises a
cogulating action on animal tissues,
more especially so if the contact is pro-
longed. Hence, the hands and fore-
arms of cellarmen, who almost always
have their hands steeped in the wine,
are subjected to prolonged soaking
in alcohol and tannic substances dis-
solved in the musts, the lees, the marcs
and the wines. In this case the de-
hydrating action of the alcohol coagul-
ates and precipitates the albumens,
and that of the tannin also coagulates
the albumens and collagenous sub-
stances. Under their combined action
the skin becomes blackish, dry, hard,
cracked and sometimes covered with
deep and painful sores. The water
from the musts and wines, penetrat-
ing the tissues of the hands, reinforces
the caustic action of the tannic mat-
erials by maceration.

Other processes in the manipulation
of wines are worthy of note, such as
sulphuring the receptacles, both vats
and barrels, and certain treatment for
correcting any irregularities or faults
in the wines by the use of sulphuric or
sulphydric acid.

Under the heading of “distillation
and manufacture of spirits” may be
grouped the distillation and refining of
alcohol (for details, see article “Alco-
hol”); the manufacture of brandy,
obtained through distilling wine or the
lees of the vintage; the preparation of
special liqueur-brandy, with the help of
trade-alcohol and of substances to
improve the quality; and, lastly,
the manufacture and distillation of
liqueurs, such as aperitives and ordi-
mary or choice liqueurs.

The inhalation of carbon dioxide
of wine fumes given off from musts
and from vinasses and wines, and of
alcoholic vapours in distilleries and
liqueur factories, represents the most
important occupational risk. This risk
can be mitigated or overcome by pro-
viding spacious, clean, well-ventilated
workplaces, and using mechanical de-
vices for crushing the grapes in the
vats, for pressing the vinasses and for
racking the wines. The processes of
distillation, of rectification and the
manipulation of alcohols and liqueurs,
can be carried out in closed vessels,
by ensuring the transit of the liquids
from one receptacle to another by means
of compressed air or by pumps.

Rjasanow in 1931 studied the per-
centage of carbon dioxide present in the
fermentation rooms of distilleries and
alcohol factories. The daily cleansing
and disinfection of the fermenting vats
sometimes necessitates the workmen
entering the vats or bins — a danger-
ous practice, too often fraught with
fatal results.

The amount of carbon dioxide depends
on the stage of fermentation. Rjasa-
now found quantities ranging from a
minimum of 2.4 per cent. to a maxi-
imum of 16 per cent. These amounts
vary according to the ventilation of
the premises; ventilation is also essen-
tial, within certain limits, for a good
production.

The cleaning out of the vats and bins
ought to be done under a jet of cold
water, which much reduces the amount
of carbon dioxide owing to its solubility
in cold water; hot water, on the other
hand, increases the amount.

**Hygiene**

Every step possible should be taken
to avoid the risk of scalding, through
splashes from jets of hot alcohol or
fluids.

In accordance with the precepts of
occupational hygiene and social wel-
fare, all young persons, children and
women should be prohibited from work
at storing and manipulating wine in
cellars and distilleries, and also all per-
sons predisposed to neurotic symptoms,
as, for example, neuropathics and
epileptics, because these occupations
offer opportunities for drink and for
acquiring harmful habits. It is true
that alcohol inhaled and circulating
in the human body becomes, at any rate
in small quantities, oxidised and
utilised as a source of heat and energy;
but, in this case, the amount of alco-
hol drunk should remain always very
small, and the inhalation of wine fumes

1 "Ex odore et vini spiritibus per aorem dis-
persis, ac per os et nares. . ." (Chap. XXI).
should form an exceptional occurrence, and not a daily occupational rule.

Be that as it may, the selective action of alcohol on the nervous system is, even in very small quantities, to be feared for young people, whose nervous system is in course of development, and consequently ultra-sensitive to all poisons.

As regards its effect on the female organism, it will suffice to say that alcohol exerts a maleficient influence on the ovum, just as it does on the spermatozoon, on the embryo and the foetus, and that it is excreted through lactic secretion, which is a danger for the organism, on the ovum, just as alcohol on the nervous system is, and not a daily occupational rule.

Adequate measures must be taken to ensure good ventilation and sufficient lighting of underground places; cement floors with narrow grooves and so sloped as to ensure the drainage of fluids are to be recommended. Mechanical methods should be adopted for barrelling and bottling. Measures for individual cleanliness must also be provided.

**Legislation**

In Belgium young persons under fourteen years are not allowed to work at distilleries, in malt-houses and places where the fermentation is carried out, nor at distilleries for liqueur spirits, in the places where the actual distilling is done. Special laws have been passed in Germany: in Prussia (1901) relating to work in the fermentation departments of distilleries, and in Bavaria (1903) relating to the arrangement of wine-cellars during the fermentation of the wine.

Compensation for chronic occupational intoxication among the workers in distilleries is accorded in Chile.

**Coopers**

The health conditions of coopers are similar to those of makers of vats, tubs, kegs and casks, so that all these men may be grouped under the general heading of "makers of receptacles for wine", and what follows relating to the occupational health of coopers applies also to that of these other workers.

A cask is a wooden vessel which is used for the collection and transport of liquids, and especially of wine. It consists essentially of staves, that is to say, of tapering strips of wood, which constitute the body of the cask, whether cylindrical or oval in shape, and of two circular ends, which close the cask, one at the top and the other at the bottom. Planks of wood are used which are straight or slightly convex towards the interior, so that they can best withstand the pressure of the liquid.

A cask is provided with an opening or bung, that is to say, a round hole made in the upper part of the body of the cask in its widest part. It is through this hole that the liquids are emptied out. A cask is also provided with a small opening, low down near the end in front, which is used for cleaning the inside or for fixing the tap ready for drawing the contents.

For the construction of casks, wood of hard and close fibre is used, which does not allow liquid to leak through, and preserves it well, whilst the wood, in contact with the fluid, becomes harder, more compact and more resistant.

Large squared planks of wood pass from the hands of the woodcutter to the hands of the cooper, who, with saw and axe, rough-hews them and makes them equal in size. Rough hand-work with the axe produces a tremendous quantity of wood-chips, but not dust; whereas work with the mechanical or hand saw makes dust, but nevertheless not very much of it, the wood worked not being too dry. These operations are tiring, but are not bad for the health of the worker.

On the other hand, the ordinary planning and work with the moulding-plane, as well as hollowing the grooves necessary to take the two ends of the cask, produce small chips and much dust, especially when the wood is dry.

Generally speaking, in modern factories, these processes are carried out by machinery, but in small workshops hand-tools are used. In both cases dust is abundant, a dust which is fine, hard, stinging and full of tannins.

It must be added that the machines spray out the dust to some distance, and throw off little chips so violently that the workmen have to protect themselves with respirators and goggles. With hand-work the raising of dust is less important, but the workman raises it from time to time with his hand or with a brush, or even blows it up with his mouth, from the piece on which he is working.

The workers complain of coughs, and of a parched feeling in the nasal and pharyngeal mucous membranes. The inhalation of dust may set up tracheo-bronchial catarrh.

The pressing out and curving of staves is done by putting the dry staves, already prepared, into special boxes, which soften them and make them pliable and unlikely to break. Accord-
ing to an old custom, still quite extensively followed, the staves are softened by being left in hot water for about twenty-four hours. In up-to-date factories, the staves are put into large metal vessels, into which steam from boiling water is passed. The water in these baths changes into a blackish liquid, rich in tannic matter.

As a rule, the workmen occupied in pressing and curving suffer no injury, but if they put their hands and forearms into the liquid, or handle the damp staves, the local and direct action of the tannin on the skin, where the humidity, by macerating the skin, helps the action of the tannin, desiccates and hardens the skin, and sometimes causes cracks which may be comparatively deep and painful. The actual curving of the staves is done by machines.

As soon as the cask is mounted, held together by a temporary hooping of wood and adjusted, the outside surface is planed and smoothed. This procedure also generates dust. Lastly, the cask passes on to its real hooping, with iron rings, to which are also added wooden hoops, to protect it against joltings when being rolled on hard surfaces.

Sometimes the outside of the ends are varnished, and liquid paraffin is poured into the cask in order to coat the inside wall with a thin layer, and so make it less permeable to liquids. The paraffin is melted by heat in a cauldron. Irritation of the conjunctiva has been reported, and of the respiratory passages, with coughing. In serious, but very rare, cases, fits of suffocation occur, and also bronchitis and dermatitis due to direct irritation of the skin.

**Hygiene**

The workers should be protected against accidents due to flying chips by goggles, and against the sawdust by respirators. When the work is done by machinery, protection is easily effected by fitting the machines with suitable safeguards, and localised exhaust ducts. Measures for protection must also be taken during the preparation and use of paraffin.

**Prof. G. Pieraccini**
(Florence).

---

Women's Work

The industrial employment of women, largely brought about by the industrial revolution which commenced in Great Britain at the beginning of the nineteenth century, finds its explanation in the following reasons: application of mechanical power to operations until then confined to men; increase in the demand for semi-skilled or unskilled labour; industrialisation of certain products until then prepared by women in their homes (spinning, lace-making, knitting, sewing, fruit-preserving, etc.).

The lack of male labour brought about by the war naturally increased the number of women employed in industry. This fact soon drew the attention of Governments to the evil consequences of factory work both for the woman and for the race. To-day economic and political reasons certainly compel women more and more to abandon domestic and family life for industrial, commercial and intellectual occupations — factors which determine the pathology and hygiene of women's work, giving to the first its seriousness and to the second its importance.

Available statistics show that the number of women engaged in industrial work are as stated in the table on the next page.

In Japan the number of active women between fifteen and sixty years of age is, according to Teruoka, 16,731,000, of whom about 60 per cent. have some occupation (agriculture, 6 per cent.; industrial employment, 14 per cent.; commerce, 9 per cent.; domestic service, 6 per cent.; public institutions, 3 per cent.; factories, 9 per cent.; transport, 6 per cent.). In 1892, 856,182 were employed in industry, 71,349 in mines, 331,372 in other occupations (13 per cent. of the female population). In 1923, 74 per cent. (about 856,000) of the women workers were in factories, of which 736,153 were in the textile industry and dyeworks, 14,394 in engineering workshops, 51,549 in the chemical industries, and 21,955 in different industries.¹

¹In Japan the largest number of women work, as has been said, in the textile industry and dyeworks (86 per cent. of all working women) where 86 per cent. are of the female sex. According to the 1923 statistics, among the 856,000, women workers in factories, 966,000 were female young persons under sixteen years of age, of whom 900,000 were employed in textile mills and dyeworks. It is important to remember, too, that 80 per cent. of the women worked ten to twelve hours a day, and that, in 1922, 30 per cent. of the factories working night
The injurious effects of labour on the female organism are established by quite a series of statistical data. At the same time, according to some authorities (Collis), as the verification of these statistics is difficult it would be well to accept them with a certain amount of reserve. Women indeed are not generally subjected to industrial influences for more than ten years, but it is also true that, in contradistinction to what is the case with men, many more women are exposed during this relatively short period to the detrimental effects of industry. So much so is this the case that the definite effect of industrial labour on the female population is much greater than that represented at any given moment by the number of women employed in factories. An effort would, therefore, require to be made to seek to find out the remote consequences of employment on women who have left work — a thing which is practically impossible. On the other hand, industrial work constantly increases or aggravates the number of maladies from which young women suffer: chlorosis, anaemia, disorders of the nervous system, of the organs, etc.; disorders which, more than in the case with men, stand in close relation with external factors (wages, housing, food, clothing, etc.). This is the reason why the unskilled worker, to which class women belong, reveals statistically infinitely worse health conditions. Climate, social environment, and technical organisation determine, in different countries, and even in the same country, the differing sanitary conditions to which women workers are subjected in the same industry. Thus, for example, in Japan, while formerly the example, in Japan, while formerly the

</table>
women workers were unmarried or young women, to-day there are a great many who are married, because the number of women who take to industrial work without the spur of necessity, to obtain money for marrying or for other economic reasons, tends to increase more and more.

The systematic recruitment of female labour from the rural districts is pushed very much in Japan, and it is so expensive that, by way of compensation for the loss incurred, wages have had to be lowered and hours of work increased. It is not necessary to enter into greater detail as the information can be found in the works of Teruoka (1926). It will suffice to say that the majority of the women employed in these factories (89 per cent. at least) live in hostels belonging to the factory, which ensures them lodging and food. The importance of this for the young working woman is evident. Although the nourishment furnished by the factory yields about 2,000 calories and contains about 50 grm. of protein daily (for a girl of 40 kg. weight, 50 calories is about equal to 1 grm. of protein per kg.), the researches of Shimazono go to prove that this quantity is not enough for a growing girl. He considers that the food again is insufficient in protein and in vitamin B. The food, as well as the environment, explains the high incidence of absence from work and sickness. It is not however possible to draw conclusions about a particular class of industrial worker, because, to cite one example, the tobacco industry in a country in which it is a monopoly (Italy, France) shows a minimal morbidity, while in other countries where the work is mainly done in the home, the situation from a health aspect is much more serious.

### Statistics

The injurious effect of employment is proved by the sickness statistics of sickness Insurance Societies, etc. According to those published by the German Labour Ministry, the sickness rate of women, when compared with that of men, shows an increase in the number of cases for the age groups from twenty to fifty-five years of age, as well as an increase in the number of days of sickness for the group of sixteen to fifty-five years.

In the German textile industry (Deutscher Textil Arbeiterverlag, 1925), the morbidity rate was 48.1 for women and 28.7 for men. The Leipzig Society makes the following comparison:

According to Hirsch (1927), of 3,165 pregnancies occurring in the textile industry during the period 1924-1926, 34 per cent. of the confinement cases ought to be regarded as pathological; in 30.3 per cent. assistance from a doctor was called for; 46.8 per cent. of the pathological cases and 39.2 per cent. of the lying-in cases which necessitated the intervention of the doctor occurred to women working in a standing position; the percentages are lower for those working seated; 30.7 for the pathological lying-in cases and 24.1 for those requiring medical intervention. In the State of Baden, the figures for the average population (1920-1925) are sensibly lower than in the textile industry.

In 13.2 per cent. of the cases there was partial incapacity for work during the pregnancy of which 16.6 per cent. were standing at their work and 12.1 per cent. sitting; 24.2 per cent. of the women were totally incapacitated and of these 25.3 per cent. worked standing and 22.2 per cent. sitting. Total incapacity commenced in a few cases at the third month, but in the great majority of the cases in the course of the seventh. It was observed that the women who worked either seated or standing complained to the same degree of dorsal and renal pains. On the other hand, abdominal pain was more frequent in the latter and varicose veins three times as numerous as in the case of the women working seated.

The conclusion may be reached that the professional class who work standing (86 per cent.) are the more exposed to injury of the genital organs.

An official enquiry in the State of New York in 1919 showed that women present a higher morbidity and a longer duration of sickness than men:
The statistics show, therefore, that the average incapacity for work and average duration of sickness are higher among women than men. But two other important considerations arise: one is that among working women more than one-half of them are under thirty years of age and nearly three-quarters under forty years; the other is that 93 per cent. of the children (German statistics) are brought into the world by women of from twenty to forty years of age (twenty to thirty years, 60 per cent.; thirty to forty years, 33 per cent.). The conclusion, therefore, is evident that the combined action of the occupational influences and of pregnancy do constitute a considerable danger for women.

Statistics drawn up by the Carders' Union of Great Britain give the following value for the causes of absence:

According to Bernays, the rhythm of machinery is not adapted to the female organism, which requires an effort to follow it and in consequence becomes exhausted. This fatigue, more noticeable in pregnant women, makes them less attentive (whence the greater frequency of accidents among them) and more susceptible to intoxications. In English munition factories, Osborne found that women employed on light work for sixty-one hours a week had an incidence of accidents 91 per cent. higher than that of men doing the same work. When hours were forty per week the incidence fell only to 78 per cent. more than that of the men.

Campbell found that among 2,800 women employed in munition factories, 42 per cent. were away on account of overwork or illness. In the Austrian State tobacco factories, 47.1 per cent. of the women were ill at a given moment as compared with 28.7 per cent. of the men. In Switzerland Schaller found a morbidity rate of 129 for women as compared with 100 for men. Prior to the war, the excess of sickness among women in Germany and Austria was calculated at about 10 per cent.; but after the war it certainly increased, even with a shortened working day.

According to Phillips, the hours for women are still too long — at any rate in certain countries: sixty hours, for example, per week, in Bulgaria, and in India; seventy in Japan (1922), etc.

Finally, intellectual work is said to be a still heavier cause of sickness among women. Statistics from Stettin, Kiel, Mannheim, Munich, and Hamburg (1902-1909) as to school mistresses gave an incidence of 6.4 to 10.3 for them as against 2.8 to 5.0 for men, and a duration of sickness of 14.8 days on an average as against 6.7 for men. The same holds good for those engaged in office work. Frcdet (1924), after observing for six consecutive years 667 women employed in an administrative service on the French railways, found that they were ill three times as often as men in the same department and that the sick leave in the case of the women was 4.4 times as great as that of the men. Neither pregnancy, nor confinement and their sequelae were counted. A Swedish Commission (1924) was able to establish the fact that the proportion of illnesses among the women officials was 14 per cent. higher than that among the men. Several enquiries during the war tended, however, to show that occupational work is not such an important factor in morbidity and occupational mortality as some authorities think.

Where, however, the morbidity rate is higher among women than among working women, the reason is that the duration of work in the case of the latter is, especially in some countries, insufficient to cause serious occupational disease.

Detailed study of the causes of sickness immediately brings out the fact that it is the function of maternity which is most affected, because general illnesses, such as those of development, etc., are more
frequent among men, although it may not be always possible to establish, for certain of them, a direct relation with the occupation.

On the other hand, in the case of anaemia among women it is easy to show its relation to work. As a matter of fact, for the age group 15-19 years, anaemia is fifteen times more frequent than among males and for the group above 49 years, seven times. In 75 per cent. of the cases observed it is believed to be the cause of chlorosis, anaemia and neurasthenia (Roth). The same conclusions hold good for general causes, such as exhaustion, loss of energy and malnutrition. The highest incidence of cases of these illnesses is accompanied by the greatest duration of incapacity.

The statistics of mortality show generally that the average death-rate of working women is higher than the general average and than that of men up to the age of thirty to forty years, that is, at the age at which female labour is especially recruited. As compared with 100 men who die, the mortality of women in the different age groups is as follows:

<table>

</table>

With reservations to any criticism which may be passed on the way these statistics are drawn up, several of them tend to show that anaemia is greater (in age groups 20-35 and 45-50) among working women than among those who have not to work (Leipzig Sickness Insurance Society).

The excess of mortality between twenty and thirty-five years of age can be explained by the influence of the sexual life, which is at its height at this period. On the other hand, in the case of women between forty-five and fifty years of age, the high mortality may be attributed with probability to the suppression of the function of maternity. The same reason can partly explain why mortality at the same age groups is higher in women than in men.

GENERAL PHYSIOPATHOLOGY

The influence of employment on the female organism depends on two sets of factors: (a) those which depend on the female constitution, and (b) those due to the work itself.

(a) Sex is one of the coefficients of aptitude for work which cannot be denied. What was shown and seen during the war proved that if women were carefully selected and placed under good conditions of work, they were, if not superior, certainly equal to men when it was a question of light work. Opinion varies as to the somatic differences of the two sexes: length of limbs, trunk, etc. What is certain is that woman being built on a different model from man, the particularities of structure and activity affect the organs the function of which is of prime importance for the future of the race. She is, as Montessori has said, above all and especially "the toiler of the species".

The article "Children" shows what are the differences in the development between boys and girls so far as height and weight are concerned. As to strength, when weight and height are equal a woman possesses rather more than half that of a man, and her output comes to about three-quarters that of a man.

According to the values obtained by Joteyko, the index of strength (as shown by the dynamometer) of women is \( \frac{570}{1,000} \) that of man; the index of resistance (by the ergograph) is \( \frac{670}{1,000} \).

According to Joteyko, in women the power of resistance is superior to the power of muscular effort. She is more apt at yielding a moderate effort than at giving a single big one. With the same height the respiratory capacity of man is one-third to one-fourth greater than that of woman.

The respiration, pulse-rate, composition of the blood, etc., which even in the normal woman differ from those of man, show more marked variation during pregnancy. This exercises, especially during the later months, noticeable compression on the heart, a diminution of the amplitude of the respiratory movements, a retardation in nutrition, a diminution of muscular power, a certain difficulty in the circulation of the blood, and a greater susceptibility to toxic and infectious agents. While certain autho-
rarties (Collis, Joteyko) hold that these
differences are due less to woman's
native constitution than to a failure of
physical power due to social habits of
life, there is no question that in practice
women are excluded from industries
involving heavy labour.

From the point of view of psychical
activity, there is no difference in degree
of intellectuality or of brain power in
quantity, but rather in quality: the
working of the brain in men and
women is not identical (Amar). On the
other hand, woman submits readily to
industrial discipline, adapts herself
easily to a life in a narrow atmosphere,
as well as to work which calls for rela-
tive immobility, looks after detail, har-
mony of forms, has a great deal of
patience (Rubino), etc., so that she is
due to the failure of
authorities would allow the favourable
influence of work with increased physi-
cal activity, while menstruation is said
to become more regular and less pain-
ful. This opinion, expressed by Ramaz-
ini, as based on facts obtained from
weavers, seems to break down as the
result of numerous recent observations
(Great Britain, United States). It does
not seem as though the duration of
work can be directly blamed because it
is the position in which work is done
(sitting, or prolonged standing, walking
or tramping, continuously, vibrations
over the pelvic regions, knocks, direct
friction over the abdomen, etc.)
which produce menstrual troubles (dysmenor-
roha, amenorrhoea, menorrhagia).

While a standing position is tiring,
a sitting one which is prolonged is still
worse (as it causes passive congestion
of the organs in the pelvic basin; tend-
cency to constipation). Obviously, alter-
ation of the two positions is the best,
and, as a matter of fact, in cases where
this alternation is possible, the number
of cases of absence due to dysmenor-
roha have fallen 50 per cent. as com-
pared with those occupations where
women have to sit constantly (Mock).

Women employed in foot pedalling
present more marked troubles: 15.7 per
cent. for sewing as compared with 3.5
per cent. for those sewing by hand (Leh-
mann).

A prolonged upright position with con-
tinual tramping, such as is observed
among ironers, predisposes noticeably
to dysmenorrhoea (30 per cent.: Falk),
to profuse menses, displacements of pel-
vic organs (retroflexion, prolapse, etc.).

(b) The external factors, cold, heat,
confined air, vitiated air, etc., awkward
work or work carried on under awk-
ward conditions (as, for example, by
washerwomen), favour the development
of particular maladies and arrest of
menstruation.

Opinion differs as to the lesser resis-
tance of woman to the action of poisons1.

But to glance through the literature
(on lead poisoning especially), suffice
to discover the data — all too abundant —
on the lesser resistance of woman to the
action of lead and its compounds.

1 For industrial poisoning among women work-
ers, cf. the recent work of Frois (see Bibli-
ography at end of article).
WOMEN'S WORK

Observations made in Great Britain among women employed in white lead factories and pottery manufacture have shown that they succumbed more quickly than men to poisoning and had more severe symptoms (Oliver). This expert has been led to the conclusion that women are more susceptible than men to the action of lead, and that this susceptibility was already great between eighteen and twenty-three years of age, while in men symptoms developed at a later age.

When economic conditions of life were equal, poisoning was higher among men. Hamilton, however, has to admit that symptoms in the two sexes are different and that chronic constipation, anaemia and menstrual troubles due to lead do not appear in statistics as occupational diseases of women; whence perhaps the reason of this so-called lesser frequency of poisoning. The incidence of lead poisoning is certainly greater among women than among men, for men employed in pottery paid, were 56.7 cases per 100 men as against 28.6 per 100 women and 20 per 100 men. The men, too, it should be remembered were those rejected from military service, while the women were in good health. In 1916, at Düsseldorf, there were 66.7 cases per 100 men as against 66 per 100 women. When, in 1918, the blockade aggravated the food conditions, the rate exceeded 100.5 in the case of men and 119 in that of women.

In Great Britain, women were found so susceptible to the action of sulphuric ether as used in smokeless explosive factories that men had to be substituted for them.

The same fact was brought out in the United States. The majority of these poisons, and of lead particularly, induce quite a series of troubles in the generative organs which they derange both functionally and organically: irregular menstruation, amenorrhoea, anaphrodisia, inability to conceive, etc. These troubles often follow general ill-health: anaemia, chlorosis, due themselves to occupational influences.

Fertility — Pregnancy

Without entering into details of the difficult and vexed question of the low-

</tbody>
</table>

In American potteries Hamilton found saturnine encephalopathy among one out of 17 cases of lead poisoning in men and one out of 4.5 cases of lead poisoning in women.

Curschmann, Loewy and others, have for a long time insisted on this lessened resistance and on the very strong reaction of the female generative organs to industrial poisons. Experience demonstrates this lessened resistance to nitro and amido derivatives of benzene (as, for example, the experience in England during the war with trinitrotoluene, carbon bisulphide, etc.). Recent unhappy experience has brought into relief the sensitiveness of women to benzene: serious haemorrhages, fatal menorrhagia (see article "Benzene") also were found to be more two months.

During the war the same facts were in evidence with regard to trinitrotoluene which affected the workers of munition factories in a proportion of 28.6 per 100 women and 20 per 100 men. The men, too, should be remembered were those rejected from military service, while the women were in good health. In 1916, at Düsseldorf, there were 66.7 cases per 100 men as against 66 per 100 women. When, in 1918, the blockade aggravated the food conditions, the rate exceeded 100.5 in the case of men and 119 in that of women.

The same fact was brought out in the United States. The majority of these poisons, and of lead particularly, induce quite a series of troubles in the generative organs which they derange both functionally and organically: irregular menstruation, amenorrhoea, anaphrodisia, inability to conceive, etc. These troubles often follow general ill-health: anaemia, chlorosis, due themselves to occupational influences.

Fertility — Pregnancy

Without entering into details of the difficult and vexed question of the low-
ered birth-rate noticeable to-day in all great industrial centres, it must be re-
recognised that this fall particularly af-
facts the working class. Thus, for ex-
ample, the fall in the birth-rate, which
was 18.5 per cent. for the city of Berlin,
reached a rate of 21.1 to 30 per cent. in
the working class areas (Siberglerit).
In ten English towns the birth-rate has
fallen between 1881 and 1901, especially
where there was a large number of mar-
rried women workers (Sydney Webb).

In an industrial town like Blackburn
the birth-rate was found to be in strict
relation with the number of industrially
employed women. Thus (after correc-
tion for age) the percentages of fertility
in women as follows:

<table>
<thead>
<tr>
<th></th>
<th>Women not employed</th>
<th>Working women</th>
</tr>
</thead>
<tbody>
<tr>
<td></td>
<td>5.3</td>
<td>3.0 to 3.6</td>
</tr>
<tr>
<td>Average</td>
<td>3.8</td>
<td></td>
</tr>
</tbody>
</table>

The preliminary enquiry made in
Italy for maternal assurance brought
out the birth-rate values shown in the
accompanying table (page 1242).

Although assuredly the actual fall in
births is partly accounted for by a vol-
untary factor, it is not right to under-
estimate the importance of the factor
of female fertility. Even among the
agricultural population, according to
Hirsch, a fall in the birth-rate is found
due to the nature of the work carried on
(intensity and duration of the physical
efforts demanded without taking account
of hours, temperature, etc.), and this
effect on fecundity is more serious
in women employed in mines and un-
healthy industries.

Gestation, parturition and the puerpe-
ral period generally are also influenced
by occupation. Obviously, the physi-
ological changes which take place in
the organism in the course of pregnancy
in a working woman leads to the con-
clusion that "the pregnant woman
suffers from her surroundings, which
in turn are none the better for her
presence" (Vicarelli). The intimate
relations between pregnancy and the
organism are affected by the factors
which act mechanically (position
assumed at work) or biologically
(poisons). On the other hand, accord-
ing to certain authorities, industrial
work does not to-day seriously af-
fact the normal course of pregnancy,
because women are excluded from un-
healthy trades or, when pregnant, they
abandon work of their own accord, or
are dismissed at a more or less advan-
ced period of their pregnancy, either as
a consequence of statutory requirements
or the improvement in the economic and
social conditions of the working class
(Vicarelli). On the other hand, it should
not be forgotten that too many working
women still ignore to-day the fact that
pregnancy, even when normal, should
be specially safeguarded and that preg-
nant women should not work longer
than they can properly do, only call-
ing in the doctor at the moment of child-
birth or in case of grave troubles. Ac-
cording to Hirsch, this fact explains why
maternity troubles in general, and preg-
nancy in particular, furnish the great-
est contingent of sickness in German
working women, and why the patholo-
gical conditions caused by employment
in pregnant women render them unable
so frequently to conceive later or render
them incapable, sometimes permanently,
to gain a remunerative livelihood.

The figures of the Leipzig Sickness
Insurance Society are very interesting
on this subject.

Of 100 accouchement cases there were:

The Union of German Textile Workers
has proved that of 1,110 cases of ac-
couchement at full term, 300 were nor-
mal and 801 (72.16 per cent.) pathological
— due partly to the frequency of con-
tracted pelvis induced by admission to
labour of girls at too young an age.
All the complications of gestation:
miscarriages, abnormal presentations,
preadterm rupture of membranes,
"placenta praevia", toxaemias of
pregnancy, eclampsia, psychoses, etc.,
as well as varicose veins of the vulva
and legs, and haemorrhages, are very
frequent, so various authorities state,
and very severe among working women.
At the same time, miscarriage and
premature confinement which are, so
far as the obstetrical pathology of the
working mother is concerned, the most
frequent clinical forms assumed, are
rarely thought (Vicarelli) to be ascribed
solely to "industrial work". Ac-
count must be taken of other concomi-
tant injurious and morbid causes such
as organic weakness, congenital or
hereditary, inappropriate treatment or
improper upbringing in childhood,
constitutional or venereal diseases,
unhealthy living, prostitution, alcoholism,
etc.

According to Vicarelli, while the work-
ing woman in certain occupations is
subjected to arduous work and some-
times to injury or vicious attitudes capa-
cible of menacing or compromising the
normal course of pregnancy, this occurs
relatively rarely because the pregnant
woman generally gives up her occupa-

*Note: The numbers represent the distribution of full-time workers and parturient workers by age group*
tion or, if she goes on with it, does so with greater care and prudence.

The same physical factors which affect the catamenial function may also interfere with pregnancy. In some trades these factors are more powerful than in others. Thus, for example, a bent position, with the body crouched, combined with heat and moisture, lead to metrorrhagia, miscarriage, prema-

extension, stretching out and drawing back, sometimes rapidly repeated in order to follow the rhythm of the machine demanded today of the worker in a textile mill; it is sufficient to realise the bending, the twisting, the leaning forward necessitated by the requirements of the machine, and that the woman must often have to lift, drag or push heavy loads, to appreciate how 

![A pregnant woman at work in a German jute-spinning mill.](image)

The position assumed at work gives rise to pregnancy troubles in seamstresses, textile workers, and in women employed in transport, etc. It suffices to recall the whole series of movements of the body of the woman is obliged to sustain shocks, blows and bruises which naturally affect the foetus.

Bonnaire distinguishes three occupational attitudes of the pregnant woman corresponding to the postures: vertical without movement, vertical combined with locomotion, and sitting. He considers the continuous upright attitude
without movement is always unfavourable for the expectant mother; less trying is the upright station with locomotion, although this does not eliminate fatigue. If not carried to excess walking maintains the suppleness of the body, thanks to the intimate massage of the tissues and the stimulation of the venous circulation which helps in the play of the muscles. Often a woman who has been long standing feels more refreshed after a little walking than after sitting. Of the three attitudes, that which best responds to the needs of industrial hygiene for the expectant mother is sitting, especially when walking from time to time can be combined with it.

Accidents at work, and particularly those of a traumatic nature, may have very severe consequences, such as intra-uterine fracture on the head of the foetus, rupture of the amniotic sac, etc. Among external factors which, in the course of work, constitute an indirect source of injury to pregnant women are dusty trades and the textile industries, in which it is frequently possible to observe that respiratory troubles are aggravated by the maternal state, constituting a menace to pregnancy in its turn; the unhealthy or poisonous industries, affecting the hepato-renal system or the blood, directly interfere with the normal course of gestation, etc. The woman worker, with her organs of elimination already weakened when she has become pregnant, succumbs more easily and more severely to the auto-intoxications of pregnancy.

Fig. 200. — A pregnant woman at work in a German silk-weaving mill.
To show the influence of intellectual work on pregnancy is more difficult, as the majority of women employed as secretaries, school mistresses, etc., are usually confined at home—a fact which interferes with the collection of data. Although biology and experimental psychology show that intellectual overwork brings about modifications either of the organs of vegetative life or organic changes, it can be said at the same time that these women, in spite of work often carried out under rather unhygienic conditions, and in difficult circumstances, combined with defective and inappropriate diet, are rarely endangered by pregnancy. On the other hand, intellectual women workers, already the subjects of some weakness and a certain amount of excitement of the nervous system, pass through the stage of pregnancy with a high degree of nervousness and increased reflexes which are accentuated by greater intolerance and hyperaesthesia of the uterus (Vicarelli).

**Sequelae of Confinements**

Occupation influences also the sequelae of a confinement and increases mor-

Fig. 301 — A pregnant woman at work in a German jute-twisting mill.
tion of the uterus, uterine or vaginal prolapse, sterility, miscarriages, etc.

Sufficient rest is all the more indispensable as early getting about may lead to haemorrhage or "post partum" embolism. This is why international agreement was reached as to compulsory rest after confinement.

Work of the Mother and her Offspring

A whole series of observations show the influence of the parents, and of the mother in particular, on her offspring. The absence of rest before confinement and the nature of the work done by the mother, besides other factors to which reference has been made above, give to the offspring in working-class families from the time of their birth the stamp of physical defect. It is noticeable that the average weight of the foetus rises as the social conditions of the mother improve, and that the percentage of foetuses of a weight below the average in women of different social status is so much the lower as conditions are better.

Allaria has shown that the average weight of the newly born infants of mothers employed in factories is below that of infants of other working women. He gives the following figures:

<table>
<thead>
<tr>
<th>Occupation</th>
<th>Grm.</th>
</tr>
</thead>
<tbody>
<tr>
<td>Housekeepers</td>
<td>3,100</td>
</tr>
<tr>
<td>Peasants</td>
<td>3,050</td>
</tr>
<tr>
<td>General servants</td>
<td>2,950</td>
</tr>
<tr>
<td>Working women</td>
<td>2,950</td>
</tr>
<tr>
<td>Factory workers</td>
<td>2,900</td>
</tr>
</tbody>
</table>

Analysis of 18,865 confinements in the clinics and hospitals of Rome, during the period 1912-1918 gave the following values for the weights of newly born infants of working mothers.

<table>
<thead>
<tr>
<th>Occupation</th>
<th>Grm.</th>
</tr>
</thead>
<tbody>
<tr>

</tr>
</tbody>
</table>

According as the mother is accustomed to hard or light work, so the weight of the newly born varies equally. Thus, for example, seamstresses and corset makers working with sewing machines have weaker children than those having lighter work at which they sit; agricultural labourers who, owing to their strong constitution, ought to have vigorous children frequently have children below the average. At the same time the children of housekeepers, of women engaged on sedentary work, among whom the relative immobility of the body during work favours a longer duration of pregnancy, as well as those of multipara, are better developed, heavier and longer.

This rule has its exceptions which affects women employed in unhealthy industries. Thus, Frongia has found that 90 per cent. of full-term pregnancies of workers in the mines of Sardinia result in cachectic children, 30 per cent. of whom die in the first months or years; of those who reach twenty years of age 90 to 95 per cent. are unfit for military service (see Bibliography).

An adequate period of rest enables the foetus to become of average weight, and this increase is so much the more marked as the period of rest before lying-in is prolonged. Vicarelli has shown that the weight of the newly born in fact increases on an average 62 grm. after a rest of ten days; 238 grm. after a rest of twenty days, 246 after thirty days and 412 grm. after forty days (see Bibliography).

Merletti gives somewhat different figures; but account must be had of other factors which play an important role in this question, such as the legitimacy or illegitimacy of the pregnancy. Illegitimate pregnancies often modifying profoundly the development and weight of the child, which does not always respond to the compensatory advantages of long attendance at a clinic. That a rest of some weeks before confinement suffices to improve the weight of the child is proved by a whole series of data. Thus the infants of persons living a retired life are usually in excellent condition. Bazin has said with reason that "women factory workers are the devourers of men", and Alfieri, more recently, that from the material and moral point of view, "maternity and factory work are antithetic terms".

These facts being recognised, it is not to be wondered at that infantile mortality increases amongst the children of women employed on industrial work. As early as 1908 an enquiry made by the Humanitarian Society of Milan showed that working-class families had the lowest percentage of living infants and that working women who were mothers had the highest percentage of stillbirths. The enquiry by Woodbury (1925) relating to 22,967 children at nurse, made in eight towns in the United States, brought out the fact that children of less than a year whose mothers were employed away from home had a mortality 2.5 times as great as those whose mothers were employed at home. Similarly, the mortality rate in the first year of life was 9.8 per cent. for children whose mothers had not been employed during confinement, 11.46 per
cent. for those whose mothers had been engaged in home work, and 17.61 per cent. for children whose mothers had worked during pregnancy. This serious situation is reflected on the whole population, because, according to the statistics of Prinzing, Newsholme, etc., the general infantile mortality increases on parallel lines with increase in industrial employment of women.

Newsholme gives the following figures for Great Britain:

<table>
<thead>
<tr>
<th>Number of women employed in industry</th>
<th>Deaths in the first year for 100 infants born alive in Staffordshire towns</th>
<th>Whole of Great Britain, 1881-1890</th>

</tr>
</tbody>
</table>

Those who do not accept the importance of the factor of "employment" consider that account must be taken of "poverty" in the case of the woman and of the household in general in order to explain the infantile mortality amongst the working classes.

Greenwood, Brown, Rochester (of Baltimore), and others do not consider there is direct relation between "poverty" of the mother and infantile mortality. When crises occur (strikes, lockouts), the infantile mortality in industrial districts is not influenced. This is what has been found in Great Britain (1912), France, etc., where during a period of very great demand for female hand labour the general mortality rate has not varied; but, on the other hand, the infantile mortality rate has considerably increased as the children have been uncared for and have been without supervision from their mothers engaged in the mills.

In social depression in Lancashire an increase in the general mortality rate has been observed as the result of the hardships met with; on the contrary, there has been diminution in the infantile mortality rate because the mothers had little to do but to act as nurses and devoted themselves more to their children.

Similarly, infantile mortality varies very little according to the different social classes. Thus, for example, Forbes, of Brighton, made out the following mortality (per thousand births):

<table>
<thead>
<tr>
<th></th>
<th>Illegitimate children</th>
<th>Poor families</th>
<th>Working class families</th>
<th>Middle class families</th>
</tr>
</thead>
<tbody>
<tr>

<td>First month</td>
<td>48.0</td>
<td>33.1</td>
<td>30.1</td>
<td>27.7</td>
</tr>
</tbody>
</table>

Raffaelli (1924) cites the following data in regard to 1,000 births (Westminster, 1907-1908): Infantile mortality, therefore, depends not only on the social and hygienic conditions in which the mothers are placed during the time of pregnancy, but also on maternal care (Salisbury Hughes, 1925). This is also the opinion of Sir George Newman, who has written as follows: "Poverty alone is not responsible for infant mortality, because it is low in certain very poor districts. Housing and external environment are also not responsible. Infant mortality is on the contrary in strict relationship with certain conditions of the social life of the population."

In 1858 English opinion was that infants died because of maternal neglect. During the war many women were employed in factories and the infant mortality rate was not increased because a good system of infant welfare was organised.

The enquiry of the Women's Industrial Council of the United States (1917) did not bring out noticeable differences between the infant mortality and birth-rate of mothers of the housekeeping class and working women. Other enquiries, however, have yielded very different results: in France, in Belgium, and in the Netherlands, the death-rate of infants of working-class mothers was double the average. Other factors must play their part here, such as housing conditions, density of population, etc. Nor should the lessened resistance to disease of these infants — already born less in weight than the average — be forgotten. Couvelaire, Schauta, Léopold, Resinelli, etc., have contributed to the knowledge of this fact of great so-
cial importance. Pinard has said: "Everything which removes the child from its mother places it in a state of suffering and in danger of death. Nothing can ever replace the heart and milk of a mother." The more recent statistics published for Great Britain and other industrial countries lead to the same conclusions.

The increase in this mortality then has a relation to different causes of a infant mortality rate in the first year of life to be 16.93 per cent. among the children of mothers who had given up work a month or more before confinement, 18.75 per cent. when the mother had given up work for less than a month, 24.41 when she had continued work up to the time of her confinement. Similarly, in regard to the excessive mortality of nursing infants in their first year of life, the enquiry in question showed

Fig. 202. — A pregnant woman at work in a German cloth-weaving mill.

general and special kind. Of the first it will suffice to cite the lack of rest for the mother before her confinement; the continuation of work afterwards; resumption of work depriving the child of milk and maternal care; the bad method of bringing up nurseries (digestive troubles, etc.). Thus Woodbury's enquiry in America showed the that the children of mothers who resumed work less than two months after childbirth showed a mortality three times as great as the average.

Among the special causes, the nature of the occupation carried on by the mother is of import, these trades offering a risk of poisoning being particularly detrimental. As a matter of fact, the
poison absorbed by the maternal organism passes through the placental circulation directly to the foetus. Lead, phosphorus, arsenic, bromine, chlorate of potash, etc., are known to pass through the placenta and set up very severe lesions. Mercury does not pass through the placenta, but accumulates there in abundance. Phosphorus sets up placental haemorrhages which permit of intoxication of the foetus where even an hepatic steatosis has been found. The alkaloids also reach the foetus on which they confer a certain power of resistance to the action of these poisons.

The effect on the product of conception of chronic poisoning by alcohol, lead, mercury, etc., is notorious; they cause notably miscarriages, or still-births, or debilitated infants which develop badly and are likely to die young. Carbon monoxide reaches the blood of the foetus which, however, contains less than that of the mother; the quantity of lead also varies, but generally it is very small, etc. Elimination takes place especially through the placenta, because the amniotic fluid does not contain it; similarly it is not found in the urine of the foetus collected at the moment of birth. Researches show that the foetus is more resistant than the adult to certain poisons, as, for example, nerve poisons — a fact explained by the poor development of the nervous centres of the foetus. If death comes it is due to mechanical troubles in the placental circulation: lowering of the blood pressure of the mother (carbon monoxide, carbon dioxide, chloroform, etc.), whence arise miscarriages.

For long no doubt has existed that lead poisoning of the parents is a cause of injury to the life of the foetus and provokes morbid changes or induces death. Enquiries by specialists on this point are numerous, and it will suffice to recall the work done by Hamilton (Industrial Poisons in the United States, p. 110: "Lead as a Race Poison") and other contributions by Devoto, Teleky, Olivier, etc.

Dineufbourg (1905 thesis) gives particulars of observations on women classified as follows: (a) those whose husbands were engaged in lead employment without being themselves exposed to contact with lead; (b) women who formerly were exposed to the risk of lead poisoning but whose husbands were not in contact with lead; and lastly (c) women previously in contact with lead and whose husbands were employed in lead industries.

The ratios fall as follows:

<table>
<thead>
<tr>
<th>In contact with lead</th>
<th>Number of pregnancies</th>
<th>Miscarriage</th>
<th>Stillbirths</th>
<th>Percentage</th>
<th>Born alive of 100 living in the first year</th>
<th>Percentage of 100</th>
</tr>
</thead>
<tbody>

<td>33</td>
<td>4</td>
<td>4</td>
<td>35.0</td>
<td>15</td>
<td>66.6</td>
</tr>
</tbody>
</table>

Lead poisoning on the paternal side is also as disastrous from this point of view as lead poisoning on the maternal. While Dineufbourg's figures for the two last groups are rather too small to draw conclusions from, other researches can be cited which seem conclusive. Thus, for example, Reid found in the case of 100 women:

<table>
<thead>
<tr>
<th>Miscarriages and still-births</th>
<th>Deaths in the first year per 1,000 born</th>
</tr>
</thead>
<tbody>
<tr>
<td>Housewives</td>
<td>43.2</td>
</tr>
<tr>
<td>Factory workers (not using lead) before marriage</td>
<td>47.6</td>
</tr>
<tr>
<td>Factory workers (using lead) before marriage</td>
<td>86.0</td>
</tr>
<tr>
<td>Factory workers (using lead) after marriage</td>
<td>125.5</td>
</tr>
</tbody>
</table>

This proves that the factor "Factory Work" alone aggravates the infantile mortality in the first year of life and that contact with lead aggravates the incidence of miscarriages and of still-births.

Oliver has shown experimentally the destructive action of lead on the embryo and foetus. This action is so notorious that salts of lead are used by people lacking medical knowledge as abortifacients.

As early as 1860 Paul formed the opinion that the abortifacient action of lead was more important than syphilis, and since then a number of statistical enquiries have shown the correctness of this view.

The available data show that the longer the poisoning has lasted, the more profoundly is the mother intoxicated...
and the more dangerous are the pathological conditions of pregnancy. On the other hand, if the poisoning is not very marked and if the woman gives up her unhealthy work at the commencement of her pregnancy (about the third month), the gestation may be a normal one. Similarly, it has been shown that normal confinements can follow on miscarriage if the woman gives up her unhealthy work, but that pathological pregnancies return on resumption. Premature confinements are also frequent, favoured by industrial fatigue, and especially under the influence of industrial poisons, particularly lead. Lead is said to kill one-half of the products of conception.

Frongia comes to almost the same conclusions (44.1 per cent.).

Mercury also causes miscarriages, a high infant mortality and serious injury to the child. Thus tremor has been observed in the children of mercurialised parents. Alcohol is a notoriously frequent cause of nervous accidents in the offspring of alcoholics.

Arduous work exercises a baleful influence, not only on the woman, but also on the products of conception (see article "Occupational Diseases: Loco-

![Fig. 203. A pregnant woman at work in a German jute-weaving mill.](image)

where the woman continues to work right up to the time of childbirth (24 per cent. in the case of women who have worked to the end of pregnancy as against 12.6 among those who have ceased work beforehand).

Devoto and his co-workers and Frongia have shown the great effect of lead poisoning in the father on the offspring. Carozzi brought out the fact that in 361 working-class families the fathers in which were working in lead, there were 1,418 conceptions of which 203 ended in miscarriages; 528 infants died at an early age and only 687 grew up.

motor System"). As to injuries due to the carrying of too heavy loads, it will be sufficient to mention Conrad’s statistics, which, as far back as 1870-1874, showed the frequency of stillbirths among women employed in arduous work (4.15 per cent. of births as against an average of 2.1 for all births among all social classes).

The serious incidence of mortality occurring among the children of the working class can also be traced in later years. Further, the children who survive up to the time of conscription exhibit signs of physical degeneration (rickets, scrofula, lymphatic diathesis, etc.).
Here also it is the consequence of the failure of maternal care rather than of poverty which plays the important part.

Mention has been made above of the influence of the work of the mother on breast feeding and the role this play in infantile mortality. This function of maternity should be insisted on as it completes maternity. To nourish or not to nourish a child at the breast is to influence favourably or otherwise the nursing. On the other hand, employment exercises an influence on the faculty of breast feeding which, in consequence, may have to be diminished or suppressed. Further, some poisonous substances may have a baleful effect on the health of the child, partly compensated for, however, by the fact that the capacity for breast feeding in these women is minimal and diminishes rapidly.

Where economic conditions require the mother to resume her work as soon as possible after her confinement, recourse must be had to artificial feeding. As a matter of fact, the available data indicate that women working away from home nurse their children much less than others.

The American enquiry already referred to relating to the first three months of life of 22,967 newly born infants showed that artificial feeding accounted for 51.4 per cent. of the months of life of the children whose mothers worked away from home and only 23.2 for mothers not in employment.

Statistics compiled by Marie Baum show that 63 per cent. of mothers who work away from home adopt artificial feeding as compared with 33 per cent. of mothers not in employment.

Special Pathology

The anatomical and physiological peculiarities of the female organism explain the differences between the general pathology of women and that of men. While the injuries caused by professional environment are the same for the two sexes those due to other factors (position adopted at work, movements of certain segments of the body, etc.) explain the clinical picture observed in women. Thus, for example, prolonged maintenance of the same position (upright, seated, bent) has a baleful influence on children and adolescents, who present not only troubles or arrest of development of certain tissues or systems, but even pathological changes (displacement of organs) of the generative system and various circulatory troubles (see article "Children"). It is unnecessary to insist on the injury caused by the maintenance of the position mentioned above. Industrial poisonings also raise very important questions. Mention has already been made of the greater frequency among women working under the same conditions as men of the incidence of poisoning. In addition to particular causes (menstruation, etc.), the fact must be admitted that a larger amount of poison comes into contact with a woman than a man because of her hair and clothes, which become a receptacle for poisonous dusts. It has been seen, too, that in addition to pregnancies reaching full term and producing infants more or less vigorous and resistant, quite a number end in miscarriages, premature confinements or stillbirths. Certainly all the other causes apart from employment which are capable of interrupting pregnancy (general or local diseases of the mother, injury to the ovum, embryo, etc.) and of leading to abortion or premature confinement ought not to be underestimated. These causes do not act to a greater extent in the case of working class women than in other women. But where an excessive number of miscarriages and premature confinements are noted among working women, it would be logical, apart from the effects of special cases of poisoning, to attribute them to too arduous or prolonged physical work up to full term, to the lifting of heavy loads, to blows, or to the effects of vibration, etc.

Fatigue and over-pressure of work, the result of too long or too arduous toil, are without doubt a greater cause of female sickness than poverty. This is why for a long time past the duration of employment of women and children has been limited. At the same time night work has also been prohibited or curtailed, its baleful influence on health and social life having been recognised. The fact that a woman who has worked all night has to attend to her domestic duties instead of resting cannot be overlooked and this increases her state of fatigue. During the war, in Great Britain the output of women in alternation night shifts was decidedly lower than that of women working in alternate fortnightly day and night shifts. The problem of fatigue and strain is of the first importance in relation to the question of heavy work, carrying of heavy loads and charges, by their direct or indirect effect on the female organism and particularly on the development of the chronic maladies of the sexual organs.

When women have habitually to carry heavy loads (e.g. in the country or mountainous districts), skeletal deformi-
ties are noted (of the vertebral column, lower limbs), alterations in the thoracic capacity and abdominal walls. Thus, for example, a broadening in the lumbar region of the spine in women who carry loads with crushing together of the vertebrae, bringing about diminution in height, deformity of the pelvic basin with harmful effects on the development of pregnancy. Occupational cramp of the lateral muscles of the neck, pains of the brachial plexus, sub-occipital nerves, moveable kidneys, cardiac and thyroid hypertrophy, etc., have been reported.

The question is of such importance that it has been made the subject of numerous enquiries, e.g. in Great Britain (Industrial Health Research Board) by Cathcart, Overton and Bedale, etc., in Germany by Atzler and Saupe, in Italy by Patrizi, who have enquired into the optimum weight which should be carried. (See article "Transport Industry": B. Porters, etc.)

A satisfactory explanation of the greater sensitiveness of women to fatigue is not easy. Opinion on the question is divided. It might be thought that work adapted to her strength would fatigue a woman proportionately less than a man; but a woman is not able to engage in efforts of strength or physical activities as intense as a man.

It has been seen that though women adapt themselves readily to monotonous work, they are very easily affected by the effects of nervous fatigue if the work calls for great intensity and especially when passing through the menstrual period, pregnancy and the after-effects of childbirth. The special conditions of woman’s work at home should not be forgotten. While marriage, household cares, and especially the need of looking after their children cause many women to cease working in the factory, it is true also that they often try to make up for it by work done at home. Wages made in this way are notoriously low and the women try to increase them by working long hours. This overwork, associated, as so often is the case, with the bad hygienic conditions under which the work is done, aggravates the ill-health of this class of worker.

Lastly, the role played by fatigue induced by household worries ought to be emphasised, especially among women carrying on daily work at the factory or workshop, and for whom the double effort constitutes an important cause of lessened organic resistance. A woman, and particularly the mother of a family, has not finished her job on leaving the workshop or office. Having to look after domestic matters, to see to the needs of her husband and children, she is obliged to go to bed late and get up in the morning early, so that her daily rest is almost always insufficient. This state of chronic overwork exerts its baleful influence not only on her own health, but also on that of her children owing to inadequate maternal care (see above).

The special pathology of women workers as compared with that of men shows itself in the figures furnished by the Leipzig Sickness Insurance Society (in rates per 10,000 members):

Diseases of the sexual organs (not counting venereal diseases) are more frequent among women than men (255 as compared with 49 per 10,000 members); but these rates certainly do not give an exact picture of the situation. This excess is readily explained on thinking over the causes which might help to produce them (loss of menstrual blood — about 2 kg. per year — preg-
nancy, confinement, breast-nursing). Metritis and parametritis, for example, in 1915 represented among 150,000 members of the Munich Sickness Insurance Society 2.6 per cent. of all illnesses. Faulty positions are favoured by the arduous work and the upright position. Laubenburg (1916) found that such defects were three times more frequent among women working upright; Hamburger has brought out the fact that miscarriages are twice as frequent among working women as among those in easy circumstances (17.9 as compared with 8.2), etc.

Among the skeletal deformities of which mention has been made above, the most important are certainly those which affect the pelvic basin. Excessive and prolonged contraction of the muscles of the neck, of the dorsal and lumbar muscles, as well as of the muscles of the lower limbs which are inserted on the pelvis, influences its growth and subjects it, at a period of incomplete ossification, to a traction in a determined direction. The effect is so much the worse the more the worker suffers from latent or declared rickets and when the home conditions are bad. This is why rickets, osteomalacia, tuberculosis of the bones and joints, etc., enter into the aetiology of pelvic derangements so common among working-class women. The mechanical effects described above favour narrowing of the basin whence arise dystocia, difficult labour, increase in the frequency of instrumental intervention (forceps, caesarean sections, premature confinements or induced labour), and increase in the morbidity which has been referred to. To these pathological conditions are added, in young, poorly developed working women, a weakness of the soft parts (neck of the uterus, vagina and perineum).

The results found by Govoroff (1924) concerning the influence of occupations on the development of the female pelvis are given in the following tables.

<table>

Okunjewa, Steinbach and Schtcheglowa studied in 1927 the effect of weight carrying among 1,450 persons (women) employed in different professions: peat, coal, metallurgical industry, etc. As a control, textile workers and tramway conductors in Moscow were selected. The lifting and carrying of weights give rise to lesion of the sexual organs: menstrual troubles 65.5 to 76 per cent. as against 26.5 to 39.2 per cent. among the controls. It should be noted that these troubles are most frequent especially for the age group 19-25 years (peat workers) and that the incidence diminishes the longer they have been at the work.

Among metallurgical workers, dysmenorrhoea and menorrhagia are very frequent (61 and 17 per cent.); among coal workers, dysmenorrhoea (69.3 per cent.); among peat workers, amenorrhoea (37.5). The worst cases were found among multipara and those who had had miscarriages: haemorrhages, prolapse troubles connected with preg-
nancy, etc. Enquiry showed that these lesions were in direct proportion to the amount of occupational work.

Politi and Flamini, of the Rome Obstetrical Clinic, found a higher rate of eclampsia among ironers, textile workers and compositors (from excessive work).

The attitude assumed plays an important role; very bent (see article "Clothing Industry"); upright (premature confinement); very bent forwards (hindrance to the longitudinal expansion of the abdomen and favouring shoulder presentation); special employments; in the rice fields (see article "Rice"), which favours anteversion and lateroversion, dysmenorrhoea, amenorrhoea; transport (vibration among women employed as tramway conductors or working on sewing machines; carrying of baskets supported against the abdomen, etc.).

All the available data show that chlorosis, anaemia and tuberculosis are the diseases which affect the working women most. While recognising the full the part played in their development by bad general conditions of life (housing, food, clothing, etc.), as well as particular predisposition or susceptibility either hereditary or acquired, it is nevertheless often impossible not to recognise the prime importance of bad working conditions (lack of exercise, work in rooms that are confined, hot, humid, dusty or badly lit, fatigue, overwork, etc.). Overtime is one of the most frequent causes of chlorosis and anaemia, especially among women employed in dressmaking and in textile workshops; it is sufficiently high in paper factories, letter-press printing works, and chemical works. Those most affected are young people between fifteen and nineteen years of age who show an incapacity from anaemia and chlorosis fifteen times as high as workmen. Women above forty-nine years of age show incapacity from the same maladies only seven times as high as that of men of the same age.

The fact need not be insisted on that anaemia and chlorosis prepare a soil favourable to the development of all other diseases, especially tuberculosis. While the total morbidity from this disease is less frequent among women than men, the mortality of women is higher especially at early ages. As a matter of fact, the rate for men is 30.2 as against 33.5 for women; and is 22 as against 32 in the age group 15-19 years. This occupational effect, shown particularly at early ages, is brought out, among others, by the Prussian statistics, where the general mortality from tuberculosis has fallen from 21.13 per thousand in 1900 to 17.26 in 1906, while that of women between fifteen and twenty years of age has increased, in relation to the general mortality rate of this class, from 43.90 to 48.34 per cent. (Hirsch).

Women most exposed to risk are those employed in dusty industries, sorting of paper, rags, spinning and weaving of cotton, jute, hemp, the manufacture of brushes and brooms, etc. An enquiry by Ishihara (1915) on the frequency of tuberculosis among Japanese women working in the textile mills has shown that this is a very important social question in Japan. Further enquiry made by a medical inspector relating to 4,341 women in a western province of Japan, recruited in 1922 by textile factories of other provinces, showed that 62 (46.6 per cent.) did so on account of tuberculosis. Teruoka considers that this infection is a common end of female young persons in modern industry.

A great preventive effort was made by Ohira, Chief Medical Officer of the Tokyo Cotton Spinning Company, employing 40,000 persons. His method of selecting workers enabled him to reduce the annual mortality from tuberculosis from 20.1 to 13.2, 11.2 and 9.7 per 1,000. He tried also inoculation with a prophylactic autogen — a method which might well be thoroughly tested by experts.

Fatigue and overwork are the most frequent causes of tuberculosis among working women, who at first only suffer from a cold — the precursor of tuberculosis.

Statistics show an absence from work on account of colds in winter of 10-15 per cent. of the workpeople, and in summer a similar rate from affections of the digestive tract.

Beri-beri is also an occupational disease weighing heavily on industry in Japan. Its progress during the year shows a characteristic seasonal curve commencing in the first months of the year, reaching its maximum in summer, and then falling month by month up to the end of the year.

This incidence varies, however, in different districts according to the climate and the individual conditions of the workers in the matter of nourishment. But the summer maximal is attributable to fatigue as neither the hours of work nor its exacting nature are lessened.

The digestive troubles are most commonly due to a state of anaemia and it affects mostly women employed in sedentary work. On the other hand, an important role is played by insufficient or unsuitable food. These again depend on lack of time or inadequate accommodation for taking meals — especially the mid-day meal — poor wages, etc.
Among the most important maladies of the circulatory system are varicose veins in the leg, which are especially common in trades where the women have to assume a continuous upright position, and are favoured by the injuries to which they are exposed. These varicose veins sometimes constitute a serious infirmity becoming complicated by eczematous inflammation and ulceration, which are the most frequent as sweat and dust irritate them and lead to scratching. They may have their seat in the vulvar region with danger of breaking either at the moment of confinement or as the result of accident.

German statistics (1925) give the following values as to incidence of varicose veins among textile workers per 100 women:

- Working continuously in an upright position: 12.70
- Standing and treading: 4.04
- Sitting most of the time: 2.90
- Always seated: 0.00

When the work demands sustained attention and continuous effort, the development of nervous diseases (psychosis, neurasthenia, etc.) is increased.

The increase in the diseases of the sexual organs is strikingly favoured by certain factors such as sexual perversion, malthusianism, miscarriage (fairly frequent among the working classes), occupational work, etc. — an increase which may partly be more apparent than real, as improvement in gynaecological diagnosis must be taken into account. The utero-ovarian maladies and their complications physically are the most dangerous for family life, as they are so often associated with states of moral and nervous disequilibrium causing havoc with domestic tranquillity and peace. Under these conditions evidently industrial work exercises an especially harmful effect either in relation to the generative system or the general health of the woman.

Observations made by Gutzmann relating to 2,373 women in a Berlin hospital and 356 dressmakers employed on pedal sewing machines brought out the following facts:

<table>
<thead>
<tr>
<th></th>
<th>Among women in hospital</th>
<th>Among sewing machine workers</th>
</tr>
</thead>
<tbody>
<tr>
<td>Inflammation of the appendages</td>
<td>6.6</td>
<td>18.8</td>
</tr>
<tr>
<td>Perforations of the lower appendages</td>

<td>11.0</td>
<td>21.0</td>
</tr>
<tr>
<td>Retroversions and retroflexions of the uterus</td>
<td>16.8</td>
<td>22.3</td>
</tr>
</tbody>
</table>

Strassmann found 18.8 per cent. of diseases of the appendages among women engaged on sewing machines as contrasted with 6.6 per cent. for other women; 21 per cent. diseases of the uterus as against 11 per cent.; 22.3 per cent. displacement of the uterus as against 15.8 per cent. The majority of these troubles are due to vicious attitudes assumed at work, injuries, fatigue, etc. Metritis and endometritis, prolapse, apart from other causes (venereal diseases, post-abortive or post-puerperal inflammations, infectious diseases, venereal excesses), find in fatigue a factor of great importance affecting women, both those who have or have not had children — those of feeble constitution, the anaemic, the chlorotic, the pretubercular, those employed in unhealthy and dusty occupations, those forced to maintain a fixed position, etc.

Prolapse, which normally is the result of repeated pregnancies or a difficult confinement, is recognised among working women as following on strain in all its forms. The weakening of the ligaments holding the uterus in position, (large ligaments, utero-sacral, etc.) and of the supporting pelvic floor is sufficient to cause it.

Where to the mechanical factor of labour are added the biological factors of repeated pregnancies, sometimes painful and laborious, the frequency of prolapses is explained in this occupational class. Prolapse, it should be noted, is met with less frequently among childless working women.

Peigney examined 800 women from workshops — some having to sit and others to stand. Among the childless he found anteversion of the uterus 45 times (normal 40), retroversion 25 (normal 25), and prolapse, once (1:800); and among women with children, anteversion in 30 (25), retroversion in 65 (40), and prolapse in 30 (10).

Women with tumours of the generative organs may notice the condition becoming aggravated under the influence of work. Lifting heavy weights, strain of every kind, shocks and vibration, may set up torsion round the neck of the cysts of the ovary, myomata of the uterus, etc., with all the usual pathological consequences. Further, general impoverishment of health, bad domestic conditions, food insufficient to repair the daily deficit, etc., favour cancerous degeneration of benign tumours of the uterus.

As regards accidents of work to women (in respect of susceptibility, etc.), the data are not very abundant. Pregnancy certainly increases the risk of accident, just as do certain moral or
psychological factors, more than in the case of men. The great increases in the number of women employed during the war in munition factories increased the number of accidents. Thus, for example, Thiele found that for 100 accidents which befell men, women had 47.6 in 1917 and 91.4 in 1918 in Germany. Here it must be remembered too that the conditions under which women did their work, unfamiliar as they were with the handling of dangerous tools, complicated machinery and lastly the guarding of machinery, often left much to be desired.

A question that has been raised quite recently is that of the relation of accidents and lesions of the genitals (Au-vray) when the region involved is the vulvoperineal. An injury might occur to the uterus and its appendages across the abdominal wall as the result of an escape of the pelvis involving concomitant injuries to the intestine or bladder. In certain cases the injury might cause inflammation of the appendages, ovaritis, infectious or otherwise, or exercise an influence on a pre-existing tumour of the uterus or ovary.

Prolapse of the genital organs can undoubtedly come about under the influence of a physical and psychical injury (violent exertion, acute uterine version, prolapse of the ovary or Fallopian tube, general prolapse, utero-ovarian troubles, due to a shock, amenorrhoea, haemorrhage, pains). According to Au-vray, however, the absolute relation of cause and effect between the injury and the disorders found is exceptional.

Hygiene

Under the present social conditions, the acceptance of paid work is an imperative economic necessity for a great number of women, and whether it be a desirable state of affairs or not it is one which in all countries is in course of rapid development. Consequently, there exists a strong obligation to provide adequate means of protecting as far as possible the physical well-being of women workers.

Social hygiene ought to pursue the aim of diminishing, if not suppressing, the causes injurious to health. Preventive measures in the case of women and mothers in employment are very numerous and may be either voluntarily accepted or statutorily imposed. There is no branch perhaps in which preventive medicine can do more good.

Medical supervision from the time the girl enters school, the granting of a certificate of fitness on commencing employment subsequent to medical examination, periodic medical examination during adolescence while at work, are the needful steps to ensure the normal march in development of the young girl and to enable her to choose the work most fitted to her physical and intellectual qualities.

The question of occupational orientation in the case of a woman is certainly not too simple. Account must be taken not only of her greater susceptibility to poisons, but also of the great emotional side of her life, her impressionability and quickness of reaction.

Abolition of night work and diminution of the working hours have certainly played an important role in bringing about the almost total disappearance of chloro-anaemia, which was so frequent until only a few years ago among working women.

While acute or chronic diseases do not exercise great influence on the choice of a profession, gynaecological diseases according to their nature play a different role. Hence exclusion from heavy work in the case of ptosis or uterine prolapse; similarly, too, in cases following inflammation of the appendages, which sets up pains hindering all activity and sometimes necessitating operation, etc. Venereal diseases exclude those suffering from them from a very important set of occupations, notably children's nurses, servants, children's governesses, sick nursing, handling of alimentary products in the factory or at home, etc.

Generally constitution and temperament impose conditions in the choice of a profession. This is why Lehmann is able to state definitely: "All advice as to choice of a profession is held up by the fact that for weaklings there is no profession they can carry on without harm to themselves, and injurious trades require the best human material, which in the end is only destroyed by them.".

Hence the prime importance now admitted of a good medical unity in the factory: examination at the commencement of work and periodically afterwards. The surgeon should pay particular attention to troubles of the generative system enabling him to detect pregnancy at an early stage and to give all the information that might be useful then. He should assure himself that the woman is not suffering from her work and that the work is placed in the hands of those most

1 P. Salé (1922), in his book Gynécologie et Accidents du Travail, has analysed the role of emotion and nervous influences.
competent to do it. To carry out effectively this double task, the surgeon must possess the confidence of the management and the workpeople, as well as a profound knowledge of the technique of the processes carried on in the establishment.

It can be readily understood for what reasons this post can be best filled by a woman doctor already possessed of some practical experience. The medical supervision should be organised in such a way as to afford proper treatment for accidents, dental defects, eye affections, etc. (see article "Medical Inspection"). In the article "Social Welfare" are described all the activities that are desirable for the protection of the woman worker. Further on (under Legislation) the dangerous, injurious and unhealthy industries which are wholly or partially prohibited by law for women are mentioned. It should not be forgotten that these restraints, necessary to safeguard the health of the woman and maintain the standard of the race, raise considerable economic or technical difficulties on which there is not space to dilate here.

But every difficulty must be overcome where protection of the expectant mother is in question.

It has been seen that sufficient rest, peace of mind, sufficient food, and a healthy mode of living constitute the fundamental basis for ensuring the normal progress of pregnancy and physical development of the offspring.

On the other hand, it is advantageous, both for the employer and employee, that the latter should work as long as possible without risk to herself or child.

Antenatal consultation, therefore, should be organised so as to afford adequate advice and medical supervision through the whole period of pregnancy. The sanitary service should be in close touch with the management so as to secure such change of work as may be desirable. The expectant mother should not be given work involving more than moderate effort in its character and duration. The view being accepted that every process injurious to the health of woman is still more so for the expectant working woman, should lead the doctor to ask for her transference from the third month at least of pregnancy to a department free from risk of poisoning. Similarly the expectant mother should not engage in any occupation exposing her to accident, fatigue, or vibration, etc. The half-day system, with a maximum of six hours, should be applied for preference. Naturally there should be no night work.

Every woman in whom pregnancy appears to be developing abnormally should not be allowed to continue at work, and should only be allowed to return to work on production of a medical certificate.

Any change in employment, reduction or cessation of occupational activity should not involve diminution of salary for the expectant mother.

So far as the woman with an infant is concerned, the necessary welfare arrangements envisage particularly facilities for nursing her child (see article "Social Welfare"): these take the form of nurseries, crèches, nursing rooms, rest pauses for working women to allow of nursing, distribution of milk, etc.

**LEGISLATION**

Reference should be made to the article "Children" for legislative enactments as regards girls. Generally speaking, legislation relating to women's work is less strict in the case of adult women, because the majority of countries have enacted laws to protect females up to the age of eighteen or twenty-one years of age, as well naturally as during the time of pregnancy and childbirth.

It is necessary, however, to extend this protection, especially where questions of fatiguing, unhealthy or dangerous work are involved. Thus, for example, women are excluded in some countries from dangerous work (explosives, etc.) or very fatiguing work (mines, etc.); loading and unloading of ships controlled by cranes; work as mechanics or chauffeurs; oiling and cleaning machinery in motion; attending to belts; work with circular saws and other dangerous tools; metal casting; glass blowing; carrying of burning materials; sale of distilled alcoholic drinks, etc. The expectant mother should never be allowed to lift heavy weights.

Hours of work of women, weekly rest period, prohibition or limitation of night work and a period of absence from work before and after childbirth are statutorily regulated.

These matters of statutory observance have also been dealt with internationally: the International Conference at Berne in 1908; as regards night work; the International Labour Conference, Washington, 1919, and later ones on other questions.

The following Conventions were ratified by the States named or approved by the national competent authority up to 1 September 1928:

---

While factory work is not good for the expectant mother, it is not right to exaggerate and pretend that it is one of the main causes of the lowering of the birth-rate. Protection of the female worker has been the subject of a full discussion in the Academy of Medicine of Paris (1915-1917) — a discussion which gave expression to certain resolutions (cf. Frois: *La santé et le travail des femmes pendant la guerre*, p. 125).
...at any rate twenty-one (women employed at the mines in Belgium, Spain, Italy, or, at any rate, their admission is only authorised under certain conditions laid down in regulations). Certain industries or processes attended with less risk are permitted in the case of girls aged from sixteen to eighteen years, as well as women, provided that the employer adopts the proper measures for removing the danger in question (by fans) such as dusts, fumes, gases, etc.

Generally speaking, it may be said that women and young persons of less than eighteen years of age cannot be employed in injurious or unhealthy establishments where they would be exposed to manipulations or emanations prejudicial to health, except under the special conditions laid down in regulations for each one of the industrial processes.

 Mention should be made here of the method followed by the Netherlands Factory Act, authorising only the employment of women and young persons in factories and workshops where a required cubic space per person, a minimum standard of lighting, sufficient ventilation, and a temperature not defined, are provided in the case of girls aged from fourteen to sixteen years of age and of girls and women if the work of lifting, dragging, pushing, lifting and for expectant mothers: all carrying and removing a heavy object, demands too great effort or presents danger to health.

Other countries have laid down in detail the limits which must not be exceeded in pushing, dragging, etc., according to the age and sex of the workers. Thus, for example, these weights must not exceed for:

Children aged 12 to 15 years, 15 kg.; girls, 5 kg. (Italy).
Under 14 years, 10 kg.; girls, 5 kg. (France).
Children of both sexes, 5 kg. (Greece).
From 14 to 15 years: boys, 15 kg.; girls, 8 kg. (France).

...
Under 16 years: boys, 10 kg. (Argentina, Spain); girls, 5 kg. (Argentina); 20-25 kg. in the textile industries (Great Britain).

From 15 to 17 years: boys, 25 kg.; girls, 15 kg. (Italy).

From 16 to 17 years: boys, 20 kg.; girls, 10 kg. (France).

From 16 to 18 years: boys, 25 to 32.5 kg. (Great Britain, textile industries).

From 16 to 20 years: women, 10 kg. (Argentina).

From 17 years and over: women, 20 kg. (Italy).

Less than 18 years: women, 20-25 kg. (in the textile industry, Great Britain), 10 kg. (Greece), 13 kg. (Victoria).

From 18 years and over: women, 30 kg. (France); men, 60-75 kg.; women, 25-35 kg. (textile industry, Great Britain).

Women: maximum, 36 kg. (California), 11 kg. (Ohio, New York), 16 kg. (Russia).

The maximum loads which may be pushed or dragged, including the vehicle, are the following for different age groups and different types:

(a) Trolleys, Wagons, or Trucks, with 3 or 4 Wheels

Less than 14 years: boys, 35 kg. (France), 30 kg. (Spain); girls, 20 kg. (Spain).

Less than 15 years: boys, 120 kg.; girls, 40 kg. (Italy).

From 14 to 16 years: boys, 50 kg.; girls, 40 kg. (Spain).

Less than 16 years: boys, 35 kg. (Argentina); girls, 35 kg. (France).

From 14 to 17 years: boys, 60 kg. (France).

From 15 to 17 years: boys, 200 kg.; girls, 120 kg. (Italy).

From 16 years and over: girls, 60 kg. (France).

Less than 18 years: girls, 35 kg. (Argentina), 50 kg. (Greece).

From 17 years and over: women, 160 kg. (Italy).

From 18 to 20 years: girls, 50 kg. (Argentina).

(b) Hand Barrows

From 14 to 16 years: boys, 40 kg. (Argentina, Spain).

From 14 to 17 years: boys, 40 kg. (France).

From 18 years and over: girls, 40 kg. (France).

(c) Trolleys with Handles and 2 Wheels

From 14 to 17 years: boys, 130 kg.

From 18 years and over: 130 kg. (France).

(d) Wagons or Trucks on Iron Rails

Less than 14 years: boys, 300 kg. (France), 200 kg. (Spain); girls, 150 kg. (Spain).

Less than 15 years: boys, 300 kg.; girls, 100 kg. (Italy).

From 14 to 17 years: boys, 500 kg. (France).

From 15 to 17 years: boys, 500 kg.; girls, 300 kg. (Italy).

From 14 to 16 years: boys, 300 kg.; girls, 250 kg. (Spain).

Less than 16 years: boys, 300 kg. (Argentina); girls, 150 kg. (Argentina, France).

From 16 to 17 years: girls, 300 kg. (France).

From 17 years and over: women, 400 kg. (Italy).

Under 18 years: women, 300 kg. (Greece).

From 18 years and over: women, 600 kg. (France).

(e) Foot Pedalling Tricycles

From 14 to 15 years: boys, 50 kg. (France).

From 14 to 16 years: 75 kg. (Spain).

From 16 years and over: girls, 75 kg. (France).

Italian regulations forbid the carrying of weights by women and children for more than four hours in the working day; control and dragging of trolleys by women and young persons of less than eighteen years of age; carrying of loads by means of wheelbarrows or two-wheeled wagons in the case of children of less than fifteen years, if the work has to be carried on under special conditions of fatigue or danger; all carrying of loads by expectant mothers in the sixth month of pregnancy and after.

The work of oiling, cleaning, visiting, and repair of machinery in motion is forbidden to women, as well as all work in front of machinery which is not properly safeguarded (prevention of accidents).

French legislation (Decree of 21 June 1913) prohibits the employment of boys of fourteen and girls under sixteen years of age on outside scaffolding of warehouses and shops. Boys from fourteen to eighteen years of age and girls from sixteen to eighteen can only be employed for six hours a day, in shifts of two hours or more, with an interval of one hour at least. Children under eighteen years and women are excluded absolutely from this work after 6 o'clock at night and when the temperature is below 0° C. In the latter case the employers must place means of heating, arranged inside the building, at the service of the workpeople.

Young persons of less than eighteen years and women are not allowed to take part in the preparation and sale of printed matter — placards, drawings, engravings, etc. — which are of a kind to corrupt their morals.

1. = Industry;  C. = Commerce. The countries omitted on the above list are those of which no data are available.
It would be a good thing for women, and particularly for young persons, to be subjected to a careful examination as to their fitness for the work they are called on to do, and also to a periodic medical examination, especially when there is any likelihood that the work might be injurious to health.

Protection is especially called for in the case of the mother (childbirth, nursing). At the present time legislation has laid down the measures set out in the table on page 1260.

In many countries voluntary help comes in to aid the Government in the carrying on of statutory requirements, e.g., the "Opera nazionale per la protezione dell' infanzia e della maternità", which has just been formed in Italy (1926), etc.

Without entering here into the controversial point as to equality between men and women in regard to work, there can be no doubt that, up to the present, all legislation for the benefit of women and children has also benefited men as well. These measures have been of really great value in improving the hygienic conditions of workrooms and preventing fatigue.

The Women's Bureau of the Department of Labour in the United States is about to adopt (1928) a certain number of "standard" conditions to govern women's work. These conditions, drawn up during the war by a committee composed of representatives of employers, workpeople, and the Government, yielded after the war very satisfactory results.

The conditions asked for were:

1. Equal wages for equal work, without distinction of sex or race.
2. Eight-hour day, half-holiday on Saturday; one rest day in seven.
3. Thirty minutes at least for meals.
4. Ten minutes' rest interval in the middle of each half-day, without prolonging the working day.
5. No work between midnight and 6 o'clock in the morning.
6. Cleanliness of the workrooms; special attention to be given to the floors to prevent slipping.
7. Sufficient lighting without flickering.
8. Adequate ventilation; arrangements to be made against heat, humidity, dust, smoke, and fumes.
9. Guarding of machinery; measures to be taken to prevent fires and any other danger.
10. A chair to be provided for every woman, made to suit the position assumed at work and suited both for the worker and the work. Avoidance of always adopting the same position whether seated or standing.
11. Drinking water to be easily accessible with drinking cups for each worker, or hygienic fountain.
12. Suitable sanitary accommodation readily accessible; hot and cold water, soap and towels for each person.
13. Suitable washing accommodation (1 to 15 women).
15. Mess-rooms, separate for each sex, with arrangements for warming food.
16. No prohibition of women's employment in any industry whatsoever, unless it is shown to be more dangerous for women than for men.
17. No home work.

The Women's Bureau recommends also a department in each factory charged with the duty of choosing, placing, transferring and dismissal of workpeople, and especially of seeing that conditions of work are as good as they can be made. A trained woman should be deputed to deal with questions affecting the workpeople.

Woolen Manufacture

IMPORTANCE OF THE WOOLEN INDUSTRY

It is fairly difficult to estimate in exact figures the production of wool for the entire world, but to do so is not of great importance from our point of view. The number of sheep on the earth's surface is estimated at about 700 millions. An idea of the industrial importance of wool in industry, however, may be derived from the following rather incomplete table, which shows the production of wool in thousands of metric tons for 1927:

</table>

The countries marked 1 are engaged especially in the production and exportation of wool.

These statistics do not take account of importation of wool, which in industrial countries is very important. Thus, for example, France is equipped to deal with three million cwts. of wool, in which the native production appears as a very small figure. A further remark that should be made is that some countries enter in their statistics of wool certain fibres derived from animals other than the sheep, as, for example, Great Britain and the United States of America, which include under "wool" goat hair, mohair, llama, alpaca, and camel hair.

Nevertheless, the table cited suffices to show the distinction between producing and manufacturing countries.

PROPERTIES OF THE FIBRE

The length, fineness and colour of the wool are very variable. The wool is classified in two groups — short and long. Among the former are those measuring from 25-30 mm., and among the latter some that may reach 250-300 mm. Anatomically, the fibres are derived from animals other than the sheep, as, for example, Great Britain and the United States of America, which include under "wool" goat hair, mohair, llama, alpaca, and camel hair.

The fineness of the fibre is an essential quality, varying from one-fifteenth to one-sixty-fifth of a millimetre. Account must be taken of its suppleness, elasticity, strength, and lustre. The colour may be amber, brown or black; white wool is preferred.

Details as to the different qualities are not of importance here; these depend on the species of sheep, method of nurture, or the climate. The race producing the most famous wool is the merino sheep, originating in Spain and spreading hence by crossing with indigenous races in the producing countries or being further improved by selection.

Power to be able to distinguish the qualities of the wool is useful, in order to recognize the uses for which they may be suitable and the final object of their utilization; fine cloth, coarse cloth, carpet manufacture, hosiery, blankets, felt, mattresses, etc. A word, too, should be devoted to the hygroscopic properties of this fibre, in order to understand why it can only be properly manipulated in a dry atmosphere somewhat different from that most suitable for man from a health point of view.

Temperature and humidity are known to have a distinct influence on all fibres of whatever kind, and they cannot be easily worked beyond a certain optimum temperature and humidity. From this point of view, wool is the most sensitive of the textiles for the following reasons. Cotton fibres are manipulated in work-rooms both warmed and humidified, for by heat the fibres become more elastic and humidity gives them greater resisting power. A similar result is not required in the case of wool, the fibre of which is longer than that of cotton and more resistant, as its diameter is greater. Heat, it is true, gives it suppleness, but humidity, instead of strengthening, tends to weaken it, so that, on the contrary, it acquires on absorption of water quite a special elasticity. But this absorption takes place without difficulty, because of the hygroscopic properties of the wool.

These data are indeed in general exact, although the capacity for absorption by wools varies with their origin and other physical qualities.

Account must be had, too, of electrical phenomena. When wool is rubbed against a piece of metal, the two bodies become charged with electricity, the intensity of which increases with their dryness. It follows that there is an attraction between them and a repulsion between the fibres.
This is noticeable especially in the work of combing, where it is necessary that the fibres glide readily over the metal parts and be not retained there. Nothing like this takes place in a humid atmosphere. The presence of steam in the air renders this a conductor and hinders accumulation of the electricity generated by friction on the surface of the fibres.

**INDUSTRIAL PROCESSES**

The woollen industry comprises two main divisions, that of combed and that of carded wool.

**Combed Wool**

Combing, which is done for light and fine articles for which there is no necessity for fulling is done in two kinds of establishments, generally distinct: combing and spinning.

Combing comprises five successive operations, viz. sorting, desuinting or steeping, washing, carding, and combing proper.

**Sorting.** — The wool arrives loose or in fleeces. The former applies to the inferior qualities of wool, or to wool that has been subjected to preliminary washing in the country of origin. Fleece wool has to be sorted, that is, to be opened over screens in order to separate the fibres which are of different qualities according to the part of the body of the animal from which they are taken. Thus the wool taken from the back of the neck is very short. The wool from the back or upper part of the neck is spoken of as prime firsts; seconds come from the sides; thirds from the belly, while brittle is that which is taken from the haunches of the animal. "Fallen fleeces" is the name given to wool when it is taken from an animal after its death.

Sorting is done by workmen who have undergone a fairly long apprenticeship. The different qualities of wool separated one from the other are placed in separate baskets; coloured wools are placed apart.

Sorters are liable to breathe the dust which is given off by raw wool. Some wools are very much dustier than others. They run the risk of inhaling the spores of anthrax, particularly of wool coming from countries where no veterinary supervision of the flocks exists (see the article “Disinfection of Wool” under Dangers).

When dusty and so-called dangerous wools are handled (because they come from districts where anthrax is endemic) sorting should be done over screens or hurdles with locally applied downward exhaust ventilation, which must not be too powerful for two reasons: firstly in order that the fibres may not be carried away, and, secondly, because a strong draught diminishes the sense of touch and appreciation of the qualities of the fibre in the sorter which is based solely on the sense of touch (see also the article “Rags”).

After drawing, the wool is sometimes classed according to quality. Certain wools are passed to the willying machine (those containing a high proportion of dust and straw). Willying of dirty, dusty wool or wool contaminated with vegetal debris is done in a machine provided with powerful exhaust ventilation. The impurities are intercepted in a chamber and forced back in such a way as to be separated from the air, which passes sufficiently purified into the atmosphere.

**Desuinting or steeping.** — Desuinting has for its object the removal of the grease from the wool (French: Suin de la laine; German: Wollfett; Spanish: Grasa de lana; Italian: Grasso di lana).

The mixture of secretion from the sweat and sebaceous glands of the skin of the sheep forms a yellowish viscus mass, which contains mud, debris of straw, and other impurities, which constitute the suint on wool. Apart from the impurities mechanically adherent, it contains matter coming from the sweat glands rich in potash salts soluble in water, and matter insoluble in water — the grease coming from the sebaceous glands, which can be extracted by volatile solvents.

The suint is a complex mixture of neutral others, free acids and alcohols. There are found, in the form of salts, the following acids: formic, acetic, propionic, valeric, stearic, lactic, oxalic, succinic, malic, uric, etc., leucin, urea, chlorides, phosphates, silicates of potash, soda, etc. Its quantitative composition varies within large limits. From the chemical point of view, it is a wax saponifiable with difficulty, soluble in the majority of organic solvents, and making an emulsion with water.

The quantity of suint contained in wool is extremely variable; the finer the wool the more greasy it is. As much as 75 per cent. is found in very fine wools. The suint gives a yellowish brown dirty colour to these latter, and a rather light yellow colour to the other varieties.

Desuinting is done by treating the wool in a warm alkaline bath, followed
immediately by washing to remove the earthy matters which might further soil the wool. After having extracted the potash from the suint, the fatty matters are extracted. These are used for making ordinary lubricants, destined for the hide and skin industry, and especially for lanoline, olein, and stearin.

The suint is sometimes treated on woolcombing premises, but generally in special factories. The treatment gives rise to nauseating smells, which are unpleasant for the neighbourhood unless they are discharged into the furnace fire to be burnt, or discharged at a height into the atmosphere.

Extraction of fatty matters is done in presses, and by treating the resultant cake by means of volatile solvents: carbon bisulphide, benzene, petrol, tetrachloride of carbon, etc. (see “Fatty Substances (Manufacture of)”). Desuinting by means of solvents is becoming more and more usual. It is possible to recover the product. When carbon bisulphide is used washing is carried out in turbines hermetically closed; if petrol or gasoline be used, it is done in a series of closed vessels. There follows often treatment by water and a weak alkali or soap by means of a washing plant, washing by solvents being insufficient.

Workers at home, it should be recalled, are said to recover the suint by means of decomposing urine.

Washing. — Washing is effected mechanically in a series of four or five metal tanks, containing soapy water heated to 40 or 50° C. The wool is emptied into the first tank, and gradually worked from one tank to another by mechanically moved foris or rakes. In passing from one tank to another it passes between rollers, which squeeze out the liquid. On leaving the last tank it passes into a hot air drier and is carried to the warehouse, where it is baled or sent to be combed, if the process is carried on in an independent wool-washing establishment supplying another factory.

This is the arrangement in the British Government wool disinfecting station, near the docks at Liverpool, to secure disinfection of wool coming from countries from which anthrax infected wool may be imported (see also following article “Wool (Dis-infection)”).

It would be desirable to demand such disinfection for all imported wool were it not for the fact that it is indispensable to sort the fleece wool; and to be effective disinfection must be done on the raw material before sorting. Sorters are the first to suffer from anthrax. On the other hand, true sorting becomes impossible after washing, at any rate for the kinds most used for combing.

Carding. — Although combed wool is in question, the fibres must be passed through a carding machine. This operation has for its object the removal of the vegetable debris and burrs which have not been removed by washing, and to make the fibres lie parallel to one another, so as to form as regular a sliver as possible throughout its length. Removal of this vegetable matter is best done when wool is dry; carding requires, on the other hand, the wool to be moist. These two contradictory necessities are secured by heating that part of the cards where the removal is done in such a way as to make the wool lose momentarily its moisture, and by maintaining in the workroom a sufficiently relative humidity to allow of the fibres rapidly reabsorbing the moisture which it is necessary for them to possess to avoid ill-effects from the development of electricity. For this kind of work there is no disadvantage in keeping a temperature below 22° C. Humidity should reach 75-80 per cent.

Apropos of the temperature and humidity necessary to ensure good carding, a general remark applying to all workrooms should be made. While it is easy enough to keep up the required relative humidity, it is much more difficult to secure the same uniformity in regard to temperature, which cannot always be controlled (external influences, changes due to conduction, etc.). Moreover if the temperature varies — a fact which cannot be avoided — the relative humidity follows inversely pari passu.

In order to avoid the inconveniences resulting from a fall in temperature, and, above all, of diminution in the degree of saturation of the air, there is a tendency in practice to exceed the standards that are looked upon as optima — a result not advantageous from the health point of view (see the article “Air — Hot and Humid Atmospheres”). On the other hand, any draught is considered to lead to a drying of the atmosphere injurious to the work which technical experts think can only be carried on properly in a stagnant atmosphere — a circumstance which again increases the warmth and humidity of the air to an unpleasant degree.

In Champagne, the wool worked in the cards is formed of noils of combed
wool and waste wool that has not been combed. For a long time the cards have been provided with an unventilated method of dust extraction, of which the Lelarge system is said to give excellent results both in practice and from a health point of view.

**Combing.** — On leaving the carding machine the sliver formed by the worsted fibres undergoes a preliminary preparation for combing by passing between rollers of a comparative rapidity set to work in such a way that the number of fibres placed side by side diminishes progressively so as to form a sliver both finer and less charged with fibres. The sliver then goes into a machine which divides it into sections, combs it, removes all the impurities and inequalities without leaving the smallest bit or the smallest fibre not of the desired length, and then reconstitutes a continuous sliver. All this is done automatically. Without going into unnecessary details it will suffice to say that there are two kinds of combs: one worked cold and the other hot.

Combing is spoken of as "greasy" when done before smoothing, that is, before removal of the small quantity of oil added to the wool after the drying following washing, to render it less friable and more supple. Combing is spoken of as "fine" (French: maigre) when it takes place after smoothing.

As in the card room a temperature of 22° to 25° C. and a relative humidity of from 75 to 80 per cent. is considered necessary. In practice not infrequently the temperature rises to 30° C., sometimes even 40° C. with a relative humidity of from 70 to 75 per cent. In the rooms where the drawing, combing and smoothing, etc., frames are found, as well as the many steam pipes (often without insulating covers).

**Back washing.** — Back washing is the process taking place either before or after combing, and has for its object the removal of the oil impast on the oiling process.

The wool is placed in tanks containing water at 50° to 55° C.; from there it passes between a series of steam-heated cylinders to remove the excess of humidity.

To draw off the steam and to prevent loss of heat from the cylinders their upper part is surrounded by a hood of special design in which a current of air circulates.

**Finishing after combing.** — After leaving the combs the "tops" are made to pass through various drawing machines to make them uniform; these are named according to the use for which they are designed: Gilloch intersecting à pots tournants (Gilloch intersecting mit Drehloffen); étrage à pots tournants (Strecke mit Drehloffen); étrage en gros (Grobstrecke); étrage frothoirs (Frottirstrecke); bobinoir intermédiaire (Mittelfrotteur); bobinoir finisseur (Feinfrotteur), etc.

In the course of these drawings the original sliver becomes reduced in thickness, the fibres composing it lie more and more the one against the other, constituting a kind of mesh which must permit of lengthening in spinning and of torsion. This indispensable process in the manufacture of wool is called preparing. It is even spoken of as the soul of spinning.

The wool fibres naturally during all these processes, stretch, dry, and become electrified. A fair temperature must be maintained (22° to 25° C.) and a certain humidity of the air (75 to 80 per cent.).

**Spinning.** — After leaving the preparing machines the sliver has become a mesh which is converted into a thread by spinning.

This change is effected by means of a machine which works intermittently, named "self acting" or a dividing machine or by means of machines spoken of as "continuous spinning frames": the first yielding a very fine thread, the second having a larger yield proportional to the cost of manufacture. At self-acting mules the workers are men or young persons, at spinning frames women or girls.

The temperature and state of humidity in the spinning room depends on the kind of thread spun, the material being worked, and the kind of machine used.

With the spinning frames producing threads of not more than 45 counts for warp and 40 counts for weft, 75 to 80 per cent. of humidity and a temperature of 22° to 25° C., as in the preparing, is required.

With mules capable of producing threads of counts up to 120 (120,000 metres to the kilo) the temperature and humidity required is as follows:

<table>
<thead>
<tr>
<th>Humidity</th>
<th>Temperature</th>
</tr>
</thead>
<tbody>
<tr>
<td>Per cent.</td>
<td>°C.</td>
</tr>
<tr>
<td>From No. 10 to No. 35</td>
<td>80</td>
</tr>
<tr>
<td>...</td>
<td>35</td>
</tr>
<tr>
<td>...</td>
<td>60</td>
</tr>
</tbody>
</table>

For surface used the spinning frames give off more heat than do mules. More powerful methods of humidification must therefore be in-
ststituted in summer for them than for mule spinning.

Carded Wool

All that has been said applies to combed wool; the work of carded wool is rather different, although not dissimilar.

Both fine and coarse materials, the staple of which is deficient in length and curl, are used for carded wool. Waste from combing is added under the name of noils and even waste from shoddy and sometimes cotton (see also the article "Shoddy"). The processes used are as economical as possible because of the inferior quality of the wool.

They are less numerous than in combing. All that is wanted is to obtain a thread which is resistant and regular — this last condition being essential. The processes through which the material passes are: blending, oiling, carding, and spinning.

Blending. — The object of this is to blend the raw materials so that they correspond with the quality and price at which the thread to be manufactured is sold.

Into the blend enters a proportion more or less high of fresh wool, so called because hitherto it has not been worked up. Although blending is an essential process, further description of it need not be given except to say that it frequently ends by being willeyed or passed through machines called "devils" or "willeys".

Oiling. — This has for its object to counteract the defects in the fibres specially chosen for carding because of their lack of length or because the texture of the fibres permits an easier slipping action than with carded wool. The process consists in sprinkling the wool with a mixture of oil and soap of which the proportions vary according as to whether the thread to be prepared is intended for warp or weft.

Carding. — After oiling the wool is willeyed to equalise the distribution of grease and is then despatched to the card or rather to an assortment of three or four cards, each of which has a special rôle.

The first card (scribbler) commences the unravelling of the fibres; the second or third and fourth follow (if there are four cards) and are called intermediates. The last card (condenser) is provided with an apparatus which divides the wool upon the doffer into several strips passing between rubbers which are intended to roll them and change them into sliver.

Spinning. — On leaving the cards the sliver passes on to mules somewhat similar to those referred to before to be converted into spun thread.

According to the kind of thread required this operation is done once or twice; if twice the process is done successfully on two mules. There is coarse and fine spinning. Spinning of carded wool is intended for the manufacture of closely woven goods.

If it is desired to spin coloured thread the wool is generally dyed en masse before oiling. Blends can then be made with different shades so as to arrive at special shades or particular effects (see article "Dyeing").

Oiling having for its object to supply the fibres with greasy matter to give them the suppleness they lack, the conditions for its treatment in regard to temperature and humidity are not the same as for combing. Nevertheless precisely on account of the presence of a greasy material which must not congeal but remain smooth and slippery the temperature must be above the average. Experience shows 22° to 24° C. is about right in the case of carded wool while the humidity should not be less than 60 per cent. for carding and 70 per cent. for spinning.

Spinning of carded wool — this being inferior in quality to combed wool — has in France, at any rate, produced the only cases of anthrax which have been verified from wool.

English Methods

In Bradford the processes, if not the equipment, differ a little from that which has been described. In combing, the temperature and humidity do not need to be so high as in France. This is due to the fact that in Great Britain even the long and fine wool is more abundantly oiled. Thus when question is raised as to the injurious action of the warm and moist air in wool spinning, the English have always had in mind spinning carried on by the "French process".

Gassing the Threads of Wool

However carefully mule spinning or spinning frames are run, the extremities of the filaments of the thread project beyond the compact cylindrical portion of the thread. To make this look nicer the extremities are burnt by making

1 This method is followed in about a dozen establishments in the region of Bradford.
the thread pass at great speed through a gas jet. During this operation — known as "gassing" — matter which is deposited near the jets, carbonic acid gas, smells and a little carbon monoxide are given off. The jets are supplied with coal gas, water gas either alone or mixed with coal gas or again with a mixture of air. Only a portion of the woolen threads undergo gassing.

A visit to a gassing room is always unpleasant and particularly so in the case of wool because of the albuminoid matter burnt. Further the heat is considerable and there is much fine carbon dust.

Researches by Thorpe, at the request of the Home Office in London, showed that for every cubic metre of gas burnt from 1.24 litres to 2.23 litres of carbon monoxide was given off depending on the kind of burner used and the kind of gas.

Such ventilation, therefore, must be assured as will exert a downward exhaust below each burner through an opening of small diameter so that the air aspirated comes from above, sweeping across, so to speak, the worker's breathing level without affecting the flame jets. Mr. Smith saw this system at work near Bradford in 1903 and expressed satisfaction with it. Use of burners with the flame reversed avoids certain inconveniences.

More recently gassing of the threads has been tried using platinum wires heated by electric current instead of gas jets. This method, even in the case of cotton, which gives rise to less waste, has been discontinued.

The bleaching of the wool, which has for its object to obtain unshrinkable material as slightly sensitive as possible to the phenomena of felting when washed with hot soapy solutions and to enable the wool to fix successfully certain imprinted dyes, is done generally with chloride of lime by a single or two bath process (hydrochloric acid bath and chloride bath). Recently the proposal has been made to fix simply dry chlorine or liquid chlorine on the dry wool while it is being stored for the purpose of dying. A fan removes the excess of chlorine.

DANGERS

The danger varies with the different industrial processes. The sorters run the risk of dust and anthrax. The woolwashers, on the other hand, are exposed to extremes of temperature, humidity, caustic and irritating action of alkaline solutions and acute and chronic intoxication from the volatile solvents.

Carding throws into the air fragments of wool fibres which remain suspended a long time and may set up lesions of the mucous membranes, especially of the respiratory tract. Spinning does not create dust because of the moisture present in the atmosphere.

As the effect of warm and moist air is the subject of a special article (see "Air — Hot and Humid Atmospheres"), reference to it here would be out of place. Nevertheless it must be admitted that a noticeably unpleasant atmosphere exists in fine wool spinning rooms. The temperature below which it would not be practicable, on technical grounds, to fall is 25° C. and a relative humidity of 90 per cent. for preference. In summer, however, difficulty is experienced in not exceeding this, with consequential necessity of maintaining the saturation of the air. Soon after the spinning frames start working a portion of the mechanical force destroyed becomes transformed into heat. At midnight the effect of the external temperature is felt still further and frequently the thermometer may reach 30° and even 35° C. And the high temperature is further aggravated by the fact that movement of the air is avoided, especially in the mule-spinning out of order to prevent the thread becoming entangled.

During recent years the barium chloride method of treating wool for mattresses has been introduced. Wool thus treated is said to have a better appearance, to be whiter, to lose part of the impurities which the ordinary method fails to remove, to be more resistant to moths, to disinfection, etc. The wool is treated with a solution of chloride at 10-14° B. and dried. Although chloride is fairly toxic, no case of poisoning of industrial origin has been known to occur. Nevertheless, it is advisable to ensure for workers employing this method certain aids to personal cleanliness (wash basins, douches; mouth rinses for carders).

PATHOLOGY

This varies with the different processes. Thus, for example, wool-sorters run the risk of dust inhalation and of anthrax infection — by no means negligible (see the article "Wool (Disinfection)"). Forms of

It has been noted at times to have attained about 60° C. during combing.
mycosis are reported (from Aspergillus niger or flavescens) localised in the external auditory meatus, middle-ear inflammation; tonsillitis, conjunctivitis, etc.

Among woolwashers, there occur cases of poisoning (dermatitis principally) caused by the arsenic used to preserve the fleeces; intolerable discomfort and even ulceration of the skin (when not protected); bronchial irritation from use of a soap prepared with a silicate containing microscopical spicules of fossil animalculae (Gilman Thompson, U.S.A.). The dermatitis described is closely connected with the use of alkalis. Poisoning from volatile solvents is possible but rare.

Dermatitis has frequently been set up by the use of wool waste mixed with silicates to form non-conducting material for insulating boilers and pipes. This occurs, too, in workers engaged in desuing wool in dye-works, etc. In this department cases of poisoning by lead (from chromates) anilin, arsenic colours, vapours, acids, etc., may occur.

The oil causes among spinners, especially in young persons and apprentices, an acne on the unprotected parts of the skin. Dryness, high temperature, and lack of cleanliness favour its development. The acne is situated mostly on the arms. (For twistcrs' cramp, see the article "Cotton").

The effect of the conditions described cannot readily be shown in figures. Comparison can be made between districts where no woollen industry exists and those where it does. Thus, for example, British comparative mortality statistics show that wool operators have a lower death rate from respiratory diseases than do all occupied and retired males. In France, in the southern portion of the Département du Nord, two very distinct and different industrial groups are found, namely, that of Fourmies (wool) and that of Maubeuge (iron). If comparison is made of the proportion of workmen rejected per year or, what is more satisfactory, for a group of years (from 1904 to 1908), it works out that 31.7 per cent. of spinners are unfit for military service and only 12.9 per cent. workers in other trades.

The same relation is found at Sains-du-Nord: wool spinners 30.7 per cent.; other professions 12.6 per cent.

The same facts emerge if another textile district in the Département du Nord, that of Roubaix-Tourcoing, is selected, although not quite so saliently, because along with the wool industry the cotton industry flourishes, and it is not always possible to know to which of these two industries the rejected conscripts belong as both are entered as spinners or piecers, or fly-frame helpers without any indication as to whether they belong to the woollen or cotton industry. In 1908 the proportion was 38 per cent. for piecers and 27.3 per cent. for other occupations.

These data are confirmed by those for mortality in the same districts. The effects of the work in wool spinning is, therefore, shown to be more deleterious to health than that in other occupations necessitating greater physical exertion. Thus, the number of deaths in Fourmies per 1,000 men of the same profession during the years 1900-1904, 1905, 1908 and 1909 during which the description of employment is unequivocal is as follows:

<table>
<thead>
<tr>

The mortality of piecers and spinners is higher from 15 to 30 years. Figures as to mortality from tuberculosis show that, as compared with an average of 50 per cent., that for piecers and spinners is 93 per cent. for the age period 20 to 29 years. (See the article "Textile Industries").

**Hygiene**

The British Woolcombing, etc., Regulations require that alpaca, peltian, East Indian cashmere, camel hair, and Persian cashmere shall not be opened except (a) after steeping in water or (b) over an efficient opening screen before any operation of sorting, which again must be done in a room set apart for the purpose. A sorting board shall not be deemed to be efficient unless 75 cubic feet per minute are drawn by the fan from beneath each sorting board. No sorting table may have a surface area less than 12 x 34 feet. Damaged wool (dead fleeces) shall be opened only by men skilled in judging the condition of the material and then washed without being willeyed.

Bales of ram mohair must be steeped before being opened. Alpaca, peltian, cashmere, camel hair, and Persian shall not be willeyed except in a room set apart for the purpose, and the willeying machine must be provided with mechanical exhaust draught so arranged as to draw the dust away from the workmen and prevent it from entering the air of the
properly constructed receptacles to be machines.

Cleanliness of the floor, walls and ceiling is enjoined; eating meals or changing clothes in the workrooms is forbidden; no person having any open cut or sore shall be employed. Means for ensuring personal cleanliness are required with provision for first-aid treatment of cuts or scratches.

In carding it is the "swift" which detaches the woollen fibres from the big drum. If the swift is well regulated and hooded over properly the workroom can be easily kept free of fluff. Arrangements have been thought out and applied for enclosing certain parts of the card to minimise escape of dust and fluff.

Viewing the industry superficially it might be admitted that the conditions from a health point of view are not bad. Apart from certain special points — grinding the cards, willeying, gassing — the workers are not exposed to risk from dust. Spinning rooms are large and spacious. Cubic space is ample — sometimes 100 to 150 cubic metres of air per person. But statistics tell their tale of working hours in the heat and humidity and a stagnant atmosphere. The practicable remedy already applied in many cases for securing good conditions without diminution in the temperature or saturation required is as follows:

(d) To have the factory built in such a way as to make it, as far as possible, independent of external influences so far as rooms are concerned in which the temperature must reach 20° to 25° C. and humidity 60 to 90 per cent., and not to allow the temperature considered necessary for good work to be exceeded.

(b) To have the air of the workrooms renewed so that the temperature and humidity remain within the limits fixed by experience as most suitable. Such ventilation, further, gives a margin before temperature and humidity become objectionable, and experience has shown that it is not attended by any fresh difficulty for spinning, while it does improve the atmosphere considerably from a health point of view.

Residual Waters

These waters are unpleasant, and undergo putrefaction and fermentation as they are rich in salts and in organic matter. To purify them one must commence at their source, for the processes vary according to the impurities present and the matter it is desired to extract.

The brownish black washing water contains the impurities soluble in water and grease. Wools classified as dangerous may contain anthrax spores. Waste waters from these ought not to leave the premises without previous disinfection. The soapy lye used in the removal of the grease flows away as a brownish yellow liquid containing in suspension or solution sand, excrement, wool fibres, emulsified grease, and the substances used in washing. This water used over and over again and concentrated in the form of mud can be burnt. The salts of the fatty acids are converted into carbonates — the fatty acids liberated are burnt.

If evaporation is carried on in open tanks evil-smelling, disagreeable vapours for the neighbourhood are given off. They should be carried away into a chimney stack with the gases from the furnace fires.

Extraction from the cinders is attended with certain dangers because, if not completely burnt, they give rise to evil-smelling vapours and dust irritating to the mucous membranes.

The suspended impurities in the lye waters are separated by sedimentation. The vegetable fibres are kept back by a sieve and used as cheap textile material. The lye then purified is subjected to a series of operations having for their object the extraction of the grease and the fatty acids. These substances are recovered by decomposing the lye by means of a mineral acid — generally sulphuric of 50-60° Be. The mixture is subjected to pressure and from the cakes obtained the fatty matters are extracted by various processes (hot pressing with acid solution). The crude grease is bleached with bi-chromate of potash and sulphurous acid. The residue is used as a combustible or subjected to volatile solvents. Solvents are also used for extraction.

The soluble soaps also can be converted into insoluble by means of caustic alkalis, which enables a soapy solution to be used over again for wool washing.

These processes expose the workers to several dangers: caustic action of the acids and alkalis, weather conditions; dust from the cinders, etc.

Cleanliness of the different working parts of the spinning frames and mules is essential. Friction of the sliver against the machinery it comes
into contact with detaches the fibres which stick there or fly round the machinery. When the fibres accumulate they can be taken up again by the sliver or constitute "beards" which revolve round the spindle. The combs similarly get choked as well as the covers and the brush below. Generally these parts are cleaned three times a day for material of first quality and as much as six times a day for the others. Finally, the gearing of the parts of the different machines, arranged at the ends of the spinning frame or mule, are cleaned once a week. Further, oiling must be regularly carried out by the "oiler".

To clean the combs the workwomen make use of a tool with a handle the extremity of which is equipped with a strip of card. The woman kneeling underneath the bobbin carrier applies the tool to the comb as it is travelling; to remove the fluff which soils the sleeves, the cleaners rub the surface of the leather with their hand or with another tool with a longer handle. The combs, the brushes and the rollers have the fluff which obstructs them removed after being uncovered. These operations often cause accidents from inattention; the cleaning implements, lightly held, are drawn into the spinning frame or mule, and instinctively the cleaner stretches out her arm to recover it. If the cleaner sees a plug lodged in the comb or a "beard" which will not come away with the brush, without thinking longer she tries to remove it with her fingers.

In removing or replacing the "casing" and rollers, the hand heedlessly is placed close to the point that is held for the casing, taken hold of and strikes a dangerous part. Or if the badly-replaced casing is about to fall on the comb the arm is rashly stretched out to catch hold of it.

Oiling is done with an oilcan having a long neck, the use of which would seem to be quite free of risk. But often the little holes for oiling are blocked. Then the workwoman puts a little oil on the end of her finger which she then places on the part to be oiled, at times very near the combs.

What tends to encourage these practices is that cleaning is easier and more quickly done while the machine is in motion, although this is forbidden by law.

The measures adopted as far as practicable to prevent these accidents or, at any rate, to reduce them to a minimum are:

(a) cleaning and oiling to be done by a trained workwoman over 18 years of age or by an old workman;

(b) use of automatic or semi-automatic methods of cleaning;

(c) guards for gearing wheels so arranged as to be removable except when the machine is stopped and requiring to be replaced before a start can be made.

**LEGALISATION**

Prohibition of the employment of young persons of less than 14 years of age in processes of deburring, willeying, dust extraction, unravelling, carding, combing, etc., unless dust is removed by mechanical means (Belgium); of less than 16 years from attending machines used for woolsorting, carding, and all processes in which injurious animal dust is given off (United States (Alabama, Arizona, California, Connecticut, Kentucky, Maryland, Massachusetts, Missouri, Ohio, New Jersey, New York, Tennessee, Wisconsin)); of less than 18 years from willeying, carding, cleaning, removal of vegetable debris by a wet method in which acid vapours are given off (France); of boys under 15 years of age in Italy from willeying, carding, cleaning, unless effective localised ventilation for the removal of dust is provided and maintained; of less than 16 years in Spain under like conditions to those in Italy; and from desalting waste wool by means of petrol, carbohydrates, etc., when poisonous fumes escape, from carding and cleaning in Canada (Quebec); and girls of less than 21 years in Spain and Italy under the same conditions as boys.

Women are prohibited from removal of vegetable debris from wool and cloth when done by a wet method if acid fumes are given off (France).

As to prevention of anthrax see the article "Disinfection of Wool." Cases of anthrax in persons employed in the woollen industry receive compensation in Great Britain and most of the British Dominions. In the Netherlands arsenical poisoning among persons employed in wool washeries is statutorily notifiable.

Special legislation on the woolen industry has been enacted in Austria (1922), India (1922), and in Great Britain to guard against anthrax infection. Great Britain has also issued Regulations dealing with sorting, dust extraction, washing, combing, and carding (16 December 1908, No. 1,929); on the use of wool coming from East India (18 December 1908, No. 1,887), and, further, in 1909, Regulations on the degree of maximum humidity to be permitted in spinning merinos, etc., by the French process (No. 1,114). Seats are required to be placed at the disposal of the workers during combing at night and during rest periods.

**BIBLIOGRAPHY**

This has pointed to the desirability of disinfecting the wool or hair prior to its use in industry, and measures with that object are in fact taken in various countries. Unfortunately it has been found that they cannot always be relied upon to destroy the infection without damage to the material, more particularly when applied in individual factories under variable conditions and with varying degrees of skill. These difficulties were considered in 1918 by a Committee appointed by the British Government to consider what further steps should be taken to prevent infection by anthrax in the manipulation of wool, etc.; and a new method of disinfection suitable for central disinfecting stations was worked out under the direction of the Committee. This method has been put into operation on a commercial scale and improved in various ways at the Central Wool Disinfecting Station established by the British Government at Liverpool; it has been markedly successful as regards both destruction of the anthrax spores and condition of the disinfected material.

The British Wool Disinfecting Station is a State organisation carried on under powers given by Parliament in the Anthrax Prevention Act, 1919, which enacts that provision may be made by Order in Council for preventing the importation into the United Kingdom, either absolutely, or except at specified ports and subject to conditions, of any goods infected, or likely to be infected, with anthrax. Powers are also given for the establishment of works for disinfection of such goods. An Order in Council made in 1921 (No. 352) under this Act prohibits the import into any port in the United Kingdom except that of Liverpool—and there only subject to the condition that such goods must be delivered to the Director of the Central Wool Disinfecting Station for disinfection—of all goat-hair from or through India and all wool and animal hair from or through Egypt. Such materials are, on arrival at Liverpool, taken charge of by the Customs and transferred to the Disinfecting Station.

In establishing any central station for disinfection of wool two considerations are of fundamental importance,
wool (disinfection) — 1272 —

i.e. (1) that in such an establishment the material handled may possibly be dangerously infected, with corresponding risk to the disinfecting station workers unless precautions are taken, and (2) that disinfected materials will be transported to factories in a condition of risk and will, therefore, be handled in industry without even such precautions against anthrax as it is possible to take in factories. It is essential, therefore, that the method of work should be such as to avoid contact with the raw material, or dust from such material, and that sterilisation shall be absolute in every case.

Anthrax spores in wool are frequently, perhaps usually, associated with albuminous substances in such a manner that they are afforded a considerable degree of protection. Consequently the process of disinfection must provide for the removal of such protection and the process of disinfection in use is accordingly arranged in three stages, in the first of which the spores are made susceptible to the action of the disinfectant, while in the second they are brought into contact with the disinfectant and killed, and in the third excess of disinfectant is removed from the material and the latter dried. In the actual carrying out of disinfection, which is a wet process, the bales of material are placed on a travelling platform and the coverings removed. The material itself is not handled, but is carried on the moving platform into a machine where it is sufficiently loosened to permit it to be fed by machinery at a predetermined rate into the first solution. The considerable quantity of dust which escapes in this operation is extracted by fans and conveyed automatically to the boiler furnaces and there burnt.

The actual disinfecting plant consists of five bowls or baths of the type used in wool washing, each of which contains a solution maintained at a temperature of 102°-110° F. (39°-44° C.) through which the material is to be disinfected is propelled by means of reciprocating forks at such a rate that it remains in contact with each solution for ten minutes. The material is passed through squeezing rollers at the end of each bath in order to remove air bubbles and excess of liquid and prevent dilution of each succeeding solution.

The first of the five baths contains a solution of sodium carbonate in water, the strength of which varies according to the type of material being disinfected, but is normally about 4 per cent.; and the second contains a solution of soap in water of a strength of approximately 1/2 to 1/4 per cent. The treatment in these two baths constitutes the preliminary part of the process in which the albuminous protection of the spores is removed and the spores made susceptible to the action of disinfectants, and each bath is provided with: (1) apparatus for removing from the solution the dirt and foreign matters washed out of the wool, and (2) apparatus for automatically adding sodium carbonate and soap in order to maintain the strength of the solutions.

The third and fourth baths each contain a solution of formaldehyde in water of a strength of approximately 2 per cent., and they are completely enclosed in order to prevent escape of formaldehyde into the air. These two baths are connected with a common system of purifying plant in order that the solution may be cleansed of foreign matters and used over again, and to each is fitted apparatus for automatically adding formaldehyde to the solution in order to maintain its strength, as, especially in the third bath, it is being constantly diluted by the water carried on the wool from the preliminary treatment.

The fifth bath contains a very dilute solution of formaldehyde and to it fresh water is being added constantly in order to keep its strength down to approximately 0.2-0.3 per cent. of formaldehyde, since its purpose is to remove excess of formaldehyde from the wool. After leaving this bath the wool is carried by rollers into a duct, through which it is driven by means of a current of hot air at a temperature of approximately 240° F. (116° C.) into a wool-drying machine. The volume and temperature of the current of air are so arranged in relation to the quantity of material carried by it that, by the time the material reaches the drying machine, the temperature, as a result of evaporation of the moisture in the wool, is reduced to approximately 160° F. (60° C.). Following the drying machine is: (1) a cooling machine in which the temperature of the wool is reduced to that of air, (2) a machine by which moisture is added to the wool to bring it to the standard condition of moisture content accepted in commerce, and finally (3) a baling press, in which the wool is made up into pressed bales of convenient size.

The machines are arranged in sequence, and the speeds of each part are so regulated that the material passes automatically through each, and from one to another, at exactly the same rate, with the result that in normal
conditions it forms a continuous band from one end of the plant to the other, and it is unnecessary for any person to touch it (except so far as may be incidental to removal of the bale coverings of the raw material) from the time it enters the machines to the time it is baled again after disinfection. The rate of disinfection is approximately 2,000 lb. per hour per machine.

The costs of running the Disinfecting Station are borne by the Government, but are partly covered by a charge made for disinfection, which is in accordance with a statutory scale (Statutory Rules and Orders, 1921, No. 1044), i.e. 1d. per lb. for material losing up to 20 per cent. in the course of disinfection, 1½d. per lb. when the loss is over 20 per cent. and not more than 50 per cent. and 1½d. per lb. when it exceeds 50 per cent., in each case calculated on the weight of raw material.

Careful control of the whole process is essential, since, being continuous, the strength and temperature of the solution varies from moment to moment, and it can be calculated that accurately as soon as the flow of the strength of the formaldehyde solutions may be reduced below the disinfecting strength in from three to five minutes by the introduction of water carried by wool from the preliminary process. Temperatures are controlled by means of thermometers readings made at fixed intervals by the machine minders and entered on a daily report. These are checked by the chemist in charge, also at fixed intervals, and recorded on an independent report. Strengths of solutions are maintained by means of automatic addition apparatus, which can be adjusted as required, and the solutions themselves are analysed at fixed intervals, the results being recorded on the chemist's report and at once communicated to the machine minders in order to afford data for adjustment of the automatic addition apparatus. Condition tests on the disinfected wool are also made to make sure that it is being sent out as nearly as possible in commercially accepted condition in regard to moisture content.

In addition to the expert control of strength and temperature of solutions, careful bacteriological control is maintained. Samples of the raw materials before disinfection and of the disinfected materials are taken at intervals of approximately three hours, those of disinfected material being taken one and half hours after the corresponding raw material samples, in order to secure comparative samples, since material requires approximately one and a half hours to pass through the process. The bacteriological examinations are not made in the Disinfecting Station or under the control of the Station authorities. Some samples are sent to the Public Health Laboratory of Bradford, some to that of Liverpool, and some to a bacteriologist retained by the Home Office, who report the results they obtain.

Wool and hair contain spores of many organisms, usually non-pathogenic, in addition to spores of anthrax, and one of the most widely distributed, bacillus mesentericus, is considerably more resistant to destruction than even anthrax. In order to ensure that the disinfection is maintained at a high standard of efficiency, an empirical standard has been evolved to which if the cultivation from a sample of disinfected material of more than five colonies of such "other" organisms is reported, careful enquiries are made as to the cause. Even though these may not point to any defect in the method of destroying anthrax, the constant possibility of enquiry resulting from this method of control ensures a high standard of working efficiency.

It will be seen from the table giving the results of bacteriological examination of samples of material disinfected in the Disinfecting Station (page 1274) that only two samples of disinfected material have been found to contain anthrax; these were taken soon after the disinfecting station was started and were traced to known defects of control, and no instance has occurred since, so it can be assumed that disinfection is complete. It will also be observed that the degree of infection varies considerably in different raw materials, but on the average somewhat less than 10 per cent. of all the material handled in the disinfecting station is infected with anthrax, while nearly 70 per cent. of the disinfected material is completely sterile.

It may be urged that the establishment of a central disinfecting station merely transfers the risk of contracting anthrax from the workers in factories to those at the Station, but such an argument is fallacious. In particular, it is possible in an establishment specially designed and carried on...
RESULTS OF BACTERIOLOGICAL EXAMINATIONS OF MATERIALS DISINFECTED IN THE GOVERNMENT WOOL DISINFECTING STATION (HOME OFFICE), LIVERPOOL, FROM OPENING OF STATION JUNE 1921 TO 31 AUGUST 1929

*In the early period of disinfection, before complete routine control of the disinfection process was fully established.
for disinfection purposes to take precautions which would be impossible or ineffective in an ordinary factory, and experience at Liverpool shows that the risk is quite small.

The material compulsorily disinfected is mainly used in Bradford and district, and the incidence of anthrax there as well as the severity of the disease have greatly decreased since the establishment of the Disinfecting Station, though some materials, e.g. Persian wool, etc., are not required to be disinfected compulsorily. The following table, drawn up from particulars supplied by the Bradford Inspector of Factories, shows the incidence of anthrax in Bradford and district in the nineteen years 1902 to 1921 before disinfection was established, and in the eight years 1922 to 1929 since:

In no case has infection been traced to disinfected material, but in a large proportion infection has definitely been traced to materials which have not been disinfected.

It is generally considered that there is some occupational risk in handling formaldehyde, which is used in disinfection of wool. Experience of disinfection seems to indicate, however, that this is very small. No case of illness due to this cause has occurred among the workers, though two mild cases of an eczematous condition of the skin have been observed. The workers concerned were, however, occupied in remedying special defects of the plant, during which they were in close contact with the formaldehyde solution used and no affection resulting during normal working has occurred.

Some discomfort amongst workers handling disinfected wool was at one time reported as being due to the escape during manufacture of formaldehyde retained in the wool. Enquiries showed that this was justified and that there was definite discomfort and possibly some risk from this cause. At that time no steps were taken to remove formaldehyde from the wool, but as soon as the effect was observed special measures were taken to render disinfected wool free from formaldehyde, since which time no trouble has arisen.

The central disinfection of wool involves, of course, important economic considerations which cannot be dealt with in the scope of the present article, but mention may be made of a report recently issued (1923) by a Committee appointed by the British Government to enquire as to the additional charge to the industries using East Indian wool which would result from its disinfection as carried out at Liverpool. This report indicates that if disinfected East Indian wool were used in place of undisinfected in the manufacture of carpet yarns and felt the additional cost would be not more than 1d. per lb. of carpet yarn and not more than 1d. per lb. of felt. This is equivalent to an increase in the cost of carpets and carpet felts of slightly more than 1d. per yard.

Anthrax Prevention Act. 1919 (9 & 10 Geo. V. ch. 23).

Order in Council, dated 9 March 1921, regulating the Importation into the United Kingdom of Certain Goods likely to be infected with Anthrax. Statutory Rules and Orders, 1921, No. 352.

Report of the Departmental Committee on Disinfection Costs appointed to enquire as to the probable charge to the Industries in which East Indian Wool is used of requiring all such Wool imported for use in this Country to be disinfected under the Government’s Disinfection Scheme on arrival in this Country; and to carry out such Tests as may be found necessary. 2 Vols. London, H. M. Stationery Office, 1923.

*Dr. G. E. Duckering, O. B. E.*

(Liverpool)
Xylene

French: Xylène; Xylol. — German: Xylol. 
Italian: Xilolo. — Spanish: Xileno.

Xylene, dimethylbenzene \((C_6H_5(CH_2)_2)\), a hydrocarbon obtained from tar, is a mixture of three isomers, \(O\), \(M\), and \(P\), the meta being present to the extent of 70 and 80 per cent. As their boiling-points are slightly different, it is impossible to separate them by fractionated distillation. Industry uses more especially the metaxylene, of which two kinds may be distinguished, the crude liquid, colourless or yellowish xylene, boiling between \(120°\) and \(150°\) C., and the purified colourless liquid xylene, which boils between \(120°\) and \(145°\) C., and even between narrower limits. These two products, however, still contain more or less considerable quantities of toluene, traces of thiophene, ethyl and trimethylbenzene, paraffin hydrocarbides, etc.

The principal source of xylene is coal-tar. The second series of products obtained by tar distillation and given off from about \(110°\) and \(170°\) C. consists of light oils of fairly variable composition which give, on fractionated distillation, light and heavy benzols. Subjected anew to fractionalized distillation, these two series give seven different series, boiling at varied temperatures; crude benzois which after several kallian and washings and several rectifications in order to free them from phenols, provide various trade products of benzene, toluene and xylene.

By reduction of xylene there can be obtained aminated derivatives called xylidines, homologues of aniline, which are used in the manufacture of colours, explosives and varnishes. The nitration of xylene gives nitro-xylenes, which, however, are not very extensively used in industrial technique. The xylenes are used as solvents for oils, fats, waxes, colours, etc., and as cleaning products, etc.

The toxic action of xylene is similar to that of benzene and toluene. Nevertheless, according to Lehmann, commercial xylene is said to be one-fifth more toxic than benzene; narcosis sets in more rapidly and recovery is slower.

This fact has been established as a result of experiments effected on animals (Koelsch): 43 mg. of xylene per litre causing narcosis at the end of forty minutes (Rambousek); 4.3 mg. per litre irritated the mucous membranes and provided derangement of equilibrium (Batchelor). In man, poisoning is manifested by paresthesias, trembling, a feeling of oppression, vertigo, headaches, loss of memory, weakness, insomnia, cardiac, respiratory and visual affections, etc. In the cases encountered, poisoning did not give rise to permanent injuries.

The nitro derivatives of the xylenes \((C_6H_5(CH_2)_2NO)\) are of less practical importance; the five isomers are mixed at a high boiling point used for preparing xyldine, which has an action similar to that of nitro-benzene, though however less marked. The animal experiments carried out by Ilzhöfer (1918) with trinitroxylene utilised in the explosive industry have proved the absolute harmlessness of this product.

The animated derivative, xylidine \((C_6H_5(CH_2)_2NH)\), obtained by reduction of nitroxylene, is a mixture of \(m\).-xylidine \((40-60)\), para-xylidine \((10-20)\), the remainder being made up of the three other isomers. Poisoning recalls that caused by aniline, but it is said to be characterised by a sensation of heat in the face, headache, etc., of very early occurrence.

During the war, the bromides of xylene and xylidine were used as tear gas under the name of "T-Stoff".

A cleaning product placed on the market under the name of "xylol", and containing also toluol and benzol, has been the cause of several cases of poisoning amongst workers engaged in helio-engraving (see articles "Printing Trades" and "Photo-Engraving"). As regards hygiene and legislation see article "Benzene".

Injuries due to xylene are subject to compulsory notification in the Netherlands, and entitle victims to compensation in Finland and Italy.

See also articles "Benzene" and "Nitro-Amide Derivatives of Benzene and its Homologues".

Zinc

Zinc (symbol Zn) is a greyish-white metal, with a strong metallic lustre and a finely granulated appearance which is crystalline or lamellar, according to the method of preparation; the melting point for the purest zinc (99.99 per cent.) is 419.4° C., and the boiling point 930°, which is the lowest point for heavy metals, with the exception of mercury. It is very stable in dry air and pure water; but in damp air it becomes covered with basic carbonate of zinc, which protects it against further corrosion. When heated to 500° C., zinc burns with a greenish-blue flame, giving off oxide of zinc. Powdered zinc, which is used as a powerful reducing agent, decomposes water even at ordinary temperature, with the formation of hydrogen and a great emission of heat; hence arises danger of spontaneous combustion in damp store houses.

Commercial zinc, as opposed to pure zinc, dissolves easily in dilute acids, and with difficulty in alkalis, with the formation of hydrogen.

INDUSTRIAL OPERATIONS

Brass, the most important alloy of zinc, as well as its manufacture from copper ores, was known to the ancients before zinc. Imported in the sixteenth century from Eastern Asia, as Indian tin, its commercial manufacture only began in Europe towards the middle of the eighteenth century, and, on a large scale, only after the elaboration of the modern process with muffle furnaces in 1798.

Zinc is very widely distributed in nature in the form of ores composed of sulphide or oxide of zinc, which almost always contain cadmium, from 0.1 to 5 per cent., as well as such other heavy metals as iron, manganese, lead, copper and silver. The most important ores of zinc are the following:

Sulphide of zinc (ZnS), known as blende or sphalerite, contains in its pure state 67 per cent. of zinc and 33 per cent. of sulphur. Some varieties contain lead oxide and silicides of iron and copper, such as Marmatite, Christophite and Wurtzite.

Calamine (SiO₂Zn₄H₂O) is a hydrated silicate of zinc which contains in its pure state 53.7 per cent. of zinc; the trade variety contains 25 to 35 per cent.

Smithsonite (ZnCO₃) is a carbonate of zinc containing 52 per cent. of zinc in a pure state, and 35 to 45 per cent. in the case of the trade variety.

Auricalcite is a variety of Smithsonite which contains copper; another variety is hydrozincite, which is a basic carbonate of zinc. Willemite, an orthosilicate of anhydrous zinc, and Gahnite, or zinc aluminate, should also be mentioned.

It must, however, be remembered that Calamine and Smithsonite are very often mixed, and that they then form a type of ore with stalactite and mamilloform appearance, classified by mineralogists under the generic name of “Calamines”.

Zinc oxide (ZnO) is found in the form of red zinc, zincite, spartalite, with 70-80 per cent. of zinc, or as Frank lime (FeMnZn (FeMn)₂O₄), a black mineral, frequently associated with red zincite and yellow to green Willemite, which is almost free from lead, but rich in iron and manganese, and contains about 18 per cent. of zinc.

Cadmia is an industrial ore formed of the dust deposited on the upper part of blast furnaces; it consists of zinc oxide coloured by a little oxide of iron.

Poor zinc ores, with only 20-25 per cent. of zinc, are subjected prior to treatment, to sorting and mechanical processes for enriching the ore, so as to obtain a zinc content of at least 35 to 45 per cent. The operations are almost always done by wet methods, either in special machines or by “floatation”; only rarely are electromagnetic or electrostatic methods of separation employed. The ores thus “concentrated” are changed, as far as is pos-
sible, on the spot or in foundries, by roasting or calcination, into zinc oxide, which has, in its turn, to be subjected to reduction. Ores with a base of carbonate or silicate of zinc are heated with charcoal in calcining furnaces, which are, in a way, similar to lime-kilns. On the other hand, sulphide ores must have the sulphur completely removed, which is easier with ores rich in zinc than with those poor in zinc. The process is carried out by the formation of zinc sulphate which, above 900° C., decomposes into zinc oxide and sulphur dioxide; blende, which contains lead and lime is, on the contrary, not readily deprived of its sulphur.

The roasting, or calcining, of sulphide ores is done in furnaces similar to those used for pyrites. Conveyors or telferspans charged in the silos carry the ore to the different apparatus, which makes it possible for the workmen to avoid all exposure to the action of dust, heat radiation and the gases given off by the roasting, and, especially, the sulphurous gases which are used to prepare sulphuric acid.

After roasting or calcining, ores containing zinc in the form of oxide or silicate are subjected to reduction with charcoal. This operation is carried out at about 1,100° C., that is to say nearly 170° C. above the boiling point of metallic zinc. The reduction of zinc oxide is not due to the charcoal, but to carbon monoxide, according to the following reaction: \( \text{ZnO} + \text{CO} = \text{CO}_2 + \text{Zn} \).

Reduction is always accompanied by distillation and to prevent the zinc fumes taking fire on contact with the air, or entering into reaction with the carbon dioxide from the combustion gases, closed retorts are used, in which is placed a mixture of ore with an excess of charcoal. The measures used to effect the reduction of zinc oxide and the distillation of metallic zinc vary in different countries.

According to the Belgian method (see fig. 205), the reduction is done in slightly conical retorts made of refractory fire-clay, 1 to 1½ metres in length, with a diameter of 15 to 20 cm. These retorts communicate at the front with a fire-clay condenser, so curved in shape that the lower portion forms a cup or basin into which the smelted zinc distils. The other end of the condenser terminates in a cylindrical sheet-iron cover or protection, which is constructed so as to favour the condensation, in the form of grey zinc dust, of fumes which escape from the curved condenser (see fig. 208). The retorts are placed in the furnaces in groups of eight to ten, superimposed pair by pair. Each furnace contains a number of retorts, which may vary from 150 in Belgian furnaces to 700 in American furnaces. The furnaces are heated by means of gas from gas generators; and combustion occurs in an atmosphere of hot air, which is introduced from heat recuperation chambers.

The distilled zinc is removed from the basin of the condenser every two or three hours by means of an iron spoon. When the distillation is finished, the residue from the retorts, which contains 3 to 5 per cent. of zinc and, very often, a much greater quantity of lead, is drawn out with iron rakes and used for the manufacture of lead. The grey zinc dust consists of finely divided zinc, the granules of which are covered with a thin coating of oxide; it is put back into the retorts to be re-distilled.

In the Silesian process (see fig. 207), which differs only slightly from the preceding, muffles made of refractory
fire-clay are used, which communicate with a condensing apparatus by a tube and are heated in a reverberatory furnace. The zinc condenses in the condenser in a liquid state, in which form it is run into moulds. Each muffle furnace has in front two openings, a lower one for extracting the residues of distillation, and an upper one for charging.

It is now some time since a successful endeavour was made to replace horizontal retorts, the action of which is intermittent, by vertical retorts with continuous charging according to the process of Roltzheim and Rémy; by these means the technical and hygienic disadvantages, associated with manual work at the intermittent furnaces, are done away with. The charge, after preliminary heating, is put into the upper part of the retorts, and the residue from the distillation, when cool, is removed mechanically at the lower part. The retorts, which are open at both ends, are closed, during charging, by the mixture which is introduced, and, also, at the opening for discharge by the residue. Each retort is connected with an elongated condenser which is bent perpendicularly on its axis.

In countries where electric power is cheap, such as Sweden and Norway, the reduction of oxide of zinc is done in a special furnace, the crucible of which is heated internally by an electric arc. This is the process of electro-thermic reduction and distillation.

The preparation of zinc electrolytically has been carried out according to two methods: (a) separation of zinc vapour in an atmosphere of carbon monoxide and condensation of this vapour in the form of liquid metal; and (b) condensation of zinc vapour in the form of dust and its fusion by electricity.

Complex sulphide ores may also be treated, after careful roasting, with sulphuric acid, which causes the precipitation of lead, silver, copper and most of the iron. The zinc which passes into solution, in the form of sulphate, is first purified by precipitation and filtration, and then subjected to electrolysis in a bath the tension of which is about 4 V. The residues are used for the preparation of lead.

With the exception of cases where ores poor in lead are used, ordinary metallurgical processes give a product
The present time alloys rich in zinc, up to 55 to 93 per cent., are used as metal coatings in plating (the metal "tenax" contains 92 per cent.; the Spandau alloy contains 89-93 per cent.); as a substitute for brass in the manufacture of armatures, cartridge cases, capsules, and in artistic foundry work. Lead is often added to brass and other alloys of zinc in the proportion of 1 per cent, or more to facilitate the working of turning and cutting.

In the manufacture of lithographic plates a thin layer of zinc amalgam is spread on the surface as a reducer, and the plate is then heated in suitable furnaces. In the textile industry large quantities of zinc powder are used for printing, and dyeing in hydro-sulphite vats.

### Compounds of Zinc

Oxide and sulphide of zinc are used as white pigments, but only the latter is used with sulphate of barium in the preparation of lithopone (see that article).

Oxide of zinc (ZnO; snow white, China white) was suggested as a substitute for white lead for the first time in 1780 by Courtois, of Dijon. Since 1786 it has been manufactured on a large scale as a pigment the use of which continues to increase.

The two processes for the manufacture of zinc oxide in actual use are the sublimation, or indirect process, and the direct process.

The first consists in combustion of the metal, which is put into retorts of refractory material arranged in a laboratory furnace, heated to 1,300 or 1,400° C.

The melted zinc, under the influence of heat, distils, giving off zinc fumes, which, in front of the partition where the retorts open out, meet a current of hot air, the oxygen of which combines with the zinc to form zinc-white or oxide of zinc. This is brought by a system of iron pipes into canvas chambers, the sides of which allow the gases to filter through, while they retain the oxide, which is collected in canvas sleeves fitted to the bottom of the chambers.

The finer and whiter oxide is collected at the far end of the chambers, whilst at the entrance the collected product is denser and not so white. The product naturally varies, as much from the point of view of colour as from the point of view of chemical composition, according to the metal used for charging, whether pure zinc, ordinary zinc, old or matte zinc.

### Compounds of Zinc

Oxide and sulphide of zinc are used as white pigments, but only the latter is used with sulphate of barium in the preparation of lithopone (see that article).

Oxide of zinc (ZnO; snow white, China white) was suggested as a substitute for white lead for the first time in 1780 by Courtois, of Dijon. Since 1786 it has been manufactured on a large scale as a pigment the use of which continues to increase.

The two processes for the manufacture of zinc oxide in actual use are the sublimation, or indirect process, and the direct process.

The first consists in combustion of the metal, which is put into retorts of refractory material arranged in a laboratory furnace, heated to 1,300 or 1,400° C.

The melted zinc, under the influence of heat, distils, giving off zinc fumes, which, in front of the partition where the retorts open out, meet a current of hot air, the oxygen of which combines with the zinc to form zinc-white or oxide of zinc. This is brought by a system of iron pipes into canvas chambers, the sides of which allow the gases to filter through, while they retain the oxide, which is collected in canvas sleeves fitted to the bottom of the chambers.

The finer and whiter oxide is collected at the far end of the chambers, whilst at the entrance the collected product is denser and not so white. The product naturally varies, as much from the point of view of colour as from the point of view of chemical composition, according to the metal used for charging, whether pure zinc, ordinary zinc, old or matte zinc.
By this process whites of great purity are obtained; a content in oxide of zinc which may reach 99.5 per cent. is easily obtained, even from relatively impure zincs; with zincs made electrolytically a percentage of 99.97 is reached.

The content of lead in zinc white obtained by sublimation is lower than 0.02 per cent. for the whites of high quality; it does not exceed 0.2 per cent. for those of ordinary quality.

In the direct process, zinc white is made by treating zinc ore or materials containing zinc direct, without first extracting the metal; the cost price is lower than that of white obtained by sublimation.

Furnaces are used, the vaulted masonry chamber of which is divided by a fixed grating formed either by a perforated plate, in the Wetherill type, or by ordinary gratings having between the bars a space of some millimetres.

A strong current of air sent below the grating, which surrounds the ash-hole, traverses the mixture of ore and fuel and makes it red hot. Reduction of the metal occurs in the interior of the mass, and the vapours given off become oxidised in the chamber (laboratory) on contact with carbon dioxide and oxygen in excess.

Often the gases coming off from the actual furnace are brought together in a collector made of refractory material set upon a block of masonry; by the help of the surrounding temperature and closer mixing of the gas, the vapours of zinc there become completely oxidised. The gases are cooled by passing through iron tubes, and the oxide of zinc reaches a system of canvas sleeves.

The raw materials should only contain a small quantity of such chromogenic metals as cadmium, antimony and tin. In the United States, Willemite and Franklinite are used with advantage.

The lead contained in the ore passes in large part into the white, and most of the ores give an oxide which exceeds in content of 2 per cent. of lead; while for some direct whites, it reaches even 10-15 per cent.

However, manufacturers of direct make use of different methods by which the lead of the ore may be removed before or after treatment of the finished product. A recent method (1931) for the production of zinc white, is that of the revolving furnace, "Wälzverfahren", in which residuary materials hitherto regarded as unusable are treated.

Calcination of the basic carbonate of zinc also gives a white powder which has been wrongly called "zinc white"; it is used in varnishes because it possesses a good covering power.

By calcining oxide of zinc (88 per cent.) and oxide of cobalt, zinc green, cobalt green or "Rimman green" is obtained.

Zinc white, which is not toxic, possesses good technical qualities as a pigment, including a covering power almost equal to that of white lead, and resistance to sulphuretted hydrogen and light. Its wearing capacity comes between lithopone and white lead (see article "Painting"). Zinc white is also used as a product for filling in and colouring products of rubber, linoleum, or imitation leather.

Zinc grey, which is a by-product of the manufacture of plumbozinc white, is used as well as zinc powder in anti-rust paints for metals.

Zinc yellow is a double chromate of zinc and potassium. Zinc sulphate (ZnSO₄·7H₂O; vitriol of zinc) is found in the native state as zincsite, white vitriol, Galician stone and goslarite; it may be obtained by dissolving zinc or zinc residue in dilute sulphuric acid, or heating zinc sulphide to red heat and then dissolving it in warm dilute sulphuric acid. The slime of zinc which forms in the manufacture of hydrazobenzene can also be changed into zinc sulphate (see article "Benzidine").

Zinc sulphate is used chiefly for the manufacture of lithopone (see that article) and some other mineral pigments, as a mordant for preserving skins and wood; for rendering textile fabrics non-inflammable; and as a disinfectant.

Zinc hydroxysulphite (Zn₃(NH₃)₂(SO₄)·2H₂O) is used as a reducing agent in dyeing with indigo.

Zinc chloride (ZnCl₂; butter of zinc) is a white, very hygroscopic, deliquescent powder, highly soluble in water; it extracts water from organic substances up to the point of carbonising them. Chloride of zinc is prepared by dissolving zinc residue, oxide of zinc, as well as calcined zinc ores, in dilute hydrochloric acid, and evaporating the solution, or by heating zinc in a current of chlorine. The concentrated solution forms, with zinc oxide, a mass which hardens rapidly as oxychloride of zinc.

It is used for the preparation of soldering salt, mixed with chloride of ammonium; in the carbonization and impregnation of wood; as a disinfectant, for preserving certain dead animals; for preparing parchment paper; and as a condensation agent in the chemical industry.
Under the name of "Cryptone CB 21" there has recently, since 1931, been put on the market a sulphide of zinc, which seems to be very useful for the preparation of opaque colours, with a very high covering power.

Zinc phosphide ($\text{Zn}_3\text{P}_2$) is obtained by heating zinc powder in the presence of phosphorus fumes or by heating a mixture of zinc powder and red phosphorus in a current of hydrogen and illuminating gas. This phosphide has a grey metallic appearance, with an odour of phosphorus in a current of hydrogen and heating zinc powder in the presence of covering power. It decomposition in the presence of acid, giving off phosphuretted hydrogen. A phosphide ($\text{ZnP}_2$) in the form of reddish-yellow crystals is also known, which, when heated, becomes red.

The first-mentioned phosphide is now much used in the country in the campaign against rats and rodents.

**Sources of Dangers**

During metallurgical operations, and during the preparation and use of compounds of zinc, the sources of dangers are represented chiefly by substances and impurities present in zinc ores with the metal or its compounds, rather than by zinc itself. High temperatures, such furnace gases as sulphur fumes and carbon monoxide, as well as dust, represent other sources of injury in the course of various industrial operations. However, occupational poisoning by zinc, beyond the special case of brassfounders' ague, is unknown; lead poisoning in the zinc industry is, on the contrary, common; but poisoning by arsenic is rare (Gibert).

Nowadays, thanks to the greatly extended use of muffle furnaces, sulphur fumes are recuperated and utilised. In addition, the work of smelters, especially at roasting furnaces of old type, calls for great expenditure of muscular force. Other very fatiguing processes which are also associated with exposure to heat, to gases rich in carbon monoxide, and to dust, are tending distillation furnaces, the management of the condensers, the emptying of the residue and cinders, and the melting of the crude zinc. Work at the furnaces exercises an unfavourable effect on the general health of the workers, and encourages the development of "a friare" diseases, e.g. rheumatism, respiratory diseases and symptoms of early wear-and-tear. Dermatitis of a pustular type has been noted quite often, especially in summer; it is due to blocking of the sebaceous glands with dust; it appears on the interior surface of the thighs and in the axillae. Similar skin affections have been also described in zinc oxide works by Turner in 1921.

Furnace workers also show affections of the conjunctiva, due to dust and radiant heat; and those who work at the distillation furnaces experience visual disturbances (hemeralopia) caused by the glare.

But the most serious danger which threatens the workers at zinc foundries, or spelter works, is that which arises from lead poisoning. This hazard is often of the same severity as in the metallurgy of lead, since almost all zinc ores have a high content of lead which, in some blends, amounts to 20 per cent, and sometimes is as high as the content of zinc. In mines, and during wet processes for preparing zinc ores, which contain lead in the form of sulphide, risk of lead poisoning is almost negligible. On the contrary, lead given off during roasting in the form of oxide, which readily becomes dusty, represents a serious hazard for men employed at the furnaces. It is usual, after cooling the products from roasting, to wet them thoroughly, by which the raising of lead dust is much reduced. Mixing the product from roasting with coke is only harmful when done by hand in a dry state. Risk of lead poisoning is much more important during work at the distillation furnaces when scouring the condensers, or drawing the residues in which the lead content may reach 10 per cent.; indeed, for this reason it sometimes happens that the residues are used in the metallurgy of lead. Some former investigations carried out where Silesian furnaces were used for distilling zinc in spelter works disclosed the presence of 6 per cent. of lead in the dust.

In the same way, the dust, which constitutes 5 to 10 per cent. of the total zinc collected, is rich in lead, 1.3 to 3.3 per cent. in Germany; 1.9 to 2.44 in Belgium; traces up to 5.2 per cent. in the United States. Considerable dust is sometimes given off when the condensers are tapped, and also during sieving and barrelling. R. P. Batchelor and his fellow workers in 1926 found, in an American smelting works, 108 mg. per cub. metre as a maximum amount; but in this case, the zinc dust was free from lead. The danger of lead poisoning is very great when the broken fragments of the muffles are utilised in the preparation of new furnaces, since scraping off slag rich in lead and crushing the fragments give rise to dust containing lead.
The lead risk is less serious during the refining of crude zinc and the use of zinc having a percentage of 1.2 in lead. If, however, the refining is done by the direct process with residues very rich in lead, then the risk of lead poisoning is very considerable (Lehmann, 1928).

The only trouble which can be attributed to zinc is founders’ ague (see below), which attacks almost exclusively brassfounders, generally during the preparation of varieties rich in zinc. More rarely, it attacks founders of “new silver” containing 16.24 per cent. of zinc, or of bronze. As indeed the first authors to describe founders’ fever (Blandet, Greenhow) remarked, this morbid condition depends on the fact that the melting point of the alloy with copper, 1,083° C., reaches, or indeed exceeds, the boiling point of zinc, 905° C.; in consequence, great quantities of zinc oxide fumes rapidly liberated as a result of volatilisation of zinc become oxidised on contact with air. This evolution of zinc fumes is particularly important, during brassfounding, when the alloy is prepared by first melting the copper and then adding the solid zinc to the product, melted at a temperature of about 1,150° C. In this case, the zinc, raised forthwith to a temperature higher than its boiling point, is subjected to combustion and rapid volatilisation. If, on the contrary, the alloy is first melted, or, if the two metals are mixed after being melted, the temperatures of melting and boiling are then found between those for the two separate metals; this condition is complied with when founding zinc or alloys very rich in zinc, such as metals for forming a subcoating in electroplating, and the metal “tenax” with more than 90 per cent. of zinc.

Founders’ ague is exceptional among men employed at distillation furnaces; it is commoner among those who work at electro-thermic distillation; and it may be observed quite often among those employed in soldering and cleaning with the oxyhydrogen or oxyacetylene flame sheets of galvanized iron, because, during these operations, the temperature exceeds 1,500° C. and causes volatilisation and combustion of the zinc (Engelsmann); and also among those who do zinc plating by means of the spray gun, and among those who empty and clean the piping. On the other hand, the disease is not seen during the melting of zinc or galvanising (Nuck, Rémy, Holtzmann).

The use of zinc in the form of residues or powder, as a reducing agent in the chemical industry, or in acid or alkaline solution in the coal-tar dye industry, exposes workers to risk of poisoning by arseniuretted hydrogen, in consequence of the presence of arsenic in the zinc and the mineral acids used. In the same way, the preparation of “cementation copper” with zinc waste and iron covered with granulated zinc, that of zinc sulphate from zinc residues or from roasted zinc ores and from products of roasting silicious ores containing zinc, may cause poisoning by arsenic hydrogen.

Practice and experiment have proved that this gas is given off when zinc utensils are used for cleaning iron receptacles for acids.

The general conditions of work in factories making zinc oxide by the direct method resemble those for the metallurgy of zinc.

**TOXIC EFFECT**

From the toxicological point of view, the analogy between zinc and copper is so marked that these two elements may be placed in a special pharmacological group, although they belong to groups of chemically different heavy metals. Soluble salts of zinc precipitate albumen and exercise in consequence, depending on their concentration, a local effect, caustic or astringent, and a general effect, due to absorption which is of quite secondary importance. In the same way there is a
ZINC... 1284...

possibility of these salts being resorbed by the digestive organs, for they have a marked emetic effect. Kobert systematically distinguishes such soluble salts of zinc as the sulphate and chloride, with a purely local caustic action, from the non-caustic salts which are capable of exercising a general effect by absorption, with paralysis of the central nervous system, and of the vascular system and the muscles.

It should be said, however, that this distinction has a theoretical importance rather than a practical one, for it is only under special experimental conditions of intra-venous or subcutaneous injections of complex zinc compounds which do not precipitate albumen, that symptoms of general acute poisoning may be provoked. Hofmeyer caused the rapid death of an animal by injecting into the circulation albuminate of zinc, which, according to Kunkel, is fatal in a dose of 28 mgr. per kilogram given by the alimentary canal.

Cases of poisoning, accidental or intentional, caused in man by the absorption of zinc chloride solution are always characterised by serious necrosis of the mucous membranes, vomiting, gastro-enteritis, and, sometimes, by fatal collapse. Digestive disturbances also predominate in cases due to insoluble compounds of zinc (oxide); but they have been observed more rarely in man. According to Spillmann (1883) and J. Macht (1931), the absorption of 10 grm. of zinc oxide causes vomiting and gastric pains; but when it was used therapeutically years ago, and doctors prescribed it in a dose of 25 cg. daily as a sedative and anti-epileptic, it found pallor, anaemia, paresis and muscular atrophy.

Schlokov in 1879 described a singular affection of the spinal cord among zinc smelters, characterised by disorders of sensation and paralysis; Murray in 1900 reported digestive disturbances and wasting among brass workers, and, similarly, McCord and Friedlaender in 1936 observed among zinc workers gastric and duodenal ulcerations which they attributed to the action of zinc. But all experts who of recent years have studied in a systematic way the health conditions of zinc workers, among others Tracinski, Lehmann, Wutzdorff, Sicard, Gilbert, Hayhurst and Ph. Drinker, are unanimously of the opinion, with regard to the isolated cases of poisoning ascribed to zinc in literature, in so far as their occupational origin can be proved, that they were due to the action of lead, arsenic and other substances which are found with zinc, its ores and its compounds, rather than to zinc itself.

Seifert in 1918 is the only one of the opinion that, in the clinical picture which he had described in 1897 under the name of "caehexia of zinc smelters", which showed itself by wasting, anaemia, digestive disorders, colics and chronic nephritis, these conditions are due not only to lead, but also to zinc.
He bases his opinion, as the other French authors who have been mentioned have done, chiefly on the presence of zinc, in addition to lead, in the urine of the patient.

But this finding is not sufficient proof, as the researches of Rost and Weitzel, Fairhall, Lutz, Ph. Drinker and their co-workers have shown. Zinc has been found regularly in the excretions and organs of man and animals, as well as in the urine of the patient. Some experiments carried out on pregnant or suckling white rats gave the same negative results and no injurious influence was noticed in their descendants.

_Generous ague_ must not be regarded as a special case of acute occupational poisoning by absorbed zinc, but as a consequence of a local caustic action of zinc oxide. Described for the first time by Thackrah in 1832 among brass-founders in Birmingham, under the name of "brassfounders' ague", it was studied from the clinical and etiological points of view by Blandet in 1845, and later by Greenhow in 1862, as a result of inhaling "fumes" of zinc oxide. This disease has since then been the object of numerous clinical researches, and later of experimental work.

While the application of zinc in various ways — by intratracheal instillation, subcutaneous injection of tartrate of zinc and soda, and the inhalation of fumes given off at the time of the combustion of chemically pure zinc — did not enable K. B. Lehmann to obtain in animals symptoms resembling founders' fever, this expert, however, caused typical attacks in persons who had voluntarily submitted to be experimented upon. Lehmann in this way proved for the first time that it is finely powdered zinc oxide, and not copper or unknown impurities in the brass, which cause founders' fever. In the same way as Lehmann, Rost also was able to cause in man, but not in animals, typical founders' fever, by using for inhalation the fumes given off in brass foundries. The inhalation of very concentrated fumes of zinc, 1.0 to 2.5 grm. per cm., causes in guinea-pigs a fall of temperature, followed by a rise reaching 3.3° C., with strong irritation of the respiratory organs and patches of broncho-pneumonia (Turner and Thompson, 1929).

The exclusive action exerted by zinc oxide on the respiratory passages is explained by Lehmann on the hypothesis that the immediate cause of the fever is not the absorption of the zinc oxide itself, but rather of albumen denatured or of a strange kind, arising either from destruction of the epithelium or from the destruction of micro-organisms in the respiratory passages. Schmidt Kehl in 1926, in
trying to confirm this generally accepted hypothesis by experimentation, was able to cause marked rises of temperature (0.5 to 1.6° C.) in guinea-pigs by injecting them, either subcutaneously or intravenously, with serum from their own species, which had been brought into contact by spraying into a chamber, with finely distributed fumes of zinc oxide.

In opposition to Lehmann and Rost, Kisskalt in 1912 and more recently Burstein in 1925 have been able to obtain rises of temperature in experimental animals by subcutaneous or intravenous injection of salts of zinc. Burstein, as a result of these experiments, maintains that zinc exerts an action on thermo-regulating centres by means of absorption; and Kisskalt, who has caused rises of temperature and conditions of irritation in the respiratory passages by causing mercury fumes to be inhaled, considers, on referring to symptoms of poisoning of a similar kind observed in cases of poisoning by the carbonyls of nickel and iron, that founders' ague is a phenomenon characteristic of the absorption of all heavy metals, and that the specific action of zinc is only due to the fact that it has a melting point which is very close to that of boiling. Symptoms similar to those of founders' ague were, as a matter of fact, observed by Hansen in 1911 and Koelsch in 1923, following the inhalation of copper fumes; by K. and Ph. Drinker in 1927-1928 who caused slight symptoms in man of founders' ague with a rise of temperature, and, experimentally, in animals, falls of temperature with fumes of magnesium, a light metal, chemically very akin to zinc. Hence the hypothesis of Kisskalt, speak of "metal fume fever".

It must be acknowledged that the possibility of founders' ague, caused by the vapoours and fumes of oxides of other metals, has only a theoretical importance for the expert in industrial hygiene. The question: "why typical founders' ague occurs only on the inhalation of zinc fumes in the nascent state and not after inhaling dust of zinc oxide, which is chemically identical," was taken up by Ph. Drinker in 1922; he emphasises the pathogenic importance of the degree of dispersion and the size of the particles of zinc oxide. Zinc fumes produced by the combustion of zinc are constituted by aerosols in a very fine state of dispersion. The effect of cooling and humidity on oxide of zinc is to separate it by flocculation in the form of a powder with coarse particles, which, even when inhaled, does not cause founders' ague. In support of this view, sometimes cases of ague are observed in zinc oxide works among men cleaning pipes not sufficiently cooled. But these attacks have never been observed in persons employed in filter chambers and in places where the product is barrelled, in spite of considerable liberation of dust. Ph. Drinker in 1927 reproduced in men the symptoms of founders' ague by making them inhale very fine zinc oxide powder (kadox) with particles 0.40 in diameter, dried for some time and pulverised at 110° C.

Burstein in 1925 also caused in three persons founders' ague by the inhalation of finely pulverised zinc oxide.

Mazzi in 1930 undertook an investigation into founders' ague; and has come to the conclusions: that the febrile attack must be assigned without any doubt to the inhalation of fumes of zinc oxide, suspended in the air of the foundries; that it cannot be interpreted as a manifestation of acute poisoning by zinc; that the pathogenic mechanism cannot be explained in a satisfactory way by the hypothesis of anaphylaxis, nor by that of disturbance of the basic acid equilibrium; and that, in the present state of knowledge, the febrile attack must probably be ascribed to the pathogenic action of zinc oxide on the extremely delicate epithelium lining the final ramifications of the air passages. The proteins, the entrance of which into the plasma, under this astringent and caustic action, appear to give rise to the formation of hetero- and meta-proteins, the entrance of which into the circulation seems to be capable, when in contact with the heat-regulating centres, of disturbing the equilibrium of these centres; in this way it is explained the heat-production reaction.

Mazzi, approaching the subject from the medico-legal point of view, does not consider founders' ague to be an accident, but as "an acute occupational disease", to be classified in what may be called a neutral zone, standing between an accident and an occupational disease properly so called. For this reason, he considers that it cannot be compensated either as an occupational disease or as an accident, but it falls within the list of ordinary health insurance diseases.

Data obtained from foundries provide information concerning the quantities of zinc oxide necessary for causing founders' ague. The ague has made its appearance when the content of zinc oxide in the air was 230 mg. per cm. according to Arnstein, and 124 to 420 mg. according to Lehmann. According to Arnstein, the amount of zinc oxide effectively inhaled could be
estimated, depending on the duration of work, at 6 to 790 mg.; according to Lehmann at 30 to 150; and, according to Burstein, at 1 mg. per kilogram of body weight. Ph. Drinker, Thompson and Finn established, by a series of experiments, a "threshold", for man of 15 mg. of zinc oxide, as fumes, per cm. of air, acting over several hours. They consider this limit as the maximum admissible from the hygienic point of view for a spell of work of eight hours. These experts, by taking into account their special investigations made in 1928, on the atomic volume and the quotient of absorption in the respiratory passages, which they found to be from 40 to 70 per cent, for zinc fumes and very fine zinc (kadox), estimate the quantity of zinc in the lungs at the time of the production of founders' ague to be 24-37 mg. In further researches in 1928 they found, in addition, that the quantity of zinc detected by analysis in the lungs only increased during the first forty-five minutes of inhalation, and that the strength of zinc in the lungs rapidly diminishes after inhalation, whilst that found in the liver and pancreas increases.

In practice, it was found that under some conditions a short inhalation of fumes during the melting of zinc, lasting only five minutes, but during which about 7 mg. of zinc oxide might be inhaled, was sufficient to cause a typical attack of founders' ague (Arnstein, Lehmann).

**STATISTICS**

Detailed statistics on the health conditions of zinc smelters at spelter works, especially taking into account the risk of lead poisoning, were drawn up in 1912 by the Prussian factory inspectors for twenty-three Silesian firms in the Oppeln district for the period 1902 to 1911. The enquiry deals on an average with 4,794 furnace workers, among whom are included men removing ashes and raking out broken fragments from muffles, while men who were employed in the manufacture of muffles and condensers, and in the transport of charcoal and ores are excluded, a total of 52,736 persons came under observation. According to this enquiry the following disease rates were observed:

<table>

</table>

The statistics for 1911 are more complete and more detailed: they deal with 4,894 workmen at spelter furnaces, and 1,466 at roasting or calcining furnaces. Among this personnel there were per 1,000 workmen:

A thorough medical examination of the furnace workers of the same firms, including those employed in the removal of ashes and the making of muffles, was ordered by the Prussian Minister of Commerce and Industry and carried out from 1909 to 1914 by Schweitzer, Wrobel and Halbey; and the results were published by the last named. Out of 6,150 workers in zinc foundries or spelter works in the Katowitz district, 2,155 persons, 156 of whom were women, were examined because they showed symptoms, or disturbed health, attributable to lead. Of this total, 1,888 were employed at spelter furnaces, and 297 at roasting and calcining.
Among the spelter furnace workers, a lead line and other signs of lead absorption were observed in the proportion of 14 to 66 per cent. of the total strength, and in the total of those examined at arsenic and lead smelting, the proportion was from 11 to 27 per cent., with an average of 24; among the workers employed on the calcining of foundries at about 15 per cent., with signs of lead poisoning in as many as 25 to 33 per cent. of all examined, which represents a surprising finding. One of the examiners found that red blood corpuscles with basophilic granulation were present, sometimes in as many as 91 per cent. of those examined at certain foundries; another found among many as 91 per cent. of those examined at certain foundries; another found among 512 smelters a blood pressure of more than 150 mm. of mercury in 28 per cent., which was not attributed to lead poisoning, but rather to such other causes as abuse of tobacco; typical chronic nephritis, with neuro-retinitis and albuminuria, was found in one case and lead paralysis in two cases. One of the examiners also found signs of mild anaemia, with diminution of haemoglobin, in 28.9 per cent., of those examined at about 26 per cent.; among the blende calciners the proportion was from 11 to 27 per cent., with an average of 24; among the workers employed on the calcining of foundries at about 15 per cent., with signs of lead poisoning in as many as 25 to 33 per cent. of all examined, which represents a surprising finding. One of the examiners found that red blood corpuscles with basophilic granulation were present, sometimes in as many as 91 per cent. of those examined at certain foundries; another found among many as 91 per cent. of those examined at certain foundries; another found among 512 smelters a blood pressure of more than 150 mm. of mercury in 28 per cent., which was not attributed to lead poisoning, but rather to such other causes as abuse of tobacco; typical chronic nephritis, with neuro-retinitis and albuminuria, was found in one case and lead paralysis in two cases. One of the examiners also found signs of mild anaemia, with diminution of haemoglobin, in 28.9 per cent. of the workers examined.

It is interesting to note that the investigation made by Batchelor and his colleagues in 1929, which was carried out at a spelter works in North America, where Franklinite, an ore free from lead, was used for the preparation of metallic zinc, and, especially, of zinc oxide, lithopone and zinc dust, did not reveal any pathological condition among the workmen, beyond slight changes in the lungs due to dust, revealed by X-rays; two cases of arterial hypertension in older individuals, and some isolated cases of slight leucocytosis. Analysis of urine and faeces of the workmen examined, disclosed the presence of quantities of zinc greatly exceeding the normal. The workmen in question were employed chiefly at the preparation and barrelling of zinc oxide.

The investigation of Lehmann in 1927 to 1928 on the state of health of German workmen who prepare zinc oxide by the direct process showed clearly that, out of 177 workmen belonging to various firms, 6 cases (3.4 per cent.) were affected with slight lead poisoning and 19 (11.3 per cent.), were regarded as "lead-poisoning suspects".

According to an investigation made by the Factory Inspection Department of Württemberg, the height of the workplaces plays an important part in the incidence of founders'ague. In works where the workplaces are from 8 to 12 m. high, some of which have artificial ventilation, there were only isolated cases of sickness; this sickness was more common in medium sized foundries with workplaces from 4 to 5 metres high, and occurred after almost every operation in works having only 2 to 4 metres of height.

An English investigation into founders'ague carried on from 1902 to 1909, dealt with twenty-one brass foundries in Birmingham employing 500 workmen, 233 of whom were founders, and with the Royal Arsenal with 58 founders; it disclosed that, out of 216 founders examined, 23 per cent. had definite indications of disorders due to foundry work. But more exact analyses showed that of 135 founders, 123 (86.6 per cent.) were affected with typical founders'ague, whilst among 58 workmen at the Arsenal employed in bronze foundry there were only 6 (about 10 per cent.) that were affected with the fever.

A further enquiry, made by Collis, for the English Factory Department, was published in 1910; it dealt with the smelting of materials containing lead and included the processes of zinc smelting. The chief cause of ill-health discussed is lead poisoning; out of 160 cases which occurred during five years, 1905 to 1909, in all lead smelting processes discussed, 73 occurred among spelter workers who were found to experience an undue amount of lost time for sickness and to remain an unusually short time in the industry.

In Belgium, during an enquiry in 1925 dealing with 325 workmen at zinc works, Gilbert found that 94.46 per cent. were in a good state of health; but 97 (29.84 per cent.) showed a lead line; 170 (53.31 per cent.) had red blood cells with basophilic granulations; and also the haemoglobin content was reduced, below 75 per cent. on the Tallquist scale, in 30 per cent. of all the workmen examined.

**SYMPTOMS**

Skin affections due to zinc and its compounds are not common. Oliver has observed ulcerations and pustules in men employed in handling non-calcined calamine; John A. Turner in 1921 described under the name of "oxide pox" a dermatitis among the workmen of a zinc oxide factory which he attributed to the ducts of the sebaceous glands becoming blocked by the dust of zinc oxide. Sweating, dirtiness and scratching, especially during the hot season, favoured the development of a papulo-pustulous exanthema (32 cases) in men in places where oxide was packed into barrels. The presence of arsenic even in traces, such as 50 mg. per 1,000, in zinc may explain the irritating effect on the skin. But other authorities (Lehmann) do not agree with this hypothesis.

The handling, in particular, of the chloride and other salts of zinc has a caustic effect on the skin, which is sometimes very serious. The use of chloride solution for soldering, as a mordant, as an application in the preliminary preparation of cloth and silk, and for dyeing, causes typical ulcerations, which were situated on the fingers, sometimes on the hands and forearms, and, more rarely, on other parts of the body. In 1921, Carey, McCord and Kikker described 17 cases of ulcers and acne situated on the fing-
ners, and less commonly on the forearms, the groins, the scrotum and the thighs, among men employed on impregnating wood, previously treated with tar and creosote, with a solution of zinc chloride. Nurnberg in 1922 reported violent inflammation of the throat accompanied by oedema in a carpenter who had worked on a copper galvanized iron treated with zinc chloride.

In Great Britain the Medical Inspector of Factories in 1925 recorded a form of dermatitis due to the action of the solution used for soldering; the eruptions only occurred in women who had burns or other eruptions on their arms and hands. The patients had tried to reduce the acidity of the solution, so as to render it less caustic; but the result was an increase in its irritating properties. Probably the irritation produced by a splash of the solution on a definite spot necessitated immediate washing of the part affected, whilst diminution in the acidity allowed more prolonged exposure leading to a more serious vesicant effect.

Orator in 1929 reported cases of corrosion of the mucous membrane of the stomach, following upon inhalation of the copper fumes and lesions to be due to zinc which had been swallowed and dissolved in the hydrochloric acid of the stomach; the resulting chloride of zinc would have a corrosive effect.

Except for founders' ague, occupational poisoning by zinc cannot be claimed to exist to-day. Zinc smelters' cachexia (Zinkhüttenstéchtum) so named by some German authors is, in its essential manifestations, only more or less typical chronic lead poisoning; for there is found the lead line, anaemia with red blood cells containing basophilic granulations, wasting, profuse sweating and marked pruritus; some hours later, arid, congestion of the face and injection of the conjunctivae; some hours later, and, in severe cases, only on the next day, the temperature falls by crisis, with profuse sweating and marked prostration. As a rule the patients are fit for work the following day. Recurrence of the disease on the following day is unusual.

Pulmonary and bronchitis symptoms may be very marked. Respiration is sometimes superficial and laboured. Associated, according to Ph. Drinker, with diminution in the vital capacity to as low as one-half; there is also a strong tendency to cough. The urine, during and after the attack, is diminished in quantity and is dense, but it rarely contains albumen (Sigel, K. C. Lehmann, Zadek). Guellmann in 1925 described some cases with glycosuria and intense hyperglycaemia (up to 0.199

Gilibert states: "Most workmen at zinc foundries or spelter works exhibit obvious signs of impregnation by lead; but it seems that the effect of this poison on their health is not generally so definite as to cause in many the classical manifestations of lead poisoning. Measures for health preservation are, however, necessary, and to regard for there is no doubt that the impregnation of lead which these men receive must have a bad effect on any tendency to sickness and on intercurrent diseases. As regards carbon monoxide, its effect seems clear; but it does not seem to exert a powerful effect on the health of the body."

The only ill-effects which can be attributed to zinc, viz, those due to founders' ague, show an extraordinarily typical clinical picture, which was well described by early observers, and completed recently by knowledge acquired regard the changes in the blood formula.

Some time after a somewhat prolonged stay in a brass foundry, possibly as long as eight hours, the workman is affected with a general malaise, which may supervene towards the end of the day's work, or, more often, during the following night. It is characterised by fatigue, extending to a feeling of prostration, yawning, pains in the limbs, cephalgia, shivering, sensation of dryness and tickling in the throat and trachea, and cough. In serious cases, there is next experienced violent shivering and a quick rise of temperature (up to 39-40° C.) with all the subjective symptoms of fever: pains in the limbs, headache, buzzing in the ears, nausea, vomiting and sometimes mental confusion, hallucinations and convulsions (Wilke, Guellmann). During the attack is congestion of the face and injection of the conjunctivae; some hours later, and, in severe cases, only on the next day, the temperature falls by crisis, with profuse sweating and marked prostration. As a rule the patients are fit for work the following day. Recurrence of the disease on the following day is unusual.
per cent.) which he interpreted as signs of disordered hepatic action. The same authority reported acute congestion of the liver, which is intense during an attack of fever, as well as chronic hypertrophy of the liver, in 3 brass founders who had had repeated attacks; and in the urine of some workmen, urobilin, haematorphyrin, and sometimes also even of indican. Lehmann has produced experimentally, in the urine, albumen, indican and hyaline casts.

With regard to the heart and blood vessels, in addition to acceleration of the pulse, a slight increase in the systolic and diastolic pressure is observed during the attack, whether febrile or not (Guelmann).

The blood formula shows a leucocytosis, especially of the neutrophiles with a polymorphic nucleus, amounting to 16,000 or 17,000 (Arnstein, Ph. Drinker and his colleagues); or a relative lymphocytosis up to 50 per cent., as well as a slight eosinophilia (disagreement with Arnstein!), and, in the brass workers examined, who had had several attacks of founders' ague, anaemia with marked oligochromaemia, accompanied in some cases by anisocytosis and poikilocytosis (Guelmann).

Although a cumulative effect of zinc cannot be demonstrated, attacks of founders' ague, often repeated, seem able to originate a general debility with anaemia and respiratory affections (Sigel), especially in the case of persons in whom there is disease of the circulatory system.

Whilst a single attack of fever is generally quite harmless and terminates with complete recovery, Graeve in 1907 described a case in which he was able to establish the relation of cause and effect between the onset of the fever and death which occurred later. It was the case of a workman who had a febrile attack during melting of zinc residue; he died a week later from acute oedema of the brain. Graeve has also described a swelling of the spleen and a certain swelling of the intestinal haemorrhage following a severe attack of founders' ague.

Some authors (Rost) regard an attack of founders' ague as typical only if it is accompanied by a rise of temperature. However, it is certain that slight, afebrile attacks, with marked subjective disorders, occur even more often than typical serious attacks. In these cases the symptoms resemble a commencing chill and are so characteristic that a diagnosis of founders' ague can be made with certainty; moreover, leucocytosis is present.

The liability to contract the fever certainly varies a good deal in different workmen.

Persons who have recently commenced work, or whose work in foundries has been interrupted for some time are more often affected than others; this points to the establishment of an immunity. It is not certain whether this can result in complete immunity or only cause a reduction in the severity of the attack, which is accepted by many workmen as something inevitable. However that may be, a serious attack is followed by increased resistance for some days, which may also be demonstrated by experimental methods (Ph. Drinker). On the other hand, it is proved that even elderly workmen may have attacks at close intervals. Thus, Sigel mentions the case of a founder, aged fifty-eight years, in whom he observed a whole series of sharp attacks with all the characteristic symptoms, occurring with intervals of two to three days. Several authors (Lewin, Roth, Arnstein), consider that only a minority of founders exhibit a natural immunity. But there is no definite proof to support this view.

In Great Britain, the Medical Inspector of Factories reported in 1927 three cases of toxic jaundice which occurred in making zinc salts, and were due to the inhalation of sulphuretted hydrogen. The affected workmen were employed in guiding loads of zinc into chutes leading to dissolving tanks.

**DETECTION**

Compounds of zinc moistened with a solution of cobalt salts give, when melted on charcoal with the blowpipe, a beautiful green head ("green cinnabar").

Zinc sulphide, or zinc white, is insoluble in acetic acid and soluble in mineral acids; it is precipitated by ammonium sulphone.

In order to detect metallic zinc powder in zinc oxide, Lehmann recommends treatment with mineral acids, in the presence of a little platinum chloride, when the evolution of hydrogen indicates the presence of metallic zinc.

Qualitative and quantitative estimation in such organic secretions and excretions as urine and faeces, etc. Inocerate the organic material by either a dry or moist method; take up the residue with 250 cub. cm. of dilute hydrochloric acid and saturate the filtered hydrochloric solution with sulphuretted hydrogen in order to eliminate copper, etc.; filter the solution and wash with water containing sulphuretted hydrogen. Remove the sulphuretted hydrogen from the filtrate and the washing water, by boiling and heating with hydro-
chloric acid; after cooling, render alkaline with hydrate of soda of a strength of 30 per cent., then render slightly acid with acetic acid and filter, after the precipitate has deposited. Take the residue from filtering again with dilute hydrochloric acid and treat the hydrochloric solution with hydrate of soda and acetic acid. Collect the filtrates, acidulate with acetic acid, and saturate with for three hours with sulphuretted hydrogen. Incinerate and calcine, with the filter paper, the zinc sulphide which has been precipitated and filtered, after washing with water containing sulphuretted hydrogen. Remove all trace of iron by dissolving repeatedly in 2 per cent. acetic acid; filter and precipitate with sulphuretted hydrogen. Separate the precipitated zinc sulphide, calcine it in a quartz crucible, and weigh it as zinc oxide.

For the detection of very small quantities of zinc, dissolve the precipitate of zinc sulphide in dilute boiling hydrochloric acid; neutralise with ammonia so that the reaction is very feebly acid; titrate by the volumetric method, using a solution of potassium ferrocyanide of a special strength (according to Fahlberg), and using uranium acetate as an indicator.

For the estimation of very small quantities (0.01 to 0.5 mg.) in organic products, R. E. Lutz in 1925 published a very sensitive colorimetric method, based on the fluorescence of zinc salts with urobinil. It requires very exact and delicate precautions during the incineration and analytical isolation of the zinc, for it only gives sufficiently accurate results with very pure solutions of zinc salt.

**HYGIENE**

In spelter works or zinc-smelting factories, hygiene demands the application of preventive measures for reducing or eliminating the effect of radiant heat and high temperatures of the air, in order to suppress, as far as possible, dust and gases arising from the roasting furnaces and from the retorts for distillation, and to reduce the physical effort required of the workers. Measures for removing dust must be adopted particularly in workplaces during operations in which dust containing lead may be given off. Spacious buildings of high construction must be provided for the roasting or calcining furnaces, and the retort house for distillation. Natural ventilation should be ensured by constructing numerous windows in the walls and ventilating shafts in the roof; in this way the hot air can be removed without having recourse to artificial ventilation. On the other hand, care must be taken to avoid any risk of chilling the workers by exaggerated ventilation, by using windows supplied as far as possible with louvres, and by regulating the closing of the opposite rows of openings. In order to reduce the trouble caused by radiant heat, free space is needed before and below the openings for tending the furnaces. A distance of at least 6 metres should be arranged between the wall of the retort house and the furnace, or about 12 metres, if the faces of the furnaces are opposite one another. The furnaces must be arranged in a single row when the buildings are comparatively narrow; in this way normally adequate ventilation can be assured. In large buildings with several rows of furnaces, natural ventilation is insufficient; it must be improved by blowing in fresh air, as in glass works, on to the working places in front of the furnaces.

The walls must be smooth; and the floor must have an even surface, so as to avoid any deposit of dust and facilitate cleaning.

The escape of such gases as sulphur dioxide from the roasting furnaces must be prevented by arranging efficient exhaust ventilation above the openings for charging and tending the furnaces.

The introduction of labour-saving devices, which were introduced originally for purely economic and technical considerations, has led to notable hygienic improvement. By this means, at the outset, hand shovelling was abolished; this required of the men employed on roasting very great physical exertion and exposed them to the ill-effects of heat, dust and gases from the furnaces. Further progress has been made by replacing the old furnaces by muffie furnaces of various types with continuous charging and mechanical transport for calcined ores. At the present time, complete desulphuration of the ore can be easily attained, whilst the gases are used to make sulphuric acid or liquid sulphurous acid. By these means a satisfactory solution has been arrived at, equally from the technical and economical point of view as from that of health, of a problem which up till recently offered difficulty with the old furnaces, viz. that of removing the sulphur fumes and avoiding sources of trouble for the workers and for the neighbourhood. The gases are conducted by a powerful exhaust directly towards a sulphuric acid plant. The roasting or calcining furnaces are in this way kept continually under negative pressure, so that the gases given off are entirely prevented from escaping and polluting the vicinity.

In smelting works where furnaces of the old type are still used, the sulphur
gas is not used, but is eliminated by milk of lime in special towers. However, the high temperature of the gases from roasting does not make it possible to obtain a complete reaction, Hence, the absorption method is replaced by diluting the gases and using a forced draft, which carries them into the air as high as possible. But this procedure is not efficient either, for the gases and the fumes have a tendency to flocculate and precipitate on the ground in the vicinity of the procedure placed by diluting the gases and using sensible be drawn towards intake ducts situated above the condensers from which an air current can be arranged over the openings of the con-

Lead, beginning of carbon and which are liberated during distillation type of furnace it should be said that the use of this which use large Silesian muffles. This to be neglected in smelting works.

The ashes rich in lead which, when the muffles are drawn, are still hot and giving off gases and dust, should never be drawn on to the floor of the foundry, but collected into special shoots, from which they pass directly after complete cooling into small trucks. Quenching or moistening of ashes which are not cooled must be avoided, for there may be danger from the evolution of explosive or toxic gases such as arseniuretted hydrogen.

The collection and further handling of dust calls for the adoption of special measures, particularly on account of the risk of lead poisoning. Sifting and packing into barrels must be done in special places and in closed apparatus, in order to avoid raising dust.

When the plant handles ores containing lead, in addition to the above-mentioned technical measures, all those relating to personal hygiene laid down for works where there is a risk of lead poisoning must be applied, e.g. the use of working clothes, and the provision of lavatories and haths, cloakrooms and canteens. Where in certain workshops there may exist an increased risk of lead poisoning, a medical examination of the personnel on entering the factory and periodically thereafter, must be arranged. Youths and women must not be employed at the roasting furnaces, the distillation retorts, or at the removal of dross.

In brassfoundries good general ventilation of workplaces is needed, with exhaust hoods above the working posts, to remove the zinc fumes given off at the time of pouring. This local exhaust may have to be arranged under difficulties, especially if pouring into mobile moulds is being carried on in several places; but, recourse can then be had to movable exhaust hoods. Lehmann has described an arrangement adopted in a German foundry which has ceased using mobile crucibles, and prefers to move the moulds one after the other towards the crucibles placed under a strong exhaust ventilation. As the technical equipment in older works does not always give a guarantee for efficiency, recourse must be had to the wearing of respirators during pouring. However, the models with a simple cotton filter or a damp sponge are ineffective.
and it is necessary to use masks with a colloidal filter which completely absorbs metallic fumes.

**LEGISLATION**

Boys under sixteen years are excluded from the work of cleaning zinc with acids in Canada (Quebec); in zinc oxide works women are excluded in Argentina and the Netherlands; young persons under sixteen years, in Belgium; under eighteen years, in France from workshops for combustion and condensation; under seventeen years, in Belgium, under eighteen years, in Argentina, from factories for the manufacturing of zinc oxide as well as its manipulation with the object of preparing it for sale, in the Netherlands. Boys under fifteen years and women under twenty-one are excluded from zinc oxide works; etc.

In Norway pregnant women and young persons under eighteen years are excluded from works where toxic materials are used, and works where the hydrated carbonate of zinc is made; young persons under sixteen years are excluded from sulphate of zinc works, in Belgium.

Special legislation exists in Germany where a Federal Ordinance of 6 February 1900 deals with the erection and running of zinc melts. It prescribes: minimal conditions from the point of view of construction; the installation and supply of drinking water; the separation of roasting and calcining sections from those for distillation; the use of closed apparatus for the crushing of ores; the provision of exhaust ventilation at the furnaces for roasting, calcining and distillation; it also recommends that the raising of dust during the loading of the furnaces should be prevented by humidification applied to the reducing mixture, as well as during drawing and the removal of dress; the use of closed separators for sifting and packing powdered zinc into barrels; limitation of the employment of women and young persons; the provision for the workers of lavatories, baths, cloak-rooms and canteens; medical supervision of workers by periodical medical examination where cases of lead poisoning occur.

Special permission is required for the erection of new distillation furnaces both as regards construction and arrangement.

In Austria, the Ordinance of 22 July 1908, issued by the Ministers of Public Works and of the Interior, regulates the erection and running of lead and zinc-smelting works established in conformity with the general law on mines. A circular dated 10 August 1910 on lead poisoning among workmen at zinc and lead smelting works contains the text of "warning notices" to be distributed to workers.

More recently, 8 March 1924, four Ordinances of the Federal Ministry of Social Administration issued in agreement with the Ministries of Commerce, Industry and Public Works, lay down regulations for the protection of the lives and health of persons employed in lead and zinc smelting works and in zinc white works, under the regulations of the Industrial Code.

In Belgium, the Royal Order of 12 March and 8 July 1925 regulating zinc works, lays down the measures imposed on employers and workmen regarding health supervision and medical service; in Great Britain, hygienic provisions relating to brassfoundries are contained in the regulations of 30 June 1908; the Regulations governing the smoking of materials containing lead include the smoking of zinc ores, and are dated 12 August 1911; and for Norway, the industry is controlled by the Ordinance of 30 October 1919.

Notification of cases of poisoning by zinc and its compounds is provided for in Poland (Ministerial Order of 30 October 1920); and in the Netherlands, of cases occurring in "yellow copper" foundries and soldering workshops (zinc oxide).

Compensation is granted in Belgium, Bulgaria, Cuba, Hungary, Ireland, Latvia, Luxemburg, Netherlands and Portugal, by national laws ratifying the Convention of 1925 relating to lead poisoning due to use of lead, its alloys and compounds; handling of ore containing lead fine shot in zinc factories; in Italy, and in the United States (Illinois and New York) during use of zinc, its alloys and compounds; in Missouri, Ohio and Porto Rico, for disease due to refining and melting of zinc; in Queensland and Chile, in Switzerland, for effects due to zinc chloride; in U.S.S.R. for lead poisoning. Dermatitis from chloride of zinc is compensated in Bulgaria and in the U.S.S.R.

**BIBLIOGRAPHY**

- An Investigation on the Effect upon Rats of Long Continued Ingestion of Zinc Compounds, with Special Reference to the Relation of Zinc Excretion to Zinc Intake." Ibid., 1927, No. 81, pp. 924.

ZINC

Dr. H. Engel
(Berlin).

"No man's work should be a danger to his health or a menace to his life."

(From the Prince of Wales's speech to the annual meeting of the Industrial Health Education Society, London, April 1931.)

ERRATA AND ADDENDA

Volume I

List of Articles in Volume II, p. xxvi: Between "Shoddy" and "Silk" read "Silicon"; between "Talc" and "Taxidermists" read "Tantalum".

List of Collaborators, p. xxi: Between "MYERS" and "OBLATH" read "NAESLUND, Dr. C., Assistant Professor at the Faculty of Medicine, University of Upsala, Sweden."

Opposite "SCHMIDT": "Medical Clinic" should read "Hygiene Institute".

ANTHRAX, p. 145, col. 2, sub-title (Spanish): "Pustala" should read "Pustula".

ARTIFICIAL SILK, p. 184, col. 1, par. 3: Delete this paragraph and insert the following text:

"In the rubber industry cases of chronic poisoning have been met with, but the symptoms were not serious.

"Amongst the most recent cases may be mentioned one by Boveri in 1929 affecting a worker in the artificial silk industry who suffered from serious glomerulo-nephritis; 2 cases reported in 1930 by Mauro amongst workers engaged in the preparation of an insecticide powder with a basis of potash soap, phenol and carbon tetrachloride; and 8 cases, one of which was fatal, studied in 1931 by Tovo and due to the breakage of a receptacle containing carbon tetrachloride."

p. 372, col. 1, "Symptoms": Add the two following paragraphs to the text:

"MacCord classified injuries produced as local injuries (dermatitis), acute poisoning (inflammation of the eyes and the respiratory passages), chronic poisoning, characterised especially by degeneration of liver and kidneys.

"In recent years Boveri (1929), Mauro (1930), Tovo, Nebuloni (1931) have drawn attention to kidney troubles said to be more frequent than had been imagined (7 of the 8 cases mentioned by Tovo and the fatal case which was due to an attack of uraemia) and which are characterised chiefly by oliguria, anuria, albuminuria, and granular and hyalin casts in the sediments. Mauro has likewise noted cutaneous irritation of the hands amongst workers coming into contact with tetrachloride."

COAL TAR, p. 470, col. 2, line 6: After "distilleries" add: "and from manufacturing tar oils in general".

DIVERS, p. 586, col. 1, par. 4: "Zenos" should read "Zervos", "1904", "1903".

ETHYLENE, p. 696, col. 1, par. 1: Figures in table should read as follows:

<table>
<thead>
<tr>
<th>Value</th>
</tr>
</thead>
<tbody>
<tr>
<td>1.0</td>
</tr>
<tr>
<td>1.6</td>
</tr>
<tr>
<td>1.7</td>
</tr>
</tbody>
</table>

FOOD OF THE INDUSTRIAL WORKER, p. 796, col. 2, last par., line 5: Add "per person per diem".
Food of the Industrial Worker, p. 797, col. 1, first table: Last figure under "Calories" should read "2,764.3".

—— p. 797, col. 1, par. 1, line 3: Add "and per 100 calories".

Gold Mines, p. 914: Insert before last paragraph:
"Compensation for miners' phthisis in South Africa was extended in 1926 to cover bricklayers and stonemasons who generally work at the surface of the mine, but whose duties take them underground periodically."

Hemp Manufacture, p. 940, col. 1, par. 1, line 6: Put full stop after "family", delete rest of paragraph and replace by:
"The principal commercial substitutes for real hemp (Cannabis sativa) are: Manila from Musa textilis, Henequen or Yucatan Sisal, from American Agaves, Sisal from Agave sisalana, Sunn hemp from Crotalaria juncea, New Zealand hemp from Phormium tenax. Aquatic hemp, Japanese hemp, African hemp and Indian ("Aloes") are of much less importance."

Volume II

Laundries, p. 98, Bibliography, line 6: "OLIVIER" should read "OLIVER".

Methyl Bromide, p. 238, col. 1, sub-title: "Monobromo Methane" should read "Monobromomethane".

Social Welfare, p. 906, col. 2, Bibliography: Add:
