**Ice-Cream Makers**

The making of ices is now effected by machinery, which is increasingly replacing the former manual work. In certain countries, however, connoisseurs are of opinion that really good ice-cream can only be produced when made by hand. This explains why ices made by hand in certain districts, such as Naples and the surrounding country and Sicily, are famous for their good quality.

The occupation of ice-cream maker, by reason of the limited number of operations which it involves, causes certain modifications which may be considered as occupational stigmata. Ferrannini, as the result of investigations among ice-cream makers in Naples, has described in detail modifications consisting of lesions situated on the arms, and strictly related to the mode of working followed by ice-cream makers and to the substances which they manipulate.

The movements which the ice-cream maker is obliged to effect are, for the right hand, manipulation of the spoon with which he prepares the mixture, and for the left hand a circular movement by which he stirs the product in a receptacle containing the freezing mixture. Besides the above, at a given moment he is obliged to pierce the crust which has formed on the surface of the freezing mixture — an operation which he accomplishes with the right hand by means of a wooden wedge (prosciutto). At the same time he adds the necessary amount of salt to the freezing mixture with his left hand, either directly by hand or by using a wooden spatula. As a result of these manipulations, the hands of ice-cream makers show various modifications, chiefly callosities of the skin and wearing down of the nails.

As a result of the continued and violent movement of the spoon, which he holds firmly between the thumb and finger of the right hand, and of the fact that the upper end of the spoon presses against the cubital edge of the wrist, there is formed towards the lower part of the cubital bone a callosity of the skin which extends about 5 to 6 cm. in a vertical direction and 2 to 3 cm. in the transversal. It is generally oval in form, thicker at the centre, diminishing towards the periphery and having a red and rugged surface. This callosity increases in depth with the time spent in the occupation. In the trade it is known as the "cal de la cuillère", "callo del cuchiajo" or "spoon callosity". The palm of the right hand, by reason of the fact that it exerts pressure on the wooden wedge serving to break the crust, develops a more extensive and more irregular callosity situated towards the middle basal part of the hand. It is connected with the internal part of the thenar and hypothenar eminences. This callosity attains a maximum breadth of 5 to 6 cm. and is yellowish in colour. It is known in the trade as the "cal du coin", "callo del prosciutto" or "wedge callosity". Finally, on the palmar surface of the hand and opposite the top of the three middle metacarpal bones and on the palmar surface corresponding to the first phalange there are found small callosities due particularly to the pressure exerted by the handle of the shorter spoon which the worker holds firmly in his hand without letting it rest against the cubital side of the wrist.

The palm of the left hand presents a central callosity corresponding to the part of the hand compressed by the handle which the worker turns when stirring the mixture. This callosity is dark grey in colour when the worker is not engaged on his occupation and turns to flesh colour when he resumes work. This fact is dependent particularly on contact with the salt which the ice-cream maker takes in his left hand.
for salting the mixture. On the back of the same hand, on the phalanges of the third and fourth fingers, there are found small transversal callosities called, in consequence of their situation and their form, "cals de l’anneau", "calli dell’anello" or "ring callosities". These callosities are occasioned by the slight and continual friction of the finger against the external receptacle during the turning movement effected by the worker.

On both hands the nails are eaten away at the edges. The workers declare that it is never necessary to cut their nails. Their permanent contact with salt and ice provides the reason for this state of the nails.

BIBLIOGRAPHY

***

Incandescent Mantles Industry

Incandescent lighting by gas, petrol or alcohol is based on the fact that numerous solid bodies, especially metallic oxides, yield a bright light when heated by a flame. The amount of light emitted by an incandescent body depends on its temperature, which, again, depends on the equilibrium between the quantity of heat furnished by the flame and that leaving the body by radiation. To obtain the maximum effect, therefore, the quantity of energy radiating to the outside must be slight. It is, however, also necessary that the body rendered incandescent should possess a strongly emissive luminous power.

Cerium oxide has a high emissive power, but it allows a large proportion of energy to be lost by radiation. On the other hand, thorium oxide has only a feeble emissive power, although its loss of energy by radiation is small. The best result therefore is got from a mixture, in suitable proportions, of the oxides of thorium and cerium. Thus, other things being equal, a luminous intensity is obtained 70 times greater than that from pure thorium oxide and 10 times that of pure cerium (Ch. Féry). Manufactured mantles, however, contain a greater proportion of cerium oxide than that stated, because this substance vaporises gradually at a high temperature. A too high proportion of cerium oxide yields a reddish yellow light.

RAW MATERIALS

Thorium and cerium are derived, like several rare earths, from monazite, a mineral obtained principally from Brazil. These two metals are present in monazite in the form of phosphates.

Monazite sand is found in alluvial river deposits or in deposits along the sea shore. The natural sand contains up to 2 per cent. of monazite; it becomes enriched to 60-80 per cent. by washing in the same way as is practised with gold.

Commercial monazite sand is heavy and of a brownish yellow colour. Its value depends on its content in thorium. In view of its density it can be handled in spadefuls without development of too much dust.

The sand, in a very finely pulverised state, is heated with sulphuric acid in a lead-lined vat provided with an agitator. Sulphurous fumes form, and these should be removed as they affect injuriously the respiratory tract; but it is difficult to prevent some escape at the moment the vat is freshly charged with sand.

The product thus obtained, consisting mainly of sulphate and phosphate of thorium, contains in addition numerous metallic impurities and a fair amount of sulphuric acid. It is conveyed in leaden wagons to a fireclay tank where purification is effected by a very complicated process in which the thorium is eventually precipitated as an oxalate by oxalic acid. The metallic impurities are eliminated by different reactions, among which hydrogen sulphide, either in the form of gas or in solution, plays a principal role.

The hydrogen sulphide is prepared in the factory itself from iron sulphide and hydrochloric acid. Occasional cases of poisoning by this gas are reported, the presence of which is revealed by its smell in a dilution of 0.001 to 0.002 per 1,000 parts. Moderate doses of hydrogen sulphide gas cause irritation of the mucous membranes (nose, pharynx, etc.). Its action on the conjunctiva may induce hypersensitivity to light and 0.5 mg. is sufficient to set up in animals bronchial catarrh or pneumonia. According to research on animals and some observations on man by Lehmann, doses of 1 to 2 mg. seriously affect the central nervous system causing loss of consciousness, collapse, and sometimes sudden death. Generally, however, removal of the unconscious individual to fresh air suffices to bring about rapid recovery. Prolonged action of hydrogen sulphide, far from leading to tolerance, increases susceptibility (Lehmann's experimental work and the personal experiences of the chemist Ludwig, of Vienna). Chronic intoxication leads to anaemia, digestive trouble, headache, slowing of the pulse and often diarrhoea and bronchitis.
The solution of oxalate of thorium is precipitated by ammonia; there is formed thorium hydrate, which is converted into the nitrate by evaporation with concentrated nitric acid. Locally applied exhaust ventilation should be applied to remove the nitrous fumes. Thorium nitrate is a white crystalline powder containing a little water of crystallisation.

Some factories make use of a new secret process instead of that with oxalate. This is of interest from the point of view of health, because at one stage in the process cerite is added to the mass undergoing treatment and this produces a crystalline acrustation of acid reaction in the vats, presenting sharp cutting edges. The workers in consequence should wear rubber gloves and clogs to protect the skin when they go into the vats.

The nitrate of cerium is prepared in the mantle factory or purchased from abroad. It is extracted from the residue in the manufacture of nitrate of thorium by a method analogous to that used in preparing the salt: solution, precipitation by oxalic acid, calcination of the oxalate into oxide and treatment by nitric acid (see also article "Cerium").

INDUSTRIAL PROCESSES

To produce the network of the mantle, a tissue rich in ash is obtained and impregnated with a solution of salts of thorium and cerium and then burnt.

The thread of cotton or artificial silk is knitted on machines which present no special danger. Naturally all the moving parts should be guarded, and placing the belt on the pulley should not be done by hand.

The tissue leaves the machine in the form of a long stocking which is carefully washed; it is treated with a 5 per cent. solution of hydrochlooric acid in order to remove the mineral impurities (iron, lime, magnesia), subjected to washing in distilled water, degreasing with ammonia and again washing with distilled water. Drying is effected by centrifugalisig.

The workers manipulating the acid baths as a rule run no risk. The tissue is however sometimes treated with a dilute solution of hydrofluoric acid to eliminate the silicious material. The preparation of this solution from concentrated hydrofluoric acid may be dangerous to the respiratory organs. The risks in connection with the centrifugal machines are recognised. The motor must not be set going until the apparatus is closed, and it ought not to be possible to open it immediately after the motor has been stopped and while the speed of rotation is still considerable. These requirements are achieved by suitable devices, amongst which may be cited those utilising either the draught of a small fan fixed on the axis of the centrifuge or the centrifugal force itself to prevent the opening of the cover. The drying of the stocking is effected in a stove at a temperature of 50° C. and then it is cut by a machine into suitable lengths. The mantles are next hemmed and, according to the particular model for which they are intended (Auer, Welsbach, Grzin lamps), provided with a band of lace or stitching at one end. This work is generally done by an electric sewing machine—rarely by one worked by foot. The mantle is then dipped in the solution of nitrate of thorium and cerium (containing often a little aluminium, magnesium and beryllium) and subsequently passes between the two rolls of a press. The space left between the rolls is calculated in such a way as to leave a definite quantity of the liquid in the tissue. As this machine works slowly there is little risk of getting the fingers pinched between the rollers; in other types of machines this risk is eliminated altogether as the mantles are introduced mechanically. The workers employed at these machines should wear rubber gloves to prevent the skin being attacked by the saline solutions. In small works alternation of employment can be arranged for, so that only short spells are worked at the centrifuges.

The mantles are placed on rests and pass into the dryer and then the upper end is treated with a solution of various metallic salts so as to harden it and enable it to be suspended by the small thread asbestos cord which is threaded on to it. Skill in fixing this thread requires much practice.

The mantles thus prepared are placed in frames and subjected to gas flames which burn the organic matter while the metallic nitrates are converted into oxides. But this operation is not sufficient to give the mantles their desired shape and hardness; they must still be treated in a flame of compressed gas. They can be presented to the flame either mechanically or by hand. Mantles thus heated give out a blinding light and the workers' eyes must be protected by dark goggles or still better by coloured windows in the machine—the last arrangement being preferable as it ensures constant security.

SOURCES OF DANGER

The gas that may escape from the numerous burners and piping constitutes a danger, especially when the
Industrial Health (Propaganda)

Collective hygiene commenced with administrative measures, such as inspection, isolation of those suffering from infectious diseases, and disinfection. Next, material improvements were added, such as general water supplies and drainage, housing reform, provision of baths, douches, etc.

Following on these measures, came the view that a healthy life presupposes a sufficient income. Then hygienists embarked on the economic and social field and associated themselves with efforts seeking to raise the wage level, to abolish unemployment, to give old-age pensions, sums of money in cases of confinement, sums of money in the case of numerous members in a family and to mothers having the charge of infants.

This public hygiene — this social service — is however merely an aid to personal hygiene, which is of fundamental import, since health depends ultimately on daily habits.

Administrative measures, material improvements and social reforms must be completed by the teaching of hygiene. Now this has for its object no less a matter than a reform in the manner of living. Yet to effect this demands a veritable propaganda campaign and the inspiration of an ideal.

The cult of hygiene has passed beyond the purely technical stage to enter on a period of proselytism, and has advanced to the stage at which hygienic measures must be imposed by authority, implying first of all only passive collaboration, which must now however give way to an era of active collaboration, extending over the whole population.

It would be easy to draw a parallelism between this "democratisation" in hygiene, and the analogous evolution noticeable in political life, in industrial life and even in family life, but this would be beyond the scope of this article. Let it suffice to state that active methods have gradually invaded the domains of instruction, education, insurance, the administration of justice, and the regulation of industry, right up to the treatment and care of the sick. Everyone must in the last resort, so say the moralists, work out...
his own salvation. This is true of the body as well as of the soul, and of escape from physical ills just as much as of perfecting of the spirit or of strengthening the character.

Already in a branch of science allied to hygiene, it has been shown that the whole adoption of protective appliances and improved material conditions inside the factory reduce the number of accidents, and it is in the education of the personnel that the greatest measure of success in this respect has been achieved.

It is just the same with hygiene. In order to make its effects penetrate into the lives of workpeople, the sense which the Anglo-Saxons call "a hygienic conscience" must be awakened — a psychological state at once individual and collective, based upon personal as well as general interest.

To arrive at this a technique must be adopted of which the beginnings go back nearly half a century, but which has been developed mainly during the last fifteen years. Its spread has been such that 10-day pamphlets and leaflets on the subject of popular hygiene exist in about fifty languages.

Propaganda on hygiene among workpeople is closely bound up with that intended to reach the general population, the only distinction being that it is addressed to a more homogeneous class as regarded from the aspects of its occupational, economic and social life.

These are the elements which have already been described by writers who have made popular education in the domain of hygiene their particular subject.

As Sir George Newman, Chief Medical Officer of Health in Great Britain, has said with characteristic clearness, popular education in this field embraces three distinct tasks which represent three stages in its fulfillment: first, it must be forced on the attention; then the necessary instruction must be supplied; and lastly it must be given practical effect.

Each of these three tasks requires a different technique: propaganda attracts attention; teaching supplies the necessary instruction; adequate training will enable it to become of practical effect.

Propaganda utilises the methods of commercial publicity, that is to say, illustration by posters, drawings, caricatures, photographs, lantern slides, cinematograph films and pictures.

Teaching makes use of pedagogic methods described as passive (talks, lectures, courses, radio talks; written instruction (notices, leaflets, brochures, articles in papers, periodicals, books); demonstrations (models, exhibitions, theatrical representations, processions)).

Education rests on active teaching methods: influence exerted by the atmosphere under which work is done (cleanliness, ventilation, washing and bathroom accommodation in schools, workrooms and offices); participation in collective efforts on behalf of health, either temporary or permanent (health competitions, health weeks, membership of health societies); and lastly the initiation of personal or family habits under the guidance of a doctor or district nurse.

Some of these methods have an extensive character reaching a wide public, but in an impersonal way; so that consequently the impression they leave is relatively superficial and fugitive; this is the case with radio talks, articles in papers, conferences, posters, films, exhibitions. Others have an intensive influence, because they are directed to the individual and involve a genuine collaboration on the part of the interested parties; this is the case with such influence as is brought to bear by a medical man or district nurse. It is precisely because health demonstrations have both an extensive and intensive character that they constitute the most perfect kind of health education.

The effect obtained, however, does not depend solely on the character of the methods employed, or the perfection of the way in which they are carried out or on the extent of the resources behind them, or even on the number and quality of the personnel engaged.

Any mention of popular instruction and especially of propaganda involves psychology; the nature of the organisation which undertakes this form of education has a direct influence on its prestige and its power of penetration.

Health propaganda will always gain by being associated with authorised representatives of the workers. Sir Claude H. Hill and René Sand were in a position to offer the workers the assistance of the Red Cross at the Third International Labour Conference (held at Geneva on 9 November 1924).

In the U.S.S.R. two original methods are employed: the "Wall Sheet", a large sheet posted on the factory wall on which any of the staff may write questions or ideas; "Mini Police Courts", where an imaginary case is taken up in which the accused has contravened the rules. (See N. Semenius; Protection of Public Health in the U.S.S.R. Paris, International Social Service Conference, 1923.)
Organisers of health demonstrations have based their efforts on the same principle.

Summing up, it may be said that in order to further health among workers two conditions are necessary: good technical equipment, and knowledge of hygiene.

Examples are numerous. It is proposed to give here an account of the most striking ones, commencing with the health of children. The importance of which is paramount because it addresses itself to all those who constitute the future generation and is supplied at the most impressionable age for the formation of right thinking and proper habits.

It takes the form of health education, infant care, domestic economy, physical culture, references to health in the course of other lessons, daily exercise of hygiene at school (washing the hands, brushing the teeth, physical culture, school meals), school medical inspection, visits to health institutions. The League of Little Mothers has united the girls who wish to begin child welfare. The Health Crusade and the Juvenile Red Cross, with a strength of twelve million members in over forty-one countries, are composed of boys' and girls' societies which engage their members to pay attention to daily health.

Programmes of instruction in schools for primary, secondary and higher education, for occupational and domestic training, and the courses held for adolescents and adults have not yet accorded to hygiene the place it deserves even in places of learning for the working classes, the workers' university colleges, those centres of workers' education which are the realisation of their own efforts and ambition; nor again in institutions with which the workers are closely associated, such as the provincial organisations for workers' spare time in Belgium, and the national work carried out by Dopolavoro and the Fasci Femminili in Italy.

To promote popular health instruction in all its forms public authorities in Austria, Germany, Great Britain, the United States, the U.S.S.R. and Yugoslavia have founded State offices, provincial or municipal, which have undertaken work on a great scale. The National Office for Social Hygiene occupies the same role in France. Mention should also be made of the museums for the protection of infant life (Berlin, Budapest, etc.), the travelling exhibitions of hygiene and child welfare (on trains, boats, in motor-cars, and in China on wheels), the village institutes (notably in Russia, where posters and models relating to hygiene and child welfare are exhibited).

On the other hand, medical inspectors of factories, social helpers, who often make periodical examination of the workers or, at any rate, of the young persons in different trades, find excellent opportunity for instruction. Some of the medical services have published pamphlets and leaflets or have organised courses of instruction.

The New York municipal health office has collaborated with all the trade unions to organise, through them, enquiries into hygienic conditions prevailing in workshops and as to the health of each of their members; this is indeed a real piece of personal propaganda in the laws of health. The German Insurance Offices have issued to their members a little book on health matters (Gesundheitsbüchlein) published by the Federal Health Office. Similarly, in England, under the National Health Insurance Act of 1911, the Friendly Societies have devoted part of their funds to health teaching and some of them have made excellent use of this means.

Action is also taken by the sickness insurance societies to attain the same end through their sanatoria, preventoria, their dispensaries and their convalescent homes by teaching health principles.

Among the activities due to private initiative mention should be made of the Red Cross societies, linked up as they are with the League of Red Cross Societies, which supplies data to, and assists in this direction the National Councils on health activities (France), the associations for giving instruction in mental hygiene, maternal hygiene, and child welfare, and for combating tuberculosis, venereal diseases, alcoholism, cancer, heart diseases, and blindness. The Rockefeller Foundation, the Commonwealth and Milbank Foundations, the press, broadcasting stations — these have all given their support.

But the largest development in this direction has been effected by certain American organisations, which have adopted the principle of insurance en bloc of factory staff; their example has been copied by British, German, Czechoslovak and South African insurance companies. In twenty years
the Metropolitan Life Insurance Company of New York has distributed 534,942,654 pamphlets on health matters; its district nurses have made 33,926,064 visits; the films which it has prepared have been shown to about ten million persons.

It provided the funds for the first health demonstration, which took place at Framingham (Massachusetts). Since then the Rockefeller, Commonwealth and Milbank Foundations, the American, Czechoslovak and Belgian Red Cross Societies, the Hungarian, Polish and Czechoslovak Health Services have joined in this effort. These demonstrations are always undertaken in collaboration with the local authorities, medical associations, employers' associations and trade unions. Their object is to supplement the medical services of the locality so as to equip them in the best and most up-to-date way: with policlincs, dispensaries, laboratories, specialists, consultants, district nurses and the means for propaganda and instruction in health matters. Preventive medical examinations are an excellent means of drawing attention to hygiene and are an integral part of the necessary equipment.

In the United States and in Germany medical associations interest themselves actively in teaching hygiene. Naturally it goes without saying that in this respect the family doctor in his daily round can become a veritable apostle in the cause.

Among university institutions, the Industrial Clinic of Milan (Clinica del Lavoro), under the direction of Professor Devoto, takes the foremost place in the role of instructor, for it has not been content merely with the application of medicine in all its branches to industrial medicine, but it has undertaken also the work of propaganda and of teaching, in active collaboration with employers' associations and trade unions.

The university clinics of general medicine themselves are mindful of their duty in the matter of popular instruction. At Cluj in Rumania, Professor Hategan, accompanied by his pupils, makes a tour of the district by motor-car every Sunday, giving lectures on health at different places. In Buenos Aires Professor Carbonell has made it the duty of his pupils to give popular health talks.

Of all the employers' institutions it is without doubt the sickness funds (caisses de compensation), flourishing both in France and Belgium, which have undertaken in the largest and most systematic measure health propaganda among the working classes, thanks to their consultations for mothers and infants and for district nurses.

Individually such employers as have engaged doctors, nurses and welfare supervisors have contributed by these means to the teaching of hygiene; the practice of instituting medical examination prior to employment or, more rarely, of periodic medical examination, the organisation of courses of training in first aid and personal hygiene, and lastly supervision of the sanitary condition of the works — provision of washing and bath accommodation, cloakrooms, mess-rooms, rest-rooms, playing and sports fields — all have a permanent effect on the workpeople in the matter of health.

In several countries employers have formed themselves into associations for the prevention of accidents and for ensuring safety in factories; many of them have published and posted up sheets containing warnings as to health risks.

Certain mutual associations may also be cited, such as notably the Joint Board of Sanitary Control in the Cloak, Suit and Skirt Industry, which, not content with having created its own policlinic and its own system of health inspection of the workshops, organises conferences, distribution of leaflets and visits paid by its staff of visiting nurses.

Finally, what has been done by the workpeople themselves deserves special mention. For a number of years past the American Federation of Labour has shown an active interest in the health of the workpeople. The Workers' Health Bureau of New York was founded by trade unionists to guide and further efforts in this direction, notably in health propaganda. The same idea has prompted the formation of the Friends of Health (Zadru gas) in Yugoslavia.

Mention should be made of what has been done in Belgium in the matter of rural hygiene by the Boeren-bonden and Boerinnen-bonden (farmers' associations for male and female workers).

Almost everywhere the trade union, insurance, and co-operative press has joined in the efforts. Youthful factory workers and union members have engaged in organising health courses and exhibitions, distributing leaflets and showing films.

The workers' friendly societies act in the same sense with their policlincs, their holiday camps, their preventoria and sanatoria, and their district
Industrial Hygiene: Workshops

It is hardly necessary to insist on the favourable influence of good hygienic conditions on the health and life of the worker, and it is for this reason that efforts should be made towards the most extensive application of such measures where it is a question of protecting workers against the risk of disease in general or against specific occupational diseases in particular.

In the most advanced industrial countries legislative measures have already been issued which in their entirety correspond to the demands of hygiene in all modern establishments. In this article there will be enumerated those measures which from a hygienic point of view it is advisable to adopt with regard to the construction and running of a factory.

There may be expected in this connection the raising of the objection that the following account represents a maximum rather than a minimum to be given practical effect. Such an objection, however, should not prevent the utmost importance being attached to these measures and the desire that every possible effort should be made towards realisation of the majority of them in industrial practice.

Whilst it is at times difficult to apply new health measures in old plant or factories which are already working, on the other hand it is usually easy to insist on the adoption of them when an establishment is in course of construction.

It must be remembered that though the provision of hygienic working conditions may seem costly, it represents nevertheless, in the words of the employers themselves, "an expense that pays" (reduction of cases of sickness and accident, improved production, improvement in the workers' health, increased efficiency, etc.).

1 A draft standard code of industrial hygiene has been prepared by the Hygiene Service (1932) and will be submitted to the members of the Correspondence Committee on Industrial Hygiene of the International Labour Office. It must, however, be recalled here that the draft in question is only intended as a vade-mecum for all those who in the different countries are directly interested in hygiene as affecting factories and workers. This article is restricted to passages from the draft edition relative to "workshops", and for questions such as "dusts", "gases and fumes", "personal hygiene", "first aid", "welfare workers", "factory surgeons", etc., the reader is referred to the special articles dealing with these questions. (Dr. L. Carozzi.)

Dr. R. Sand

(Paris)

nurses. Some of them have undertaken — sometimes with the assistance of the Red Cross — a veritable health propaganda campaign among their members.

Yet the workpeople are still far from having exhausted all the possibilities open to them in this field: workers acting as inspectors, sent as delegates to factory committees and joint councils (such workers are frequently trained for the purpose by following special courses) ought to concern themselves more than they do with problems connected with health and health teaching both in and out of season. If the creation of safety councils with workpeople on them has contributed as much as it is claimed to have done in American factories to the diminution in the number of accidents, the institution of similar councils in Europe ought to be able to effect as much.

Health teaching among the working classes is a necessary and wide field calling for all the official and benevolent co-operation possible. But its effectiveness depends on the active participation of the workers themselves.

BIBLIOGRAPHY

The hygienic conditions to which workshops should conform may be classified according to their importance, as follows: (a) general provisions, and (b) special provisions.

Amongst the former are included those which should be required for every workshop without exception, whatever the nature of the work carried on there, whilst the second are applicable to workshops where the nature of the work carried on or the special technical conditions may constitute a risk to the worker's health. In the second case mention will here be confined to giving an account of the measures to be taken in those industries where the industrial technique involves important modifications of the surrounding conditions (high or low temperature, humidity, liberation of dust, steam, fumes, gas, etc.).

**General Provisions**

**Situation and Exposure of Buildings**

The construction of factories in very damp regions or on ground recently drained, in enclosed and narrow valleys or in districts with very high buildings should be avoided as far as possible.

The factory should neither have a distinctly northern, eastern, or western exposure nor should it give on to walls or rocks which may cause annoyance by undue reflection of light. Buildings with three or four free frontages should have their four corners in accordance with the four cardinal points, or their principal axis in the direction N.W.-S.E. If, however, the building has only two contiguous sides free, it is then preferable that the angle formed should have a southern or northern exposure. Whatever the case may be, efforts should be made to avoid a distinctly, eastern or western exposure.

The considerations in question are only of practical value for countries where solar radiation is very strong, since in northern countries effort is made to favour the entry of natural light into the workshops.

In general the number of buildings composing a factory is in proportion to the importance of the establishment and the nature of the operations carried on therein. Nevertheless, it is necessary that the various buildings should be so situated that they enjoy good natural lighting and good exposure as regards sunlight. The most suitable situation is that which also assures good ventilation. For this reason efforts should be made to avoid the construction of closed courts between buildings and construction in an unduly prolonged U-form.

The workshops should be so situated as to assure the maximum of natural light and a minimum exposure to inclement weather. Workshops should be situated above the level of the ground. In exceptional cases the use as workshops of rooms situated below the level of the ground may be authorised, provided they have a sufficient provision of daylight and are protected against damp. In any case, work in a basement which falls short of hygienic conditions required for a workroom on the level of the ground should be prohibited.

**Area.** — The area required for each individual engaged on work in a closed workshop should not be under 2 sq. metres. This figure is a net figure, i.e. without deduction for furniture, machinery and fixtures.

**Height.** — The effective height for working premises should be at least 3 metres when the surface does not exceed 100 sq. metres.

**Air space.** — In closed working premises air space should represent at least 10 cubic metres for each person employed.

In the calculation of this volume the parts of the premises above a height of 3.50 metres shall not be taken into account. Furthermore, the figures relating to the air space should be taken as a net figure without deduction for furniture, machines or fixtures. It must also be recalled that the surface, the height and the air space of the workshop are in strict relation to the number of persons employed, ventilation, the nature of the work effected, the presence of internal-combustion motors, etc.

**Floor, Roof, Walls and Ceiling.**

The type of flooring in workshops varies according to the nature of the work carried on. The flooring should not be situated below the level of the ground, save in cases where special exception has been granted. In the latter case insulation of the ground, lighting and ventilation should be such as to fulfil health requirements. The flooring should be thick, solid, smooth but not slippery, firm and

---

1 The problem of factory construction was discussed at the annual meeting of the German Society of Industrial Hygiene (Heidelberg, 1929). See the reports presented at this meeting and in particular the principal report submitted by Prof. Hahn and Eisenberg.
watertight, allowing the removal of dust without difficulty either by flushing with water or aspiration. Wooden flooring must be protected against moisture (see articles "Chemical Trades" and "Nitro-Amido Derivatives").

The roof must be arranged in such a way as to prevent the workspaces being overheated by solar heat, cold, rain and wind. Rooms situated under the roof must not be used unless the roofing is constructed in such a way as to prevent overheating.

The walls and the ceilings of all workshops should have a smooth and impervious surface capable of being cleaned and so constructed that they constitute bad heat conductors. In certain cases it is advisable that the walls should be coated with a washable paint applied up to about 2 metres from the ground. The walls and ceiling should be whitened or washed twice a year.

In workshops where great quantities of liquid or organic matters are handled, it is advisable to paint the walls and ceiling, which must be maintained in good condition.

The walls must be protected against dampness from the ground and must be weatherproof.

Apertures, Windows and Doors

Premises should be furnished with windows, which must be adequate in number and size to admit the requisite quantity of light to all parts of the workroom. The windows should be constructed and situated in such a way that they can be opened and easily cleaned. They should be furnished with a sufficient number of movable adjustable panes, unless there exist other means of ventilation. The ratio be-

1 The Association of British Chemical Manufacturers in 1929 issued a pamphlet containing hygienic measures for application in the chemical industry. Whilst this pamphlet presents hygienic measures of a general nature, there will be given in a later pamphlet those connected with certain special branches of the chemical industry.

2 Working premises with lighting sheds and without windows in the wall are no longer regarded favourably by hygiene experts. Whilst this type of building gives, it is true, a uniform light free from dazzle, it is deprived of the advantage of large windows which constitute a pleasant element by reason of the outside view provided. It is for this reason that preference is now increasingly given to construction with several floors where walls are almost entirely constituted of large windows with glass panes close to each other.

3 The windows should be so arranged that they open, wherever possible, on the opposite sides of the workroom or are situated opposite continuous walls. Their arrangement should be as effective as possible, with a view to facilitating ventilation of the workroom, which is not the between the surface of the windows and that of the floor of the working premises shall be less than 1:6 (see article "Industrial Lighting").

Measures should be taken for the protection of workers against excessive sunlight and solar radiation during the hot season.

The entrance to working premises must be furnished with doors opening outwards, close fitting and closing automatically. Sliding doors should not be permitted unless the workshop is already provided with a door opening from within outwards. Doors which open in both directions should be provided with a transparent glass pane enabling persons arriving from the opposite side to be seen.

Cleanliness of Premises

Cleanliness is best attained by avoidance of soiling. Effective measures should therefore be taken for preventing soiling of the flooring, walls, benches, tools, etc. Each workroom should be kept in a perfect state of cleanliness, and as far as possible protected from the production of dust and damp. The flooring, as well as the walls, the ceiling, benches and machines, should be periodically cleaned by the wet method outside working hours. For these purposes brushes or damp cloths, and the exhaust system of cleaning (vacuum cleaner) should be used where working conditions or the nature of the flooring do not permit of flushing with water.

Ventilation

In every workshop there should be openings of a suitable size which, by their situation, permit of the circulation of air, and thus assure permanent and efficient ventilation in all parts of the room. Premises must, in addition, be thoroughly aired at least once a day (during the midday rest period, for instance).

Lighting

Workrooms should be adequately lighted. Illumination of the room should be improved on all occasions on which circumstances permit by white-washing of the walls, or at least of the case in working premises with sheds or those which possess a single row of windows. If the workroom is very high, it would be advisable to have two rows of windows, one above the other. The windows wher possible should be constructed with sliding panes in preference to French windows. Draughts should be eliminated by adopting special types of panes for ventilation purposes (casting system, ventilating panes, etc.).
upper part of the walls, or by any other reasonable means. The sources of artificial light should not function in such a way as to increase to a considerable extent the carbon dioxide content of the atmosphere during working hours. In order to endow natural or artificial lighting with its total efficiency, the panes of the windows and the globes of lamps should be kept in a state of irreproachable cleanliness. In a workshop possessing a central station for the production of artificial light, precautions must be taken for replacing this lighting in cases of accidental failure of the central installation. In order to meet the requirements of adequacy and efficiency the lighting must fulfil certain special demands (these are dealt with in detail in the article "Industrial Lighting").

Temperature

As far as the type of work executed permits of it, the temperature of working premises must be maintained within suitable limits.

In closed workrooms the temperature should not fall below 15° C. In summer the working premises should be protected against excessive heat. A thermometer must be placed in every workroom, and kept in good working order. In estimating the temperature suitable for the workers, account must be taken of the influence exercised by hygrometric conditions and the air movement (see article "Air: Hot and Humid Atmospheres"). In order to reduce the trying influence of excessive sunlight in summer, the windows may be provided with blinds, or given a blue or at times a white coating. There may also be adopted a yellow coating inside and a blue outside.

Heating of the premises should be ensured during the cold season. The heating apparatus must be furnished with appliances ensuring the regular elimination of gases produced by combustion. Regulation of the heating apparatus by means of keys or dampers which can completely close the pipes for elimination of gases and fumes should be forbidden. Radiators and heating pipes must be installed in such a manner that the workers are not inconvenienced by radiation of heat or by circulation of hot air (see article "Heating").

Special Provisions regarding Hygienic Conditions

Flooring and Inside Walls

In working premises (chemical industry, dyeing industry, tanneries, etc.) where putrescible or liquid substances usually soil the flooring, the latter must be sufficiently inclined to allow the liquids to flow rapidly towards the collecting points for evacuation. Unless workers are provided with clogs or waterproof footwear, the wet flooring at working posts and in passageways should be permanently fitted with lattices or gratings. In the case of stone flooring, working posts where workers are obliged to stand continuously should be provided with matting or other covering as protection against the cold. In workrooms in which dust, smoke, gas and fumes are liberated, the inside walls should be so constructed that these irritants are prevented from penetrating into other parts of the establishment. The interior walls and the ceiling should be so constructed that steam does not produce condensation.

Ventilation

In every workshop, in which it is impossible to ensure adequate natural ventilation, recourse must be had to artificial means of ventilation. Ventilation of this type cannot be considered effective unless the air is renewed completely at the rate of at least 30 cubic metres per hour and per worker. The disposition of ventilators should not be such as to inconvenience the workers by directing a draught towards them. The air supplied should have an average temperature of not less than 12° C. In premises and establishments in which work is specially unhealthy, the air renewal rate should be at least 60 cubic metres per hour and per worker (see article "Ventilation").

Temperature

In workrooms where industrial technique involves the production of excessive temperature — unduly high or unduly low — which it is impossible to modify, adequate measures should be taken to protect the workers.

Stalls outside shops must be furnished with awnings or other means of protection for the workers there engaged against the inclemency of the weather (see article "Temperature").

1 It is not now considered advisable to construct very extensive workrooms for a large number of workers, since ventilation in these offers difficulties, especially where workers are engaged on different processes. There is also a whole series of obstacles from the technical point of view. Similarly, attempts should be made to avoid working in a single workshop workers engaged on operations involving different occupational risks.
Humidity and Humidification

In workrooms where the atmosphere requires artificial humidification (flax spinning, wool spinning) two standardised humidity thermometers should be posted, one in the middle of the workroom and the other at a suitable spot.

Wherever artificial humidification is practised, the wet bulb thermometer should not mark more than 24° C. On the other hand, the dry bulb thermometer should mark a temperature of at least 10° C. In any case the reading of the wet bulb thermometer should not approach too closely that of the dry bulb thermometer. The water used for humidification should not contain substances or germs endangering the health of the workers (see article "Air: Hot and Humid Atmospheres").

Dust

Processes which liberate or raise dust of any kind whatsoever in the workroom should, as far as possible, be executed in closed apparatus provided with exhaust ducts. In default of this, such processes should not be engaged in, unless adequate means are provided for catching the dust as it is produced, as near as possible to the point of production. The dust should further be removed and disposed of in a manner excluding its dispersal in premises where workers are employed. It should then be subjected to treatment calculated to render it innocuous.

Withdrawal of dust by the exhaust process should be per ascensum or descensum, according to the nature of the dust in question. Apparatus and pipes used for ventilation should be solid in construction, made of material impervious to dust and so disposed as to be easy of access for purposes of inspection and cleaning. Pipes for dust withdrawal should be maintained in a condition allowing uninterrupted circulation of the dust.

Wherever it is compatible with the requirements of industrial technique, and in order to prevent the liberation and diffusion of dangerous or noxious dusts, the raw material, as well as the finished products, the floor, the inside walls, and all parts of the premises most exposed to the settlement of dust, should be kept in a suitable state of dampness by means of frequent sprinkling with suitable liquids (see article "Dust, Fumes and Smoke").

Steam, Fumes, Gas and Liquids

In workshops where steam is produced, there should be installed hoods or chimneys, or other effective apparatus, for its elimination (see article "Dyeing"). Processes involving liberation of fumes or noxious gases should be executed in closed apparatus, provided with an efficient draught, or under a hood provided with a movable glass shutter. Irritating or otherwise noxious fumes or toxic gases should not be freely liberated in the atmosphere until they have first been subjected to adequate processes of condensation, neutralisation, saturation, or pyrogenic transformation, as the case may be, in order to render them inoffensive for the neighbourhood (human beings, cattle, vegetation).

Workers should not be permitted to enter wells, cisterns, reservoirs or other similar containers, before it has been made certain that no asphyxiating, harmful or inflammable gases are present. Where such gases exist, the atmosphere must first be purified and all absence of danger must be assured. Where this cannot be done, workers should not be permitted to enter unless provided with effective protective apparatus and having a safety rope round the body. Furthermore, workers employed in such a case should not be permitted to enter one at a time and should work under the supervision of a responsible person outside. They should be relieved as often as the circumstances permit. The necessary personnel and material for affecting rescues in case of need should remain in close proximity to the work, and should be available for its entire duration.

When toxic or corrosive liquids are used in an establishment they should be kept in such a manner as not to constitute risk for the health of the workers. Their circulation should be assured by aspiration or by pressure. (See articles "Air: Hot and Humid Atmospheres" and "Gases and Fumes").

Smoke, Odours, Emanations, Residual Water and Waste

In closed workrooms, where under normal circumstances smoke of any kind whatsoever is liberated, adequate means should be taken to eliminate or reduce as far as possible its production and its diffusion throughout the atmosphere in which workers are obliged to remain. Wherever circumstances permit, special processes should be adopted with a view to precipitation or to maximum combustion.

In workrooms in which odours of
any kind whatsoever are given off, measures should be taken for aspirating these as completely as possible in the immediate neighbourhood of their production. On the other hand, all accessory installations which may constitute sources of pollution of the air should be constructed and maintained in such a manner that their emanations may not cause a noxious effect.

Waste and residues of manufacture, debris from raw material, sweepings, and in general all waste matter should be removed at the end of each working day or working shift from the workshops, collected and regularly evacuated, burned or buried, without possibility of giving rise to nuisance.

Waste waters should be regularly withdrawn by an effective system of drains provided with hydraulic traps or syphons, and frequently washed. In cases where residual water cannot be conveyed to a drain, it should be submitted to suitable treatment before being directed outside or into any water course (see articles "Dusts, etc.", "Odours" and "Industrial Waste Water").

**Noises, Vibration and Shocks**

In industries giving rise to shocks, vibration or noise prejudicial to the health of the workers, effective measures, counselled by technical experience, to diminish their intensity, should be adopted. At the same time care should be taken not to expose needlessly those workers not directly employed on such processes. (See article "Noises").

**Legislation**

The Medical Service of the Italian Factory Inspectorate (Minister of National Economy) in 1928 published a pamphlet in which the factory inspector, the employer and the worker may find analysed in a simple and exact manner the measures issued by the Regulations on industrial hygiene (1927). This pamphlet constitutes a highly essential vade-mecum of practical industrial hygiene.

The legal measures relative to hygiene in workshops which have just been described in brief are to be found scattered throughout laws relative to protection in industry or assembled in special laws. The latter exist in the most advanced industrial countries, amongst which may be noted Austria, Belgium, France, Germany, Great Britain, Italy, the Netherlands, and Switzerland. The following list should be of use to the reader as a summary account of the laws, regulations, orders, etc., relating to these eight countries.

**Austria**

**Laws**

**Orders**

I. Of 23 November 1905 relative to the amendments and additions made in the Labour Code and the general measures for the protection of the life and health of workers.

II. Of 29 May 1908, issued by the Ministers of the Interior and of Commerce, regulating industrial work in stone quarries, clay pits, sand pits, and ballast holes.

III. Of 23 August 1911 issued by the Minister of Commerce, in conjunction with the Minister of the Interior, containing special provisions relative to the safety and hygiene of the workers in industrial establishments in which printing processes, lithography and typefounding are carried on.

**Belgium**

**Laws**

Act of 2 July 1899 concerning the safety and health of workers in industrial and commercial establishments.

**Royal Orders**

I. Of 30 March 1905, prescribing measures to be observed with a view to protecting the health and safety of workers in Industrial and commercial establishments, subject to the Act of 24 December 1905.

II. Of 5 November 1910, relative to the manufacture of white lead and other lead compounds.

III. Of 15 January 1914, relative to the manufacture of white lead and other lead compounds.

IV. Of 15 May 1923, regarding supervision of dangerous, unhealthy or noxious trades.

V. Of 12 March 1923, regulating work in zinc factories.

VI. Of 20 March 1926, relative to personal cleanliness, and prescribing conditions connected with the use of heating apparatus situated in working premises engaged in dangerous trades.

VII. Of 28 June 1929 prescribing the measures to be observed with a view to protecting the health and safety of workers in Industrial and commercial undertakings, subject to the law of 24 December 1928.

**Ministerial Orders**

I. Of 26 January 1914, regulating work in compressed air caissons.
France

Labour Code

Laws

I. Act of 19 December 1917 relative to dangerous, unhealthy or noxious trades.

Decrees

I. Of 10 July 1913, amended 29 March 1914 and 23 October 1917, concerning general measures of protection of health, applicable to all establishments coming within the law.

II. Of 1 October 1913, concerning special measures of hygiene applicable in industries where the workers are exposed to the risk of lead poisoning.

III. Of 1 October 1913, relative to special measures of hygiene to be applied in hair-cutting establishments.

IV. Of 17 December 1918, containing public administration regulations in virtue of section 6 of the Act of 19 December 1917, relative to dangerous and unhealthy or noxious trades.

Germany

Laws

Industrial Code of the German Empire, published by an Order of the Chancellor dated 26 July 1900, and amended by the Acts of 30 May, 29 June, and 8 December 1908, and of 27 December 1911.

Orders

I. Of 30 July 1897, relevant to the conditions of hygiene in typesetting establishments.

II. Of 1 March 1902, relative to the installation and working of establishments for vulcanisation of rubber.

III. Of 22 October 1902, relative to the installation and working of horsehair spinning establishments, workrooms for dressing of skins and bristles, and brush and shaving brush factories.

IV. Of 16 June 1905, relative to the installation and working of lead foundries.

V. Of 27 June 1905, relative to painting, whitewashing and lacquering establishments.

VI. Of 17 February 1907, relative to the installation and working of cigar factories.

VII. Of 16 May 1907, relative to the installation and working of establishments for the manufacture of alkaline chromates.

VIII. Of 6 May 1908, relative to the installation and working of establishments for the manufacture of electric storage batteries by means of lead and lead compounds.

IX. Of 31 May 1909, relative to the installation and working of quarries and stone-cutting yards.

X. Of 3 July 1909, relative to the installation and working of industrial establishments in which basic slag is pulverised, ground or stored.

XI. Of 13 December 1912, relative to the installation and working of zinc mines and factories for roasting zinc ore.

XII. Of 27 January 1920, relative to lead colours.

Great Britain

Laws

I. Act of 17 August 1901 on factories and workshops.

II. Factory and Workshop (Cotton Cloth Factories) Act of 17 August 1911.

Orders

I. Of 4 February 1913 on sanitary conditions of workshops.

II. Of 18 March 1912, on hygrometers in the cotton industry.

III. Of 9 October 1917, No. 1068, relative to drinking water in certain factories and workshops.

Regulations

I. Of 19 June 1903 on file-cutting by hand.

II. Of 19 January 1925 on the electric accumulator industry.

III. Of 12 December 1905 on sorting, willeying, washing, combing and carding of wool, goat hair and camel hair, and processes incidental thereto.

IV. Of 26 February 1906 on spinning and weaving flax and tow, and processes incidental thereto.

V. Of 21 January 1907 on manufacture of paints and colours.

VI. Of 6 August 1907 on heading of yarns by means of a lead compound.

VII. Of 28 August 1907 on spinning and weaving hemp or jute, or hemp or jute tow, and processes incidental thereto.

VIII. Of 20 December 1907 on the use of horsehair.

IX. Of 20 June 1908 on casting of brass.

X. Of 18 December 1908 on vitreous enamelling of metal or glass.

XI. Of 30 June 1909 on tinning of metal hollow-ware, iron drums, and harness furniture.

XII. Of 2 September 1925 and 26 October 1925 on grinding of metals.

XIII. Of 12 August 1911 on smelting of metals containing lead, on the manufacture of red or orange lead, and on flaked litharge.

XIV. Of 11 April 1912 on bronzing with dry metallic powders in letterpress printing, lithographic printing, and coating of metal sheets.

XV. Of 2 January 1913 on the manufacture and decoration of pottery.

XVI. Of 23 August 1912 on the manufacture of certain compounds of lead, viz.
any carbonate, sulphate, nitrate or acetate of lead.

XVII. Of 29 December 1921 on the handling of dry or dry-salted hides or skins.

XVIII. Of 31 March 1922 on the manufacture of indiarubber and articles made entirely or partly of rubber.

XIX. Of 11 July 1922 on chemical works.

**Italy**

General Regulations on industrial hygiene of 14 April 1927, No. 530.

**Netherlands**

Laws

Act of 19 June 1915 on safety.

Royal Orders

I. Of 10 August 1920 issuing General Administrative Regulations in application of subsection (10) of section 1 of the Act of 1919 on the work of women and young persons.

Decrees

Of 27 June 1913 replacing the Decree of 7 December 1893 modified by the Decree of 10 June 1909 issuing Public Administrative Regulations in application of sections 6 and 7 of the Act on safety.

**Switzerland**

Apart from these Acts and Regulations, etc., of which a particular analysis has been given by way of illustration of the present article, there exist also in other countries legal measures connected with hygiene of working premises. Amongst these may be mentioned:

**Argentina**

Decree of 19 November 1928 relative to hygiene measures in industrial establishments.

**Brazil**

Decree No. 3876 of 21 July 1925 on the reorganisation of the Department of Public Hygiene (Chapter III: factories in general and factory inspection).

**Chile**

Decree No. 217 of 30 April 1926, containing regulations on industrial hygiene and safety.

**Ecuador**

**Hungary**

Decree No. 91560, 1926, of the Minister of Social Insurance relative to the study of hygienic conditions in factories.

**India**

Factory Act of 1911, amended 25 March 1926 (No. XXVI, Chapter 3).

**Japan**

Order No. 28 of 20 June 1929 of the Minister of the Interior issuing Regulations relative to safety and hygiene of workers.

**Luxembourg**

Act of 28 August 1924 relative to the health and safety of workers engaged in industrial and commercial establishments.

**Mexico (Campeche)**

Factory Act No. 57 of 29 November 1924 (Chapter 16).

**Peru**

Decree on measures of industrial hygiene and safety of 29 January 1926.

**Poland**

Legislative Decree adopted 1 March 1928 by the Council of Ministers on Industrial Hygiene.

**U.S.S.R.**

Orders Nos. 105 to 512 of 8 April 1928 relative to factory inspection (sections 34 to 36, 38, 82).

**Uruguay**

Order of 7 October 1925 on health services in industrial establishments.

**Yugoslavia**

Regulation on industrial hygiene and safety, 1921.

**REFERENCES**

The various measures of industrial hygiene reviewed above are to be found for the most part in the various texts referred to under legislation. References in this connection are given below:

**Situation.** — Switz. O., sec. 54. In the laws of other countries legal prescriptions relative to the situation of working premises have been edicted on grounds of public hygiene and not on those of industrial hygiene. It is a question of isolating or placing at a distance from inhabited areas constructions intended for industrial establishments.

INDUSTRIAL LIGHTING

The importance of suitable lighting in industry is obvious. But employers and technicians should not be obliged to grope about to find the standard of lighting suitable for their works, and at the same time the indefiniteness which still characterises certain regulations should be remedied.

Suitable lighting leads to cleanliness of workplaces, postponement of fatigue, prevention of accidents, easier discipline and control, limitation of waste, and better quality of work with more rapid production.

The use of electricity has for some years increasingly favoured the use of artificial lighting, with a tendency to use a very much higher standard of illumination than that recommended by hygienists. This is easily understood, having regard to the progress made in the production of light.

Undoubtedly the problem of general lighting, and industrial lighting in particular, presents aspects which have not yet been elucidated and calls for fresh experiment. But all the same, it has been possible to fix some rules which are applicable to the daily work and, for economic and hygienic reasons, ought not to be ignored.

**Sources of Light**

Powerful lights give the sensation which we call "white". While the normal eye only perceives the middle or luminous part of the spectrum, it cannot escape in the same way as the against noise, etc., have as their object: the safeguarding of the neighbourhood and not of the workers engaged in the industry.

**Waste water, refuse.** — Bel. R. O. I, sec. 11; Fr. D. I, sec. 3, subsec. (2); Ger. A., sec. 120a; It. R. sec. 26; Switz. O., sec. 36.
body does from the influence of obscure chemical and physical radiations present at the two extremities of the spectrum, at the dark or infra-red, hot end spectrum, and at the dark, chemical or ultra-violet end.

The sources of light used in practice offer a wide spectrum that is a mixture of various radiations which, when they reach the eye, give the sensation of a single colour, depending on the greater or lesser width of the spectrum and on the comparative intensity of its various parts.

Illumination may be natural or artificial.

Natural Light

Light from the sky is essentially a diffuse light. As a matter of fact, the terrestrial atmosphere contains an infinite number of small particles in suspension which reflect luminous rays in every direction.

Solar light is very rich in ultra-violet rays, most of which are arrested by the atmospheric layer, and also in blue rays.

Natural illumination or daylight is extremely variable. The conditions which influence the illumination most are represented by the seasons, the time of day, the meteorological conditions and the extent of the vault of the sky from which the light is coming. Thus L. Bargeron at 3 p.m. in cloudy weather found 185 lux on the windowsill of a workshop on the ground floor in a large Parisian courtyard, and, in similar weather, on a large square, 2,300 lux at noon and 3,500 lux at 1.30 p.m. The brightness of the sky varies a good deal under different meteorological conditions. It is greater when the blue is not seen. The American Lucifer Prism Company classifies these conditions of brightness into five groups:

1. Nimbus clouds, without blue sky or sun.
2. Cloudless sky, light blue, approaching rain or slight haze.
3. Sky for the most part blue, high clouds: cirrus.
5. Sky entirely covered with clouds, no blue sky.

Artificial Light

The sources of artificial light may be classified as follows:

1. Sources the incandescence of which is due to carbon in flames produced by the combustion of solid matter (such as wax), of liquids (such as vegetable and mineral oils and petroleum), or of gases (such as coal gas, water gas, mixed gases or acetylene).

2. Sources the incandescence of which is due to heat caused by the passage of an electric current, e.g. the incandescent mantles heated by gas or acetylene, or by vapours of other substances, such as spirit; incandescent lamps with filaments with selective power of emission or placed in a special gas, such as nitrogen in the Nernst lamp.

3. Sources the incandescence of which is due to the combustion of various substances, or to the passage of an electric current through a solid body with selective power of emission, e.g. incandescent mantles heated by gas or acetylene, or by vapours of other substances, such as spirit; incandescent lamps with filaments with selective power of emission or placed in a special gas, such as nitrogen in the Nernst lamp.

4. Sources in which the incandescent body is a vapour traversed by the electric current, as in the mercury vapour lamp.

The brightness of the flame in the first group is due to the presence of particles of carbon, made luminous by incandescence. The flame shows below a bluish part which resembles a sheath round the flame where the gas is completely burnt; inside the flame is the luminous part where the combustion is less complete.

A flame gives out light when the particles of carbon are in sufficiently great number and the combustion, without being complete, is sufficient to make the particles incandescent.

When a flame gives out light under normal conditions, its brightness depends at once on the density of the solid particles and their temperature. In order to obtain maximum brightness, the temperature of a flame must be so raised that a maximum amount of the energy radiated by the particles approaches that of the visible spectrum. All substances do not follow the same law of emission.

The more the light proceeding from a luminous body is intense, the higher is its temperature; the more the brightness of the light increases, the more its spectrum extends in gradual stages towards the violet. Increase in lighting capacity is thus accompanied by an increase in chemical rays, especially in ultra-violet rays.

Measurements and Photometric Units

Light has always been measured by comparing it to another light, taken as unity. Violle in 1889 proposed to unify photometric measurements by comparing
them to a platinum standard, of which 1/90 is fairly well represented by the "international candle", which stands in a simple relation to the unit used in Germany and Switzerland. There shall now be briefly summarised the definitions of measurements and photometric units, among which come first "the luminous flux", as the fundamental measurement in photometry, and then a definition of a corresponding unit: "the lumen".

The "luminous flux" is regarded as the fundamental measurement in photometry. The luminous flux (F) is the output of radiant energy estimated according to the luminous sensation which it produces; this definition is adopted by the International Commission on Lighting. The "flux" is the quantity of light given off by a luminous source per unit of time. The flux is then what is commonly called "the light".

The flux emitted by a luminous source is measured by a unit which is the lumen, that is to say the quantity of light which passes through an opening 1 sq. m. in surface, cut out on a sphere with a radius of 1 m., at the centre of which burns a source of light having the intensity of one candle in each direction.

The lumen may be defined as "the luminous flux intercepted by a surface of 1 sq. m., each point of which is situated at a distance of 1 m. from the source which is equal to a decimal candle".

The luminous intensity of a fixed source in any direction is the luminous flux per unit solid angle emitted by the source in that direction. The unit of intensity is the "international candle" or "decimal candle", which is estimated by means of photometry.

The luminous flux is referred to a surface which either receives it or emits it at a density which is called "illumination" when the light is received by the surface, and "emission" when it is emitted by this surface.

Illumination is the effect of light on objects; it is measured by a unit called "lux".

Lux is the illumination produced by a luminous source of a decimal candle on a level surface distant 1 m. at the point where this level surface is met by a luminous ray perpendicular to it. It may also be defined as the illumination produced on the surface of a sphere of 1 m. radius by an exact uniform source of an international candle placed at its centre. If the centimetre is taken as the unit of length, the unit of illumination is then the "phot" which equals 1 lumen per square centimetre, and, if the foot is taken as the unit of length, as in Great Britain and the United States, the unit of illumination is the lumen per square foot, called "foot candle". The "foot candle" is then equal to 10.764 millilux, and to 10.764 lux, being approximately 1 millilux or 10 lux.

The relation between "lux" and "lumen" is such that, if a lumen is used so that its light illuminates a surface of 1 sq.

**The Practice of Lighting**

**Natural Lighting**

In order to make sure beforehand of the light to be obtained from diffuse daylight, it is necessary to take into account the orientation of the workplaces.
Natural lighting in modern factories is usually well arranged and admitted through large openings either in the walls, or in the case of one storied buildings in the roof by skylights. The best way to admit light rays is from above through a glazed roof; but this system is often insufficient or excessive, depending on the season and the weather.

Unilateral lighting from the left side is adopted for schools; bilateral lighting involves a play of shadows and is only of secondary interest from the hygienic point of view. Lateral lighting can be combined with top lighting. Any combination of natural illumination with artificial gives a false and tiring light, due especially to reflections on the cornea.

The best system of lighting for one-floor buildings is that of the saw-roof used for weaving sheds. The glazed part should face north and have an inclination of 40° to 45°. For structures which cover a large area, these rooflights admit light which descends vertically into places where oblique rays, entering by windows, do not penetrate.

Windows should be as large as possible and reach to the ceiling. The distance from the window to the ceiling should never be more than 20 cm. The lower panes should be frosted up to 1.75 m. from the floor. The relation between the height and the depth of the place should also be taken into account, since illumination is inversely proportional to the square of the distance which separates the point under consideration from the wall containing the window.

Obstacles which interfere with the penetration of luminous rays, or which modify their direction, such as buildings in front of windows, should be taken into consideration.

Illumination is also modified by the glass, blinds, curtains, the colour of the walls and ceiling of the room, and by the colour of the front of the building opposite.

Next to white in varying shades, yellow is the colour which presents most luminosity. With white, light yellow, or pale grey, walls reflect from 50 to 15 per cent. of light without dazzling. Whitewashed walls are highly suitable. For the ceiling, by preference a varnish of zinc white, tetanium, etc., is used. Dust and dirty walls interfere with illumination, and may reduce the effective luminous flux of the lighting system.

The arrangement of machinery in
workplaces should be studied in order to avoid shadows cast by the workmen. To sum up, natural lighting should satisfy the following conditions:

(i) The greatest possible amount of light should reach as far as the central part of the room;
(ii) The light should fall on the place of work in the most convenient direction;
(iii) The distribution of light on the place of work should be as uniform as possible;
(iv) The walls and fittings of the room should have a colour and surface which will only absorb a small amount of the incident light;
(v) Machines and accessories should be placed so as to cause as few inconvenient shadows as possible.

**Artificial Lighting**

Artificial lighting should supply a light which resembles natural light as much as possible.

The illumination should be generally diffused, that is to say, it should not leave any part of the room in darkness nor cause obstructive shadows; it should be adequate and constant, and should avoid dazzling, either directly from the source or indirectly due to reflection from a smooth polished surface.

Three systems of illumination are in vogue at the present time: the direct system, the semi-indirect system, and the indirect system.

The direct system is that in which the source of light is visible from the place of work and distributes to it most of its rays. The light should be provided with a reflector. The direct system may be used for general, localised or mixed illumination.

The semi-indirect system screens the light from the eyes by a semi-opaque material through which the rays reach directly the place of work, whilst a part arrives indirectly by reflection from the walls and ceiling or from another reflector placed above the light. When the reflector is made of a material which has a high transparency value, the system approaches direct lighting; if, on the contrary, the degree of transparency is low, the effect approaches the indirect type.

The indirect system is that in which practically all the rays reach the working site indirectly by reflection from the ceiling and from the walls. It is obtained by putting below the light an opaque or only slightly transparent reflector which directs all the light to the ceiling. This system, which is very costly, presents great advantages, especially for work requiring great visual acuity. If well installed, it may be superior even to daylight in that it is less tiring to the eyes. Moreover, it obliterates contrasts and sharp shadows, and does away with the accommodation of vision.

Good diffusion of light may be impeded by too low a ceiling. The placing of lights should be carefully calculated so that the ceiling may be lighted as uniformly as possible.

The semi-indirect and indirect systems are most agreeable for the eye, for they allow of the elimination of part of the ultra-violet rays. It is essential that the lamps used should be kept absolutely clean.

The quality of the glass and the type of globe are also of great importance.

Indirect illumination yields a result which is a third of that supplied by direct lighting. But the diminution of waste and the reduction in accident risk make up for the extra costliness of this system. In order to reduce loss of light by absorption, work tables and walls should be painted white, and good use should be made of transparent reflectors made of white translucent porcelain. The loss can thus be reduced by a third.

The system of lighting by incandescent gas may be looked upon as an indirect system of lighting.

As regards diffusion of light, the mercury lamp is the most satisfactory system of lighting. The best results are obtained by combining general lighting with mercury lamps and localised lighting above each work bench.

Artificial sources of illumination should supply intense light without dazzling the eyes, while throwing shadows that are not too sharp.

From the practical point of view a source of artificial light — which, according to Fortin, ought to realise the synthesis of daylight — should have the following characteristics:

It should (i) be easy to use and not be too costly; (ii) resemble daylight as much as possible as regards steadiness, intensity (constancy), regularity (absence of variations in the illumination) and the spectrum; (iii) be poor in ultra-violet rays; (iv) have a moderate brilliance, but a sufficient surface for radiation; (v) not increase appreciably the surrounding temperature, especially near the worker's head; (vi) not alter...
the composition of the air by products of combustion.

The evil effects of bad lighting and eyestrain are discussed in another article ("Occupational Diseases: Eyes"). There may be recalled here very briefly the influence of lighting on the visual faculties.

Visual acuity, that is to say, the faculty of perceiving the details of objects, varies directly with illumination. It increases very sensibly up to about 40 lux. Visual acuity is estimated by minuteness of the details detected. That is why it is measured by the inverse of the limiting angle subtending which two points can be seen separately. Degrees of visual acuity are determined by varying the illumination.

Study of variations in the rapidity of vision, in terms of illumination, with which the eye notices these same details, also shows that it is advisable to raise illumination beyond 40 lux. Rapidity of vision is in inverse proportion to the time necessary for a given object to become perceptible under a given lighting.

Good lighting also increases rapidity of accommodation and continuity of vision. By accommodation is understood the faculty of adapting the eye to the clear perception of objects situated at different distances. Continuity of vision is the power to distinguish clearly an object in the course of observation of a certain duration. Experience has shown that, for individuals whose vision is defective, intense lighting is even more helpful than for normal eyes (see later).

THE TECHNIQUE OF ILLUMINATION

The Placing of Lights

The placing of lights is one of the most important points in the practice of illumination. It may in fact be said that industrial lighting constitutes the problem of the distribution of lights.

When placing lights it is necessary to bear in mind: the height and the position of the source in relation to the working place; the intervals between the lamps; the degree of contrast between the illumination of the working place and that of other parts of the workshop; the chromatic composition of the light; the power of the source and the size of the lamp; the type of globe and reflector; and also the colour and the coefficient of reflection of machines and materials.

The workplace or the surface of the work should also be considered; it should be horizontal or nearly so. It is known that the angle of incidence for a horizontal surface is reduced to 0° when the light falls vertically. Lights should therefore be placed as high as possible compared with the level of the floor. In any case the light should send its rays so that they reach the working place from the side, or better still, over the shoulders of the workman, if the light is sufficiently high. Where a machine is placed between the light and the workman, the lamp should not be in the field of vision and adjacent lamps lighting the room should not cause the production of confusing shadows.

Lamps hung at a height above 6 m. from the floor can be left without reflectors.

FIG. 2. — Placing of the light source in relation to the eye.

Lighting engineers are nowadays more in favour of general lighting than they were some years ago, both for workshops and large offices, and are opposed to separate lamps. In the same way that custom has reconciled people to central heating, it will also reconcile them to the use of general lighting. But it must not be forgotten that this reaction against local lighting is the result of a bad system of application. As a matter of fact, it is too often forgotten that it is not sufficient merely to possess powerful sources of light; a knowledge of how to place them is also necessary.

Lamps fixed to the ceiling should be suitably spaced and set as high as
possible, at 15-30 cm. from the ceiling. Whenever possible a few strong lamps should be used, rather than many lamps of poor intensity. In this way the advantage is gained of putting them outside the field of vision and of using lamps of greater power. Lamps of 500 watts and more can be suspended, for example, at 5 m.

If in a workshop there are gantry cranes, lamps of 1,000 watts may be placed as high as 10-12 m.

Once the height between the lamp and the working level (and not the ground or the floor) has been determined, the spacing must be regulated; for direct lighting the ratio of space to height should be between 1 to 2, depending on the effect of the installation under consideration; for an installation giving indirect lighting average ratios of 1 to 5 can be generally adopted.

The spacing of lights can also be calculated in the following way: deduct 92 cm. from the height of the ceiling of the room, multiply the result by 1.8, in order to get the optimum spacing, or by 2.4, if it is a question of determining the maximum permissible spacing. In practice, the results are satisfactory when the spacing is not more than twice the figure obtained by deducting 92 cm. from the height of the ceiling. Spacing is greater with the indirect system than with the direct system; hence, in spite of the higher cost of an indirect unit, the total outlay on installation is practically the same for the two systems.

In installing lamps account must be taken of several conditions. Thus, for example, the lamp of choice should be that for which the price per unit of lumen-hour produced is the lowest. The presence in the field of vision of an unprotected light is inadvisable, for it would cause fatigue and even injury to the eye at work. However, it is very difficult to determine the degree of brightness of a light and especially the degree of malaise caused by a dazzled eye.

Brightness depends on several factors: the brilliance of the light, expressed in candles per square centimetre of the luminous area; luminous intensity of the light; its distance; the angle at which the light reaches the eye; and the degree of contrast between the light and its surroundings. Clearly, if all these factors are to be taken into account, any code of rules would become somewhat complicated; meanwhile, in practice a simple test is required which enables the question to be answered as to whether a lighting system is adequate.

In practice, it is considered, after taking account of the protection which the eyebrows and eyelashes afford to the eye, that the brightness of a light is much softened if it is placed relatively high. It has also been suggested that, unless light makes an angle of less than 30° with the horizon, it does not enter the eye directly. It is further estimated that the average brightness of the sky, which is about 25 lux per 61 sq. cm., should be considered as an indication of what brightness the eye can tolerate without injury, and that in no case should lights placed on the line of vision have a brightness above this limit.

**Globes and Reflectors**

The term *globe* is given to any spherical protector made of glass, whatever the type, which completely encloses a luminous source in order to limit its brightness and promote diffusion.

The term *reflector* is given to any apparatus applied to a light, enclosed possibly in a globe, capable of reducing the intensity or of modifying the direction of the rays from the light so as to localise the illumination. As a general rule every light used for localised illumination should be protected when its brightness exceeds 0.75 lux per square centimetre.

The common types of globes are of glass, either frosted, opal, opaline, white or transparent. Experts prefer "holophane" globes, made of small lenses juxtaposed which enlarge the image of the light, soften its brightness more than other globes, diffuse the light very well and only absorb 10 to 15 per cent. They also modify the direction of the rays in the direction desired. Globes combined with reflectors are unexpectedly found.

A special type of globe should be adapted to each type of lamp (cf. British Departmental Committee's Reports).

A *reflector* — a genuine industrial contrivance — localises the light and conceals its source, thus protecting the eyes. It causes diffusion of the illumination and the necessary modification of the polar curve of the light. The luminous field projected by a reflector is proportionate to the depth of the reflector, to the height at which the lamp is placed and to the surface to be illuminated from the source of light. A reflector should completely cover the lamp, should prevent light from striking the eye directly, and should send most of the rays in the right direction. And so it is seen that calculation of the lighting arrange-
ments and choice of adequate reflectors are matters for serious consideration.

For local illumination, a light of about 25 watts and not exceeding 50 watts is advised.

Reflectors may be made of enamelled metal, china or glass. In each particular case fittings, i.e. globes and reflectors, should be chosen which give the best coefficient of use.

Reflectors are also made of polished metal or silvered glass, and are often combined with a demi-globe of the holophane type, which acts as a diffuser for the lower hemisphere.

Of course the nature and reflective power of the walls and ceiling must be taken into account. But above all the rapidity of depreciation must be carefully calculated in order to use only lamps in the best working condition.

**NECESSARY ILLUMINATION**

A practical rule has been proposed that the amount of light necessary for a working place is a quantity such as will enable the workers to distinguish readily the objects on which they are at work at a distance equal to four times the "distinct vision" of each worker.

The natural lighting within any building may be defined as the "quotient of natural light" which, according to Weber, is the difference between the luminous intensity at a working place in a room and that existing at the same time out of doors. This quotient is also a fraction of the daylight which reaches the place in question and varies for different workplaces in the same room. The minimum quotient should not be less than 0.5 per cent.

As regards artificial light, the source should be placed in such a way that the angle of illumination is as great as possible, one of 30° at least according to Weber. In principle illumination should be such that work can be carried out without any effort, even if it is prolonged.

As regards a definition of "good lighting," the second report (1921) of the British Home Office Departmental Committee on the Lighting of Workshops and Factories considers the

---

**Fig. 3. — How work at a lathe should be illuminated.** The reflector covers the light source entirely and concentrates the light on the work at the point where it is most required. The worker's eyes are protected against dazzling from the source which is of maximum efficiency. It is also necessary to make sure that the light source is fixed in the best position and one which prevents discomfort to the eye from the dazzling reflection of polished surfaces.
following conditions very important: efficient and reasonably uniform illumination of the workplace, placing or shedding lamps in such a way that the light does not strike directly on the eyes of persons at work or when they look horizontally across the workshop; and the suppression of sharp shadows and of any moving light.

But the first report of this Committee, which appeared in May 1915, did not specify any standard of illumination required to enable a given piece of work to be done efficiently; it merely suggested what should be the standards of lighting necessary for the safety of workers in general. In its third report (1922), however, the Committee drew up a list of processes classified as "fine" (requiring at least 30 lux) and as "very fine" (requiring at least 50 lux). Nevertheless, these standards do not represent the minimum legal standards, but are only suggestions for the minimum necessary in practice, for easy and comfortable work.

A well-marked distinction should be a matter of fact made between legal minimum standards and those recommended; the latter being naturally higher than the former and such as cannot be found in practice in industrial lighting.

Then again these minimum standards are only rarely met with in factory legislation, legislation often laying down standards much lower than those used by employers in modern factories. On the other hand, the codes for industrial lighting prescribed by the United States fix standards for lighting for the different industrial operations. It is significant that in the last codes, three standards of illumination have been fixed, viz.: "a minimum authorised for work"; an illumination "recommended for good work"; and an illumination "recommended for good output"; this last being recommended for factories where the management wishes to ensure a maximum output with the minimum waste.

Broadly, it may be said that for rough work, e.g. forging or in foundries, 20 to 40 lux may be necessary; for work of a semi-fine nature, such as locksmiths, from 40 to 60; for fine work in adjusting, from 60 to 80; for very fine work on machines of great accuracy, from 80 to 100; for reading and writing, at least 30; for drawing, at least 70 to 100.

In the case of work on objects the colour of which is uniform the above-mentioned standards will be required; but for sewing on white, for instance, less will be required than for sewing on dark material, as allowance must be made for the reflecting power of the objects on which the light falls (see later).

According to the French Committee on Lighting the minimum for safety in the least-lighted part of any working place should be from 1 to 5 lux. A minimum at the level of the work is difficult to fix in an absolute manner, for it depends on the surrounding conditions and the nature of the objects worked on; but it should not be less than a hygienic minimum for the eye, that is, 5 lux. A list of minimum illuminations for different categories of work should be fixed, a minimum below which employers are recommended not to fail.

These minimum standards vary in the French list between 10 and 30 lux according to the industries and operations; 50 lux is proposed for weaving dark colours, for room used for dressmaking with dark materials, handling of hides and skins, in testing and verifying small pieces in engineering workshops, and in drawing offices. Even 80 lux is suggested for dressmaking workrooms where black materials are used.

Generally speaking, artificial light is not, at least in medium and large factories, below the physiological requirements of the eye. In conclusion the minimum illumination of workshops may be fixed at 25 and 30 lux for horizontal lighting if the lighting is by diffusion from the ceiling.

With other systems diffusers of large diameter, giving a brightness of about 0 to 2 candles per square centimetre, may be used. For delicate work and in schools an illumination is needed of 30 to 40 lux, and even of 50 lux if the work is of a dull hue and if the light is not diffused from the ceiling. When the work is of a dark colour a general illumination of 10 lux may be required and a separate lamp for each worker as well, fitted with a reflector, producing a brightly lighted circle in which the worker can place his work, surrounded if necessary by black screens. In this way it is possible to have perfect illumination for work, but the localised lighting should not be too intense if the room is dimly lighted.

Rational lighting at the present time is fixed with regard to the cubic space of a room, instead of with regard to the horizontal surface to be lighted.

**The Work**

An important part is played in the problem of illumination by the "work" factor, which is of importance from
such different points of view as size, colour and brightness.

The work should be lighted so as to permit easy working, in other words so that it does not strain the eye. But it is not possible to eliminate shadows entirely, for by so doing there is risk of eliminating the contrasts which are often necessary in judging good work. Shadows should, however, never fall on the lighted parts.

Granted that visual acuity is normal, for fixed work lighting will be adequate if a text in "diamond" type can be read easily in the darkest place, and the coefficient is low, more light must be provided.

If the work itself is of a bright nature, it is helpful to provide a background which is better lighted; but if the work presents a brightness below that of white paper illuminated by 10 lux, an illuminated background will be injurious to the eye. Any white brightness around the work often increases by a third the brightness of the work. If the work and the background are dark, a more powerful artificial light should be used and the workers should be supplied with black gloves to avoid the injurious effect of glare from the hands. On the other hand clothing should be light coloured, the presence of a light-coloured diffuser being useful at this distance.

A large background of brightly lighted white paper around the work greatly increases the visual acuity, if that is good, by about 1 for illumination above 10; but it diminishes it when it falls below 1, which occurs for work that has only little brightness. The same fact is noticed if a source of light with a naked flame is placed in the field of vision.

![Fig. 4. — How work at a lathe should not be illuminated. The lamp is insufficiently protected by reflector and the light strikes the worker's eyes instead of illuminating the work. Hence eyestrain and waste of light.](image)
A very important factor is a bright surface to the work. According to the law of equality of the angles of incidence and reflection, reflected rays reach the eye of the worker, who is thus exposed to rapid fatigue of sight and is no longer able to distinguish the details of his work.

INJURIES CAUSED BY BAD ILLUMINATION

The eye is adapted to sunlight, and it is hard to admit a priori that this light contains elements which are injurious to the organ of sight.

But there are special conditions of work or a particular state of the eyes, which render harmful some elements in sunlight and artificial light and require careful examination. This is dealt with in the article "Occupational Diseases: Eyes".

This article is confined to giving some consideration to accidents and the relation between lighting and their production.

From the point of view of industrial accidents, general, and injuries of the eye in particular, the facts available show the danger of insufficient or badly arranged lighting and the necessity for legal intervention.

The British Committee, already referred to, collected evidence which proves that during the winter months, owing to artificial lighting and the necessity for legal intervention, accidents are more frequently notified.

During the day and in parts insufficient, in 7.8 per cent.; bad in 3.5 per cent.; in parts good in 29.1 per cent.; insufficient in 18.8 per cent.; good in 32 per cent.; middling in 29.1 per cent.; bad in 3.5 per cent.; in parts good and in parts insufficient in 7.8 per cent.

In some departments of a factory the difference between the frequency of accidents which occur by day and those which occur by night is greater than in others. It is probable that this greater frequency of accidents during the night period is associated also with the factor of fatigue, which workers on night shifts experience more readily; but it should be noted that no exhaustive enquiry has yet been made into the subject.

As a result of an enquiry dealing with 466 factories, Fisk was able to show that the lighting was excellent in 8.7 per cent. of works; good in 32 per cent.; middling in 29.1 per cent.; insufficient in 18.8 per cent.; bad in 3.5 per cent.; in parts good and in parts insufficient in 7.8 per cent.

Radermaker studied the lighting arrangements of 390 American factories and found that only 15 per cent. had good lighting, 29 per cent. had average lighting and 56 per cent. bad lighting. At a recent American Congress it was recorded that out of 91,000 industrial accidents 24 per cent. were due directly or indirectly to insufficient or inadequate lighting. More recent statistics give a proportion of 1 accident in 8.

It is estimated that 250 million dollars are spent yearly in the United States on industrial accidents, of which more than 50 per cent. could be avoided. Among these accidents eye lesions claim a percentage of 8.3. As a matter of fact it is calculated that eye accidents number 200,000 yearly, and that 15,000 blind persons owe their misfortune to an accident whilst at work; this represents 13.5 per cent. of the total of the indemnities paid for accidents in general is 13,332,220 dollars.

In a report presented to the Illuminating Engineering Society of the United States, Dimson mentions that according to the Travelers Insurance Company, out of 91,000 accidents notified during the year 1910, 23.8 per cent. were due to imperfect lighting.

In conclusion, some insurance office experts estimate that 25 per cent. of accidents are connected with insufficient lighting; but it should be noted that no exhaustive enquiry has yet been made into the subject.

On the other hand, researches relating to the effects of lighting on visual acuity and the discrimination of details and eye strain have been keenly pursued. With this object in view there has been measured the time required for recognising a black spot on a white ground while varying the luminous intensity. The time diminished 33.3 per cent. when the lighting changed from 30 to 100 lux and 60 per cent. when it changed to 900 lux.

Speed of discrimination showed still greater variations; for the time diminished 37.5 per cent. when the lighting changed from 30 to 60 lux and 67 per cent. when it reached 120 lux. These are rates for normal individuals; astigmatic subjects showed a more considerable diminution.

The effects of lighting on eye strain have been measured by means of a vision test lasting three minutes. Eyestrain during continuous vision causes vision with blurred details. The estimate was established by comparing the time of dazzled vision with the total time, under varying degrees of luminous intensity. The comparisons obtained have been in normal subjects 32 per cent. with 30 lux; 29 with 50 lux; 5 with 120 lux; and in astigmatic subjects 38.32 per cent. and 12 per cent.

The problem of lighting is still more important at the present time, if regarded from the point of view of increasing industrial output. A long series of experiments has shown how much it is to the advantage of manufacturers to light their factories properly; output increases from 10 to 24 per cent., which compensates largely for the expenses of putting in a good system of lighting; work is more accurate and careful; accidents are less numerous; waste is reduced; supervision is easier; the work-
place is cleaner and better kept; the operative works contentedly because he is working under better conditions.

It may be useful to quote some of these experiments.

In analysing simple manual operations, such as are met with in practical industry, W. Ruffer has shown that increase in illumination always leads to increase in output which varies naturally with the kind of operation. This increase is always pronounced as the standard of illumination rises from 25 to 100 lux, and is often considerable when it rises beyond 100 lux.

In 1921-1922 the American Board of Industrial Hygiene undertook some researches of vast scope in a number of post offices, with the object of determining if improvement of lighting in letter-sorting rooms increased the output of 4,800 persons employed there. Those who worked with the old system under poor illumination showed defects of vision more numerous than those who worked under more intense illumination. Rapidly in executing work was greater in proportion as the lighting was more intense. The increase of output was 4.4 per cent. when the average illumination was increased from 36 to 80 lux; the change represents for the Post Office an annual economy of more than 100,000 dollars, after taking into account the expenses of altering the lighting system.

In a workshop for testing pieces of machinery an increase of output with a new scheme of illumination, wherein 130 lux and 200 replaced 50, was respectively 12.5 and 8 per cent. Good lighting then increased the output by 12.5 per cent. for an outlay of less than 2.5 per cent. of the wages.

Finally there need only be quoted the experience of an American employer who has given his results in an article entitled “How We Have Increased Our Output by 25 per cent. by Improved Lighting” (1923), and obtained an increase of 13 per cent. on the output with a lighting of 60 lux, of 17.9 with one of 90, and of 25.8 with a lighting of 140 lux. The increased cost was only 2 per cent. of the wages.

Thus it cannot be denied that the beneficial results of the increase of output exceed by a great deal the cost of improving the lighting. Experts have easily shown that an average increase of output of 15 per cent. can be obtained at the price of an increase in expense equal to 2 per cent. of the wages; that is to say, the work of two men out of a personnel of 100 was sufficiently good to produce as much as 15 of their fellow workmen. Or, if it is preferred, the saving is effected of 8 minutes a day per workman as a consequence of better lighting which reimburses the total cost of the lighting.

The construction of a curve of variations in the expense of lighting used for illumination, shows that it is possible to carry the lighting from 20 to 80 lux by simply multiplying the expenses by three.

LEGISLATION

In order to establish a scheme for illumination the standard of the illumination necessary must be decided first of all; then the system of lighting must be chosen and the installation which is best suited to the place and to the processes which are to be carried on there; the height for hanging must be decided, the spacing and the number of lights required; while the power of the lamps to be used in the installation must also be calculated.

An expert well up in the technique of lighting is able at the same time to give the necessary advice for arranging an installation which satisfies both the requirements of hygiene for the eye and also the technique of lighting.

Propaganda for good lighting and good hygienic conditions for eyesight should be carried out among managers of works and workmen. It has developed of recent years and numerous pamphlets, tracts and posters have been published on the subject.

Without giving here the exact wordings, which are rather long, it may be stated that notices have been drawn up by the Illuminating Engineering Society of London, and that English, German and French posters exist which give the workers advice on the hygiene of vision, and on first-aid in case of accident to the eyes.

The question of making regulations is complex. Legislation was confined at the start to making regulations for the lighting of schools, and even that is not universal. As regards factories and workshops the law is often confined to the
in which the object is to ensure the maximum output with minimum effort. The Standard Code for Industrial Lighting prepared by the American Association of Illuminating Engineers in 1915, after having undergone a first and slight modification in 1918, was reissued in 1921. During these thirteen years the Standard Code was adopted as it stood, or with modifications in detail, by eleven American States. A new edition was published in December 1928 which gives in the first part the objects of the Code, its field of application and the minimum standards for places of work, for yards and passages; for work requiring vision essential for details, for vision less essential, very essential, and non-essential; and for vision for very small details. In the second part information is given on points raised in the first part, as well as the standards to be recommended for certain operations or industries. The third part is devoted to the benefits of good natural or artificial illumination and its economic advantages.

Industrial Physiology

GENERAL REMARKS

Industrial physiology constitutes at the present day one of the most important fundamental facts, if not the essential fundamental fact, of the scientific organisation of industry. Physiology and technique must be studied with a view to ensuring that human energy is used to the best advantage in the service of society, and with the least possible harm to the individual, who should thus furnish a maximum of production with a minimum of fatigue.

With the modern development of industrial machinery, the technique of human activity, whether it be some industrial tradition wholly manual or nearly so, has to be transformed and adapted to the new conditions of production. But the aims of organisation seem to have been limited, until quite recently, to technical problems connected with the construction of machinery and the organisation of business establishments; and, while the great progress of mechanism has caused these problems to be regarded as constituting the primordial element in production, the role of the human factor has been deemed to be of less and less importance, in proportion as the power of motors and mechanical tools has developed.

Although the necessity for studying man's capacity for work has only quite recently been recognised, it must not be forgotten that the physicists of the seventeenth century had actually turned their attention to determining mathematical formulas for maximum activity (La Hire, Amontons, Vauban). Later Coulomb collected the first data dealing with fatigue, by studying the value of, and the comparison between, the consumption of energy by studying respiratory exchanges. Lavoisier was the first to establish the relationship between oxidation in the body and the production of force. Chauveau, as well as other experts, followed this up at the end of last century.

During the war, the necessity for intense and continuous production, invested the physiological problems of industry with an importance which has not yet ceased to increase. Even technical exponents of Taylorism pure and simple realise that the mechanical and technical side of scientific organisation of industry is no longer sufficient. The problem of the organisation of industrial production is recognised to be definitely bound up with the problem of diminishing the functional strain experienced by manual labourers, who govern and control this production.

For this reason certain data which seemed to be definitely established are being revised to-day. Even machines which are looked upon at the present time as having been brought to the highest point of perfection seem to need revision as regards principles of construction in order to be better adapted to the men who tend them, for it is recognised that adequate modification of means of control and of driving-wheels can lessen the fatigue experienced by the men who supervise the starting or running of machinery.

The domain of industrial physiology extends further than the execution of work properly so called (motor or intellectual action), and is concerned with all the immediate or mediate conditions relative to work: the factors of work; the environment; the personal element, both physiological and psychological; and so-called social factors. All these conditions play their part in influencing the organism, and may in some way control aptitude for work, output and fatigue.

The aims of industrial physiology are essentially practical. It must respond to the calls which are made on it by industrial life and must elaborate measures which will ensure the greatest efficiency for the human machine. These ends can only be attained if there exists preliminary knowledge, far-reaching and accurate, of the mechanics of bodily activity. Industrial physiology relies on such solid facts as physiology, pure and simple, has been able to establish; but, in the face of new problems, it is often obliged to adopt for itself theoretical foundations suited to practical exigencies. Thus it is necessary to review the theoretical aspect and the practical aspect of industrial physiology.

THEORETICAL CONSIDERATIONS

The researches carried out up to the present have been concerned chiefly with physical work, for the very sim-
ple reason that our knowledge of this form of activity is relatively more extensive than of the processes which are at the basis of psychical work. And so in what follows there is chiefly in view activities which have for their basis the action of muscular force.

The functioning of the human machine is dependent on its physical structure, on the anatomical and morphological factors of the body, and on the available energy which is supplied by combustion within the body of the hydrogen and carbon contained in food. Part of this energy serves for performing work; the rest is used for maintaining the body temperature. Food is burnt up within the body by the respiratory oxygen, combustion of which is controlled by the rate of the organic processes. Thus by material, or, better, by their true calorific power, which is lower than the heat of combustion, since food is not used up absolutely, depending upon the coefficient of digestibility.

In the human and animal economy muscle is considered as the motor, while power is that of contraction, whether it maintains a load in equilibrium without movement (static effort) or whether it causes movement (dynamic work, movement or resistance).

The researches of Fletcher, Hopkins, Meyerhof, Hill and Embden have made fairly clear what processes lie at the basis of the shortening of muscle fibre.

studying the chemistry of the respiratory gases there is provided a means of observing the extent and variations in these processes. Without going into the problem of food, which will be dealt with separately, it is enough to bear in mind that the energy value of food is measured by the heat of combustion, i.e. by the number of calories developed by the combustion of a gramme of the a matter of fact, physically, there is only work when there is transformation of potential energy into kinetic energy; whereas physiologically even if there is not this transformation of energy, there is consumption of energy. Thus a muscle fixed in contraction does not develop kinetic energy, but is a manifestation of so much work (Allers).

lactic acid, by an unknown mechanism, causes shortening of the contractile elements of muscle; this view is, however, disputed by Embden.

In the second phase which precedes relaxation the lactic acid combines with alkaline proteins. In the final stage a small part of the lactic acid is burnt up, whilst the greater part is used afresh for the synthesis of lactic acidogen.

The thermic activity of muscle is similarly characterised in the three stages by the liberation of heat. The researches of Hill have shown that the quantity of heat given off in the third stage, that is to say, during the oxygenating or rebuilding process (Erho-
Effort by all the muscle fibrils that the yield undergoes no loss. Another source of loss of energy is that muscles which are fixed to parts of the skeleton by their tendons have to overcome the resistance of friction arising from movements of the limbs. The processes of stabilisation and balancing the body involve loss of energy. When lifting weights not only does the requisite group of muscles come into play, but also their antagonistic muscles. Whereas dynamic work requires relatively few muscles to be brought into action, static work brings into play a comparatively greater part of the total musculature, in order to fix and immobilise certain parts of the skeleton so that the body may be placed in the most favourable position for work. Further, balance must be so maintained as to prevent any loss of effort.

This yield must be regarded as theoretical, for it only refers to a fictitious contractile element, wherein there is no loss of energy during the transformation. In reality contraction uses up a certain quantity of energy in overcoming the viscous resistance of the contractile element. Hence results depreciation in the theoretical yield.

Passing now from isolated muscle fibrils to the muscle as a whole, it is found that the theoretical yield undergoes a further depreciation, because some fibrils do not take an active part in the contraction, but are involved passively. It is only in a maximum equilibrium. And lastly, account must be taken of the amount of energy needed to move the weight of the body itself (see also article "Effort").

An important task for industrial physiology is to determine the value of these different sources of loss of energy for different kinds of occupational activity carried on by the human machine. The problem is solved by splitting up the entire yield of the human machine into its separate component parts.

A little reflection shows that the general effect of all isolated activities is the same as that of the total activity. If in a case of poor total yield, the

(The four diagrams of each group correspond to a load of 10, 12, 14 and 16 kg. respectively.)
The economy of work is to be increased, simple consideration of the facts shows that high component yields do not need to be improved, but that poor ones do. The nature of this splitting of total activity into its elements and the practical consequences are phenomena which have been demonstrated by Atzler, Herbst, Lehmann and Müller in the operations of weight carrying and of working a crank handle.

The discussion so far has not dealt with the influence that training or practice (Ubung) may exert on the value of the total activity. Everyone knows by experience that an act which can only be accomplished with difficulty when there has been no training, can be accomplished more and more easily, and finally become as child's play, as practice gradually increases. Chauveau has shown that output im-

![Image](https://via.placeholder.com/150)

proves with continued work, just as with increased speed and dividing up the load. If the external work done at the same expenditure of energy is compared on successive days of practice, output is found to improve with practice, until finally, when training is complete, it attains a maximum value which thereafter is steadily maintained. The muscle fibre has now become more easily stimulated; the nerve cells and nerve fibres are more excitable; and starting is less onerous. But this economic improvement must be attributed principally to an adequate adaptation of the system of innervation. The difference be-

between a trained subject and one who is not trained is that useless accessory movements are eliminated in the case of the former. His muscles, when taking part in the execution of a premeditated act, contract under the influence of the nervous system in the most favourable succession and with an optimum intensity. The performance of a co-ordinated movement depends upon the fact that the sensory apparatus takes its part as the organ of control and modulation. In addition to this sensory-motor regulation, the deep reflexes, studied by Paul Hoffmann, exert a great influence upon the performance of finely differentiated co-ordination of the movements. If, for example, a sharp increase of tension is caused in a muscle, a contratension is caused on the arc of the deep reflex. In this way inequalities in the sequence of a movement are compensated. These special reflexes, in addition to those of external origin, are invested with the duty of facilitating the precise performance of a premeditated movement.

Reference may here be made to one form of these reflexes of external origin, viz. the reflexes of position, studied by Magnus and his pupils, which are of great importance for the maintenance of position at work. In an untrained subject, all these reflexes are under the control of the higher nerve centres. As training proceeds, the paths of the reflexes become more and more definite with the result that
it becomes impossible for any to leave the path, and movements become more and more automatic. The higher centres are thus freer in their work and can devote themselves to meet all the difficulties connected with that effective modulation of movements admired in trained workers.

With the onset of fatigue the style of movement loses its co-ordinated character, and the work of a trained subject degenerates into the type of work of an untrained subject. Fatigue is characterised manifestly by the fact that certain nervous mechanisms which overlap one with another are no longer functioning correctly. It cannot be yet said, at the present time, how these disorders arise; some speak of exhaustion of energy-carrying material, others of the accumulation of such waste products as acids and toxins which exert an inhibiting function.

While these phenomena may be produced in an isolated muscle, which can be fatigued by a series of stimulations repeated over a long time, the conditions connected with the production of industrial fatigue are essentially much more complicated. The operations of work require the participation of the central nervous system, of the peripheral nerves, the terminations of the motor nerves, and of a series of muscles, and of reflex arcs. It is not possible to analyse beforehand the part played in work by each of these different components. A special complication arises from the intervention of psychic factors, the influence of which on the shape of work curves has been especially studied by Kraepelin and his students. Mere mention may be made of the antagonising influences of fatigue and training, of habit, of stimulants (Anregung), of different kinds of incitements (Antrieb) and inhibitions (Hemmung). The conditions are rather simpler in kinds of work where the higher centres take only a very small part, as for example in monotonous work. In this instance the higher centres only intervene when certain disturbances arise during work, as for example diminution of attention. This relative diminution in complexity of automatic movements enables, as will be shown further on, the problem of industrial fatigue to be grappled with in an experimental manner. These investigations should preferably be extended to those forms of automatic work that are frequently met with, especially in modern factories. It includes movements of small and active muscles, which are limited to a restricted anatomical field, and very active nervous processes which are brought into play for the execution and accurate co-ordination of the necessary movements. Knowledge gained in the sphere of labour shows that these kinds of movements easily lead to manifestations of chronic fatigue and ought to be held responsible for the actual waste of energy.

A series of accessory mechanisms sustain the processes of work, properly so called. Accumulation of carbon dioxide due to muscular activity, as well as diminution in the quantity of oxygen in the area.
surrounding the muscle fibres, render an increase in blood supply necessary. Under the influence of acid products of metabolism, there occurs dilatation of the arteries and capillaries in the muscles at work (Caskell, Atzler, Lehmann, Fleisch); even capillaries, which in a state of rest are closed, become dilated (Krogh). Vascular areas which supply less important organs become constricted, so that an increased blood supply may be directed to parts in an active state. In arduous feats, such as are seen particularly in sport, after the "dead point" has been passed, the vessels of the kidneys and intestines are almost drained of blood. The volumes of the blood stream per heart contraction and per minute show an increase depending on the intensity of the work. If the volume per minute increases more quickly than the peripheral resistances in the arterioles diminish, an increase in arterial pressure is observed, which, in consequence of the increase in the potential pressure, leads to an acceleration of the blood flow. All these processes, which have for their object an increase of the nutritive exchanges in the working muscles, are only crowned with success when the pulmonary respiration is increased. Only so is there possibility of a more active exchange of respiratory gases than during periods of rest. As a result, the same stimulus which acts on the vessels, that is an increase in the oxygen tension of the blood, stimulates the respiratory centre in such a way as to increase the pulmonary aeration.

### Practical Considerations

People in general expect from the human machine as high an output as possible; but they should study the question of maintaining capacity for output at as high a level as possible, without decrease, during many years. These two requirements are in apparent contradiction. If exertion is daily required from a man exceeding the measure of his capacity for output, fatigue products accumulate in his tissues and there cause premature wear and tear. It is the task of industrial physiology to find the golden mean, steering between these two extremes.

The solution of this problem is possible by organising any work which is aimed at, so as to obtain a maximum production with a minimum of effort. Taylor, in the system which is named after him, aims simply and solely at maximum output, without taking into account the consumption of energy by the human machine. In contrast to Taylor's system, the physiology of work seeks optimum output.

Industrial physiology has a threefold duty to perform in order to make the best possible use of man's strength:

1. The right man must be in the right place.
2. The work required of the human machine must be such that it gives a maximum production with a minimum expenditure of energy.
3. Overstrain must be avoided.
In addition to these conditions, a large number of others must be realised in practice in order to obtain a better output in industry and agriculture.

Scientific management presupposes that a correctly organised establishment has at its disposal adequate man power, and that this power is appropriately distributed. Just as technical psychology has worked out a number of tests in order to discover the psychological aptitude of a candidate for a chosen career, in the same way industrial physiology is establishing a whole series of methods which enable either the physical aptitudes of candidates to be determined for work, whether strenuous or not, or the fitness of a subject to be detected for hard work of short duration, rather than for lighter work of long duration.

Selection of workers, carried out by these methods, removes all difficulty from utilising to the best advantage the physical powers of a worker who is fitted for a given task. Thus it lies with industrial physiology to establish for each occupational process conditions under which the human machine functions in the most economical manner.

All industrial and agricultural work can be reduced to a comparatively small number of elementary movements. In this way thirty to forty simple elements are obtained, combinations of which permit all movements, even the most complicated, most favourable conditions are those in which a given external task, say a kilogrammetre, is effected with a minimum expenditure of energy by the body. It is then that the body works at an optimum output.

As regards the human machine there must be distinguished "the industrial or gross output", which is the relation between the energy used and the total static and dynamic energy, from "the net output", which is only concerned with dynamic expenditure alone (Amar).

Accurate determination of net output is rather difficult to make on account of the numerous variations which come into play. The results vary greatly.

There may be mentioned by way of example, the turning of a crank-handle, the lifting of weights, the actions of pulling and pushing by hand, either in a vertical or horizontal direction, and that of pushing or pulling loads or wheelbarrows. Examination of the elementary movements involved enables the optimum conditions necessary for practice to be determined.

The amount of energy expended, as well as the amount of external work done, gives a clear perception of the economics for the type of work under consideration. If the external work, that is mechanical work, is divided by the expenditure of energy expressed in kilogrammetres, the total yield of the human machine for the work in question is obtained. Among the different variations of a factor of work, the

one from another, according to numerous investigations; but generally an average of 25 per cent. is accepted (Amar).

Practically, it is the industrial output of the group of acting muscles which gives the actual output and is alone of interest. It varies from 4 to 10 per cent. according as the quantity of daily work increases, and attains with difficulty 16 per cent. (Amar).

It should be noted at this point that the power exerted by a muscle is a function of its mass, i.e. its active fibres, of its degree of contraction, and of the angle that its direction subtends with that of the bone to be moved. The absolute force of muscles varies, however, according to the muscles considered; but the average force is about 75 grm. per square millimetre of section (Amar). Numerous researches and measures have been made to determine the maximum value of the force, either of pressure or traction, which man can develop with his muscles. For an adult man the average value seems to be 150 kg.; and half that for a woman (Amar). Nevertheless, the exercise of force depends first and foremost on the nature of the work and the number of alternate contractions; further, the maximum rhythm of the contractions varies for different muscles and articulations.

### A Type of Physiological Investigation

A simple example, taken from weight lifting, will illustrate the technique of the researches. The task consists in grasping with both hands a weight which, according to the experiments, is at different heights from the base, in lifting it to a fixed height and then lowering it. By varying the height from the base, and the height to which the weight is lifted, as well as the heaviness of the weight, the following results have been recorded:

The heights at which the weights were placed before being raised were 0, 50, 100 and 150 cm. above the ground. Starting from 0 m. the weights, as shown, were lifted to heights of 50, 100, 150 and 200 cm. As the starting heights were further from the ground the maximal heights to which the weights were lifted were naturally lower. The consumption of energy, stated in small calories, is calculated in relation to 1 kgrm. as the unit of external work. The subject under observation works under best conditions when he lifts a weight of 13.85 kg., placed at a height of 1 m. above the ground, to a height of 50 to 100 cm. The figures of the table also indicate that output is worst when the height from the ground is nil, that is to say when the subject is obliged to stoop.

Thus this example shows that by comparatively simple corrections in methods of work it is possible to increase output considerably.

When lifting loads it is not always possible to command optimum conditions of work, which, according to the preceding description, are forthcoming for a healthy man of average height when he has to lift through 50 cm. a weight of 14 kg. placed at a height of 1 m. Therefore, tables from which to calculate must be drawn up, and adapted to the variations of the practical conditions.

The case of having to lift objects for a certain height starting from a definite distance from the floor will recur very often. The worker has moreover the possibility of easing his task by lifting at once a larger or smaller portion of the load. The rationalisation tables should make it clear what load should be chosen given a larger or smaller portion of the load. The figures in italics, which correspond to
optima weights, figures are given in brackets which show, in small calories, the consumption of energy per kilogramme of external work. The smaller is the expenditure of energy, the better do the conditions of work adapt themselves to the human machine.

These figures show that the subject under observation works under the best conditions when he lifts a load of 15.8 kg. placed 1 m. from the floor to a height of 50 cm.

In the same way, starting from table I, other tables can be calculated, giving the best height from which to start, as well as the most suitable heights to which to lift.

The lifting of loads represents work which occurs very frequently in practice, in connection with transport, warehousing, and building. Clearly, in an industrial process so important, which is repeated so often, a comparatively small improvement in economy is of great social value. As numerous researches have shown, the "flair" of the individual should never be trusted, for the most favourable conditions of work, especially in complicated operations, can only be ascertained by scientific analysis carried out in the way indicated.

Similar research has been carried out on weight-carrying by Miss Bedale at the request of the Medical Research Council (London). Miss Bedale found that loads should be carried, as far as may be, in such a way that the body is displaced as little as possible from the normal vertical position. Thus, for example, carrying buckets and similar loads with a yoke causes the least displacement of the body; and, as a matter of fact, by studying respiratory exchange this method of carrying loads was shown to be the most economic. On the other hand it is slightly less economic to carry the load as two small sacks, one in each hand, as the body has to resist considerable swaying. Carrying weight on the back in a rucksack or haversack is also much in favour. Although this method, considered simply from the viewpoint of energy, may be considered disadvantageous, it has to be employed whenever the hands are required to be free for other purposes. Carrying loads on the head is not very advisable, for the muscles of the neck have to maintain a very strong balancing movement.

Some recent work done by Prof. E. P. Cathecart, in collaboration with Miss Bedale and other investigators of the Industrial Fatigue Research Board, and Dr. S. G. Overton, Medical Inspector of Factories, has been published by the Medical Research Council.

The investigations dealt with the work of women and the result has demonstrated that the optimum load for continuous carrying is equivalent on an average to 35 per cent. of the body weight. This proportion is somewhat comparative, for the percentage depends in a considerable measure on the way the load is carried. In practice a figure of 40 per cent. of the body weight for continuous carrying is generally accepted and 50 per cent. for occasional carrying, which signifies, when expressed in concrete figures, loads of 45 and 55 pounds respectively.

As regards continuous carrying it seems possible to go up to 50 pounds without fatigue with an extra load of 20 per cent. when it is compact, easily handled and does not embarrass walking or the normal position of the individual.

With reference to adolescents these figures have to be reduced as their bodily resistance is less on account of the period of growth. Thus, for continuous carrying, which is particularly dangerous on account of the malformations it may originate, the figures given by Cathecart and his fellow-workers have distinctly lower values. For young girls of fourteen to sixteen years of age, the maximum weight should not exceed 25 to 30 rounds, and for young girls of sixteen to eighteen years, 40 pounds.

Patrizi, of Bologna, has made investigations on carrying luggage in the hand and on the shoulders with a view to detecting signs of fatigue as soon as they appear. These researches deal chiefly with manifestations found in the circulatory and respiratory systems. This Italian expert prefers this method of proceeding to methods which deal with the muscular system, for the heart and lungs are organs which show, practically instantaneously, the least signs of fatigue. The investigations of Patrizi have shown that unilateral loads cause, in the first place, acceleration of the heart and of respiration, whilst methods of carrying loads with the weight distributed symmetrically on both sides of the body have less effect on the cardiovascular and respiratory manifestations of fatigue. The first investigations undertaken did not reach the limits for mean weights to be fixed. However, it was found that a moderate load of 22 kg., not more than a soldier's pack, when carried firmly on a level road, especially if the load is distributed asymmetrically from the beginning, causes reactions which can be detected in the systems mentioned. Thus it is possible to advance certain general proposals, under which the question of weight carrying needs to be fundamentally re-
considered; they would necessarily lead to a decided diminution in the weights which have hitherto been accepted by tradition and established by an empiricism which may be designated "physiological agnosticism". (See also article "Transport Industry".)

CONCLUSIONS

Speed, in many processes, plays an important part in the problem of economy. Thus, for example, with the crank handle 35 rotations a minute, with a spade 17 to 19 thrusts a minute in shovelling, and with a pick 25 to 30 blows a minute, form the optimum.

In this way systematic study of thirty to forty elementary movements in all directions is necessary. Here is a task which can only be carried out by years of assiduous work.

The three diagrams of each group correspond to tables gradually built up will constitute a sure basis for rationalising all human work. Whatever methods of work may develop in the future, it will always be necessary to grapple with the elementary movements in order to organise rationally methods for highly complicated movements. But it is certain that the technique will be simplified by the rules which science has provided. Among these rules, valuable for general application, may be mentioned the following:

1. The musculature called into play on a piece of work should be exactly related to the mechanical work demanded. For strenuous work, powerful muscles must be called on; for light work, less powerful muscles. Example: a bicycle, driven by the strong muscles of the leg, is more adapted for transport than is the invalid chair, propelled by hand.

2. For prolonged work with the body continually in movement it is necessary to choose muscles presenting a comparatively strong index of inertia.

3. Body movements without exterior effort must be slight. Example: work with a windlass is much more economical than with a lifting jack for performing the same mechanical work.

4. Intermediate movements, on the other hand, must not be completely suppressed, and for a good reason. The musculature, as a matter of fact, rests whilst intermediate movements are being carried out. If the proportion of the movements with no effect on the total work is too small, in consequence of exaggerated effort, the muscles work in an uneconomical manner and become rapidly fatigued.

5. The operations of work must be conducted in such a way that the least possible amount of energy is used up. It is much better to do the same mechanical work with a windlass than with a lifting jack.

6. Rhythm in work should be left without constraint. It is generally much better to work rapidly and to interpose long rest periods than to do the contrary. Air hunger, cardiac palpitation and elevation of the body temperature during work of long duration are, in a healthy individual, danger signals, indicating that rhythm has been too rapid, or effort too great.

7. Consumption of energy in maintaining a posture necessary for work should be reduced to a minimum. Examples: (a) when work is done by the arm or hand, whenever possible it should be done sitting; (b) when the arm has to be
extended for a long time, it should be supported.

8. In repetition work the muscle group concerned should be made at stated intervals to rest by putting into action another group. The blood circulation in this way is activated, and fatigue retarded. During manual work it is recommended to get up from time to time and prepare other material for treatment.

9. Static work, e.g. supporting weights and working in a bent position, must be as far as possible entirely eliminated, for in this condition circulation of blood to the muscles is almost arrested.

10. Loads should be carried in such a way that their centre of gravity is sustained vertically on the supporting surface of the body. Example: small modern handbags are much more suitable for carrying equal weights, than the old kind which were so awkward.

11. Clothing must not interfere with any movement. Clothes which are too heavy entail a useless consumption of energy.

But even if the use of these rules for the simplification of work is a means for retarding in the most natural way the onset of fatigue, it does not exclude a study of fatigue itself. It is far more important to establish the limits to which work, simplified in the way indicated, can be carried out, without incurring danger from premature exhaustion of the workers. This result can only be obtained if success in detecting with extremely delicate methods the first appearances of fatigue is attained. Complicated mechanisms, as has been seen, take part in the performance of a co-ordinated movement, and the onset of fatigue is of great import in disturbing this co-ordination. By motion study and especially by the taking of cyclograms, it is possible to observe, particularly in the case of automatic movements, the decrease of fatigue. In the same way the degree of fatigue from certain elements of typical movements continuously repeated can be determined.

The above are some of the problems which industrial physiology has to solve. But those which present themselves for study are, as is well known, the same problems studied in human physiology, e.g. dietetics, circulation, respiration, nutrition properly so called, related functions and body heat.

All these questions are worth far-reaching analysis, while taking cognisance of factors arising from the exercise of occupations, factors connected with the work itself, with the environment and with the personnel.

Among factors of work may be named the duration and intensity of work, the distribution of the work timetable, rest pauses, overtime, work at night and on Sundays. Among factors relating to the kind of work may be cited manual labour, semi-automatic, mental or physical work, its speed, rhythm, or monotonity. Questions of position at work, whether standing, or sitting, or both alternate-

(C) Height through which lifted: 50 cm.

(Same weights for the three diagrams as in the preceding plates.)
ly, and of adapting machines and tools to the workers, are also of the greatest importance.

The environment of work in its turn, includes physical factors and economic and social factors. Among the first may be mentioned the temperature and humidity of the air; the movement and composition of the atmosphere; ventilation and heating; the cubic space of the workplaces; lighting and illumination; noises and vibrations. Among other factors are included: the maintenance of output; wages which act as stimulants to speed and quality in work; other advantages, financial and otherwise, such as paid holidays; discipline; the spurt, the amount of work to be done; the various problems involved in recruiting staff (see all relative articles as well as "Welfare Work" and "Scientific Management and the Human Factor").

Personal factors are no less important: type of workers, race, sex, age, physical capacity and resistance, and liability to fatigue, as well as pathological factors which being on the border line of disease are difficult to diagnose, but generally constitute the first effects of fatigue.

The study of industrial physiology must also be engaged in in common with psychology, as has been clearly seen from what has been already said.

The social side of industrial physiology must not be forgotten. This is all the more important in that fatigue and exhaustion cease to be individual phenomena and involve the workers collectively. Bodily weakness of the working personnel involves deterioration in the quality of work, and diminution in the quantity, and, in addition, a great number of absences from sickness, diminution in the average duration of life, and collective unrest which disturbs the relations between employers and employed, and, as a consequence, increases social expenses (Tréves).

For many years statistics of insurance societies, as well as official statistics, have emphasised the serious morbidity among certain categories of workers, as compared with the average for the whole population.

Physiology has suggested the best means for putting into effect social prophylaxis; and study of the human machine has enabled physiological laws to be fixed. Full advantage from innovations in time-tables and wages can only be realised, if at the same time capital is invested in technical improvements and in the hygienic organisation of workplaces. Then again, reduction of working hours should be carried out progressively in order to enable workmen to adapt themselves to a new state of things without upsetting the even tenor of their lives. At the same time adequate educational and social institutions should be provided so that they may be able to use their new leisure in the best way.

As regards wages, experience shows that a scale of wages once gained seldom diminishes, except under exceptional conditions. Industries, in which the strong and skilled worker is appreciated, sacrifice, in times of crisis, part of their profits rather than interfere with the fundamental principles which are at the base of their workers' capacity for labour.

Thus industrial physiology teaches far deeper lessons than would appear at first sight. Its field of action is continually increasing. It is proving that psychological, physiological and economic assets are closely interwoven and that if they are well established, with a sufficient margin, they inculcate in the working class an increase of the idea of its own self respect and of the whole of that moral attitude which plays such an important part in the intensity of production, the creative force of which, as Tréves says, is sometimes much more important than capital itself.

BIBLIOGRAPHY

LEHRMANN, in Pfliigers Arch., Vol. CXI, pp. 118; Vol. CXIII, p. 464; Vol. CXIV, pp. 266 and 221.

The discharge of industrial waste water into rivers may be instances; it may cause deposits of mud which may make navigation difficult, and is often accompanied by exhalations of nauseating smells, or it may hinder the action of natural purification by the presence of antiseptics, or poison the fish by the toxic substances which it contains; it may in fact render the water of these rivers unusable for all purposes, sometimes over very long stretches. Experience indeed shows every day in an indisputable fashion that the discharge of industrial waste water is the principal factor in the pollution of streams.

The elaboration and the application of laws and orders regulating the discharge of these waste waters are very difficult, as the modifications of these laws and orders, which are everywhere continually required, show; also the policy followed by the responsible authorities varies in different countries.

The factory owner should understand that he has a double duty to fulfill: to avoid the pollution of streams and to carry on industry. Economically, there would not be any difference between them if he considered the treatment of waste water as being part of the work of the factory, and if he dealt with it by the same methods he employs in the manufacturing processes.

The war showed in many cases the waste to which we are accustomed, as much in domestic life as in industry. It is certain that many processes could be carried out more economically and numerous by-products recovered.

Thus water, when it is in abundance, is used without care. Washing is almost everywhere carried on in a routine manner, whereas the chemists knows that small volumes suffice when employed in small quantities often repeated. In this way sometimes a part of the product is allowed to be lost and goes to fill up and pollute the rivers. Sullage water, submitted to purification or simply decanted, can be used over again, sometimes with the advantage that, through the concentration which ensues, it is possible to recover with profit certain compounds and so diminish to a considerable extent the expense of purification.

Before undertaking the study of the treatment of industrial waste water, the process used in the factory should be first examined to ascertain if the products employed have acted usefully and thoroughly, if the yield of the manufactured product is in accordance with the theory, and if all by-products which are usable or for which a use can be envisaged have been extracted. Methods of work will arise from such a study which will sometimes abolish any need for discharging waste water and will almost always diminish the volume and facilitate the treatment.

OBJECTS AND PROCESSES OF TREATMENT

It will be understood that treatment must vary according to the trade and even in a particular trade according to the factories. The ends to be attained are:

(a) retention as complete as possible of solid suspended materials;
(b) suppression of acidity and substances poisonous to human beings and to animal and vegetable life;
(c) reduction to a reasonable strength of alkalinity and organic materials.

The treatment of trade effluents varies according to their composition and the degree of purification which is required and can be carried out by (1) mechanical, (2) chemical, and (3) biological processes.

Industrial Waste Water
(Treatment of)

Mankind in its evolution towards improved conditions of living has transformed the conditions of existence. In order to make work less strenuous and to increase output, man has taxed his ingenuity to construct machinery of ever-increasing power and has been led to concentrate industrial operations into small spaces, whereas formerly they were distributed over vast areas. Certain inconveniences which could be tolerated in home workshops become quite unsuitable in large factories. Further, each industry which is started compels the hygienist to solve a new problem.

The unhealthiness of certain industries has been recognised for quite a long time, and authorities have been compelled to take measures for protecting the population either by assigning certain quarters to these industries or by moving them away from dwellings. In recent years citizens have tended to assign certain parts of towns for industrial quarters more or less separated from other quarters. These measures are not always sufficient, for the carrying on of trades may cause trouble stretching far beyond factory walls.

The discharge of industrial waste water into rivers may be instances; it may cause deposits of mud which may make navigation difficult, and is often accompanied by exhalations of nauseating smells, or it may hinder the action of natural purification by the presence of antiseptics, or poison the fish by the toxic substances which it contains; it may in fact render the water of these rivers unusable for all purposes, sometimes over very long stretches. Experience indeed shows every day in an indisputable fashion that the discharge of industrial waste water is the principal factor in the pollution of streams.

The elaboration and the application of laws and orders regulating the discharge of these waste waters are very difficult, as the modifications of these laws and orders, which are everywhere continually required, show; also the policy followed by the responsible authorities varies in different countries.

The factory owner should understand that he has a double duty to fulfill: to avoid the pollution of streams and to carry on industry. Economically, there would not be any difference between them if he considered the treatment of waste water as being part of the work of the factory, and if he dealt with it by the same methods he employs in the manufacturing processes.

The war showed in many cases the waste to which we are accustomed, as much in domestic life as in industry. It is certain that many processes could be carried out more economically and numerous by-products recovered.

Thus water, when it is in abundance, is used without care. Washing is almost everywhere carried on in a routine manner, whereas the chemists knows that small volumes suffice when employed in small quantities often repeated. In this way sometimes a part of the product is allowed to be lost and goes to fill up and pollute the rivers. Sullage water, submitted to purification or simply decanted, can be used over again, sometimes with the advantage that, through the concentration which ensues, it is possible to recover with profit certain compounds and so diminish to a considerable extent the expense of purification.

Before undertaking the study of the treatment of industrial waste water, the process used in the factory should be first examined to ascertain if the products employed have acted usefully and thoroughly, if the yield of the manufactured product is in accordance with the theory, and if all by-products which are usable or for which a use can be envisaged have been extracted. Methods of work will arise from such a study which will sometimes abolish any need for discharging waste water and will almost always diminish the volume and facilitate the treatment.

OBJECTS AND PROCESSES OF TREATMENT

It will be understood that treatment must vary according to the trade and even in a particular trade according to the factories. The ends to be attained are:

(a) retention as complete as possible of solid suspended materials;
(b) suppression of acidity and substances poisonous to human beings and to animal and vegetable life;
(c) reduction to a reasonable strength of alkalinity and organic materials.

The treatment of trade effluents varies according to their composition and the degree of purification which is required and can be carried out by (1) mechanical, (2) chemical, and (3) biological processes.
1) Mechanical Treatment

This treatment has for its object the mechanical retention of matter in suspension.

Gratins, strainers and sieves are only used in the trades where animal fibres, such as wool and silk, or vegetable fibres, such as cotton and cellulose for paper, are used.

The tanks for decanting, which are universally employed, are not always suitably constructed. Their shape, proportionate capacity, the arrangement of the flow of the water either horizontally or vertically, and the speed of the flow should be determined and regulated according to the nature of the water under treatment. Very often experience alone can indicate the requirements for the construction of an installation. As a general rule, a series of small tanks, each of which can be put out of action for cleaning, should be preferred to one tank of large dimensions.

The filtration used in the trade processes is often sufficient for the treatment of waste water.

2) Chemical Treatment

Addition of chemicals to trade effluents may be made with the object of changing the reaction of the water. Neutralisation should transform the acids and bases into insensitive salts. This operation almost always causes the desired precipitation. Examples: treatment by lime of acid and ferruginous water from cleaning iron; treatment by acids of alkaline lime, salts of iron, alum, magnesia, and acids.

Chemical precipitation nearly always produces a clarification of the water. The precipitate obtained either from the deposition of the soluble matter or from deposition of added reagents produces a great sticky mass which carries down not only fine solid particles, but also colloidal materials in pseudo-solution.

Even perfect clarification produces nearly always only a partial purification and a great number of compounds cannot be precipitated practically or economically.

Chemical treatment of a trade effluent is a delicate process and the uncertain results often described are due to misunderstanding of the reactions produced or to defective regulating. As in every chemical process, definite combinations are formed which are often very difficult to determine exactly, but to understand which an endeavour should at least be made. It is necessary then to set aside a priori the formulas or general recipes; each case should be studied separately.

It is absolutely necessary to proportion the amount of reagents to the extent of the pollution of the waste water, not only to avoid useless expense, but especially to obtain the best clarification. Experience enables the concentration in hydrogen ions which produces the most complete precipitation to be determined.

In factories where refuse waters of different composition flow from different workshops it is always advisable to mix them, which will probably thus give a comparative homogeneity of composition.

The chemical products employed generally are not numerous: they include lime, salts of iron, alum, magnesia, and acids.

Chemical treatment of waste water presents two difficulties: first, the maintenance always of the most favourable concentration of reagents, owing to changes in composition of the water; and, secondly, ensuring rapid and complete diffusion of the reagent throughout the whole mass of the water to be treated.

3) Biological Treatment

Biological processes are only applicable, and then only within certain limits, to refuse water containing chiefly organic material more or less easily putrescible.

(a) Natural biological purification.

Examination of the area of contamination produced in rivers by the discharge of refuse water has led to the discovery of the phenomena of automatic purification which takes place in that area.

Indeed, it is noted that as one gets further downstream from the point of discharge, the river water, at first muddy and coloured, becomes clearer and of better colour. Compounds indicative of contamination, such as organic ammoniacal material, disappear and become changed, the number of micro-organisms diminishes progressively, and a time arrives, if there has not been a fresh inflow in the interval, when the water regains the appearance and qualities which it had upstream.

These changes are produced by the activity of micro-organisms at the expense of the organic material contained in the refuse water. They are facilitated by dilution which carries dissolved oxygen, and reduces the proportion of compounds able to hinder, or even arrest, biological processes, and by physical reactions which are carried on at their maximum in the activated sludge process, as will be described further on. But they are interfered with by other fermentations which develop in the mud and slime deposited and accumulated in the bed of rivers.

Automatic purification is effective when the organic material in solution and in suspension in the refuse water has been oxidised and transformed into stable material. The principal factor is oxygen. The dilution is proportionate to the strength of oxygen in water of the river and the quantity of oxygen necessary for the oxidation of the organic material in the polluted water. Every arrangement which aids re-oxygenation of the river water, such as rapid current, rapids and falls, allows for a diminution in the contamination. On the contrary, it must be considered as harmful for discharges into the sea where the biological action is much slower than in fresh water.
(b) Purification by the soil. — Refuse water can be purified by soil by means of two methods: filtration and distribution or irrigation.

Filtration, especially widespread in the United States where it has been particularly well studied, requires a suitable sandy soil. Sedimentation and irrigation are only practicable upon soil sufficiently porous to allow the oxygen of the air to penetrate at the same time as the water infiltrates. Distribution alone is used by trades depending on seasons, cultural irrigation being too difficult to regulate.

Purification by soil is very efficacious when the land is suitable and of sufficient size and when it can be carried out with care.

(c) Artificial biological purification. — The study of natural biological purification of refuse water in rivers and in soil has led to the invention of methods for intensifying the changes which are produced.

One of the chief difficulties met with in natural biological purification is the presence of solid matter suspended in the waste water. This slime is deposited on the bed of the river or on the surface of the ground, of which it raises the level and subsequently fermenting gives rise to objectionable effluvia and to an unsuitable medium for the oxidation of organic matter.

Simple decanting allows the retention of the water part of this matter, but the slime is not long before it produces serious trouble. In order to reduce the volume and consequently to facilitate the manipulation, fermentation is carried out in tanks of various designs, septic tanks, hydrolitic tanks, Imhoff tanks, etc., either with the liquid part which separates out, or without it.

In all artificial processes of biological purification at a certain stage the separation of the solid matter is indispensable by simple decantation or by fermentation.

Purification properly so called has for a long time been effected upon artificial ground, called bacteria beds because microorganisms play the principal part, composed of materials which present as large a surface as possible, such as slag, clinker or puzzolana. These bacteria beds ought not to act as mechanical filters. The water to be purified, freed as completely as possible from solid matter in suspension, is slowly spread in a very thin layer over the surface of the materials and freely exposed to the air. The colloidal matter in the water becomes fixed on the materials and oxidised, and a residue similar to humus becomes detached at intervals; the carbonaceous matter is decomposed into carbonic acid and water, the nitrogenous matter is reduced and then oxidised into nitrates and nitrites. When the beds are well established and their working is properly regulated, a well-purified effluent results.

(d) In the last ten years a new process based upon another principle has come into vogue. Just as in the bacteria beds an attempt is made to reproduce the best condition of a good soil, so in the process of activated sludge phenomena are reproduced which are found in a strongly flowing muddy river. In bacteria beds the liquid, exposed to the air, flows over the surface of materials crowded with microorganisms; activated sludge, on the contrary, a veritable nest of bacteria circulates in the liquid, impelled by an air current or by mechanical means which allow for the absorption of air. At the end of a period of time varying with the composition of the water the same changes occur as in bacteria beds: the colloidal matter is absorbed by the mud, the organic matter is decomposed into carbonic acid and water, or reduced and then oxidised into nitrates and nitrates, and the water, when separated by decanting from the mud, is purified.

Things do not always occur as simply as has been just briefly described, and most careful trials should always be made before deciding to adopt any process or modified process.

Control of Purification

The most careful investigations for determining the conditions which effluents from works should fulfil after their purification have been made in England. In 1915 a Royal Commission proposed that, according to present-day possibilities, effluents should be tested in two ways:

(a) By determining the amount of solid matter in suspension and the proportion of dissolved oxygen taken up from an aerated water with which the effluent is mixed. In order to fix a limit to the test, the estimation is made after five days. The Commission found that for a certain number of waste waters such a purification could be obtained that the effluent contained no more than 40 to 60 mg. of matter in suspension per litre and did not absorb more than 20 to 40 mg. of dissolved oxygen in five days. These standards, adopted in the United States in principle, may be retained, at least provisionally, as being the least arbitrary. In addition search should be undertaken for substances poisonous to living things, both animal and vegetable.

(b) The more simple test of putrescence is often considered sufficient; this consists in observing if the effluent, kept at 30° C, in a corked flask, gives off an offensive odour after a more or less prolonged period.

Aims and Processes in Treating Waste Water from Various Trades

I. — Trades connected with the Preparation of Food

The presentation, preparation and preservation of foods involve a certain amount of manipulation, during which
waste water is produced. This water, which is more or less loaded with organic matter, purifies very rapidly and then gives off nauseating smells. Such refuse water should be discharged as soon as possible into the sewer or purified.

The food trades include: slaughter-houses and annexes, factories for preserving meat or vegetables, glue and gelatine works, and also dairies.

Slaughter-houses.—Refuse water from slaughter-houses contains blood, urine and some of the contents of the digestive tract from animals killed, and the liquid which flows from the stalls and cattle sheds where the animals wait. Sometimes refuse water from adjoining workshops is added: from gut-scraping, scalding houses and tripe shops. The factories for preserving meat may be considered from the same point of view as slaughter-houses. The concentration of this water depends chiefly on the amount of water employed during slaughtering and preparation and when cleaning down the slaughter-houses; it is in consequence very variable.

Recommendations are always made for the water to be purified or for it to be discharged in the crude state, and for avoidance of solid matter, debris of food, fat, etc., which may be washed away in it; all these have a value by no means negligible. Good organisation provides for the gathering up of these materials into suitable places and their removal at definite times.

There are few waste waters which can be more easily purified by biological processes than the waste water of abattoirs.

Good results have been obtained either by land irrigation or by septic tanks and bacteria beds, also by activating sludge, but it depends on the concentration of the water not being too high.

For very small abattoirs or special slaughter-houses which are only used a few times a week, the rule is to clear the water by the addition of a chemical reagent, such as ferric sulphate, and to purify the clear fluid if it cannot be discharged directly into a river, by distribution or by percolating bacteria beds.

The treatment of waste water from gut-scraping, glue and gelatine works should include the same chemical precipitation and purification on bacteria beds.

Waste water from margarine works contains quite large quantities of fatty material which it is an advantage to retain by decantation following chemical precipitation. The deposit is defatted directly after drying or treated by an acid to extract the fatty acids.

Preserving of vegetables.—The characteristic of waste water from this class of work lies in its acidity, which increases with time. The treatment which has furnished the best results consists in the following processes: neutralisation by milk of lime, decanting as rapidly as possible to avoid the water becoming acid again, and purification by percolating bacteria beds at a slow rate. The deposit should preferably be buried fresh in the ground, or dried upon beds of clinker to be removed after the season.

Milk trade.—This trade, which is well developed, contains a certain number of branches, of which several are often combined: collecting stations, creameries, dairies, cheese factories, factories for casein, lactose and lactic acid.

It is of the highest importance, as much from the economic point of view as from the hygienic, to avoid all loss of by-products in this industry. It is a sad fact that certain dairies still throw away not only whey, but even skimmed milk, at least from time to time. There should only escape from dairies water from washing butter and cleansing the apparatus and the dairy. This water has the composition of a very dilute milk with the addition often of a little carbonate of soda. It becomes acid and putrifies very quickly, so that it ought to be evacuated and purified as soon as possible.

Precipitation by well-chosen chemical reagents clears the water sufficiently, so that in certain cases it can be discharged after this treatment into rivers.

The biological process can only give complete purification provided there is a preliminary treatment for removing fatty materials from the waste water, as that oxidises with difficulty and rapidly forms a deposit on the bacteria beds or on the soil, or checks the action of the activated sludge.

II. — Chemical Industries

In most of these industries materials of known composition are used and well-established reactions are employed. It is also very important not to lose either the materials worked up or the products obtained.

The treatment of waste water, simple as it seems at first sight, presents sometimes practical difficulties. The principle of this treatment is to render
the waste water neutral, so that it does not contain a salt the base of which may cause precipitation when mixed with the water of a river, and does not contain poisonous salts, such as sulphides, compounds of arsenic, lead, or phenol derivatives.

III. — Leather Trade

There is scarcely a trade in which the manufactured products, and in consequence the methods of work, are more varied. However, the necessary processes are the following: reviving, removal of hair or wool, washing with or without deliming, tanning by vegetable or mineral substances, sometimes more varied. All these operations produce waste water more or less strongly charged with organic matter and chemical products, of which the volume varies according to the day and even according to the hour of work. It follows then that the purification of refuse water from a tannery is an extremely difficult problem to solve. However, though results as perfect as those obtainable with other trade effluents are not to be expected, purification can be obtained sufficient to prevent the effluent, when discharged into a river of steady flow, from causing destruction of the fish or any nuisance to the riverside residents.

In order to attain the desired object it is necessary first to endeavour to obtain a water of average composition. The methods of work, in consequence of the building of large factories, keep changing, but by an ingenious combination of renewing the baths more frequently, or suitably regulating them, it seems that, by collecting in a tank of sufficient capacity, a mixture can be obtained as constant as possible of the waste waters from the various workshops. This mixture should afford the advantage of producing by the mutual reaction of all the products a commencement of the purifying process after the first decanting.

This preliminary phase ought to be first carried out whatever may be the final destination of the waste water, whether it is to flow directly into a sewer or to undergo purification. In this last case the decanted mixture ought to be slightly alkaline, which can always be ensured by adding, if necessary, lime washings from lime baths or even additional lime. The addition of a salt of alumina, or a ferric salt, will now produce an abundant precipitate.

Waste water so clarified can, whatever its concentration, be purified by land irrigation. But one cannot here compare the treatment of this waste water with the surface required for the irrigation of liquid sewage; the surfaces ought to be much more extensive and the points of discharge of the effluent upon the land further apart.

When the waste water is not very concentrated or when irrigation land cannot be obtained, the water after dilution may be treated by biological methods by percolation on bacteria beds. Experience will indicate the volume to treat per square metre of surface each day.

Special mention ought to be made of waste water containing arsenic, which must be eliminated by treatment with a salt of iron, or by filtering through waste iron or compounds containing this metal.

IV. — Grain and Starchy Materials Industries

Fecula factories. — The waste water from fecula factories is of two kinds: the water from washing potatoes and the water from washing fecula and pulp. Only the first kind can be discharged after simple decanting. The water used in washing fecula and pulp contains all the elements of the juice of the potato, that is to say, relatively important proportions of nitrogen and potassium which should be made use of. It would be advantageous for the process invented by A. Ch. Girard to be given the test of a trade experiment for the production of manure of commercial value.

A good partial purification can be obtained by treating these waste waters with a chemical reagent, such as ferric sulphate, which produces clarifying by precipitating an appreciable proportion of organic matter.

Suitably diluted with the water from washing the roots, and of course decanted, this refuse water is easily purified directly upon percolating bacteria beds.

Starch works. — The processes of extracting starch are based on the separation of gluten by mechanical action (for wheat), or by dissolving or disintegrating gluten by various chemical products, such as soda and sulphuric, sulphurous or hydrochloric acids, or hypochlorites (for all other grains and roots)

The chemical processes most employed thus produce starch, grain and waste water.

This waste water, including the highly-charged water from steeping
and that from washing, is rich in organic matter and easily putrified.

Chemical treatment, i.e. precipitation by an iron salt after slight alkalinising with lime, gives appreciable results, which may be sufficient when dilution of the effluent going into a river is important.

Purification can be obtained by percolating bacteria beds, provided the water does not contain grains in suspension.

Malt-houses and breweries. — These two trades are often combined; they discharge, as waste, liquor from soaking grain for malting, liquor from draining of the malt, and refuse water from washing receptacles, such as bottles or barrels, and the apparatus and workplaces.

These effluents contain principally hydrocarbons and not much nitrogenous matter; they become acid more or less rapidly according to the season and very soon set free foul smells.

When circumstances require the waste water to be purified, it is always an advantage to have separate outflows for waste water and water (as from refrigeration) not requiring purification.

Chemical precipitation carefully done can give in certain cases valuable results which may be sufficient when it is only desired to discharge a small volume of water into a river the flow of which is relatively considerable.

Purification by distribution, although complicated, can be carried out after neutralisation and decantation of the waste water if suitable land surfaces are available.

Artificial biological processes enable effluents sufficiently pure to be obtained, especially by the use of percolating beds.

Distillation of starchy materials. — The waste from the distillation of starchy materials ought to be treated in such a manner as to render it fit for use.

Brewers' grain should be delivered with the vinasse, or separated for feeding animals. It should be pressed and then dried, so as to be fit to send away when the local demand is not sufficient. If, on account of the process, it is not considered edible, it can be used as manure.

The vinasse, except that upon which acid has been used — as a matter of fact this is rare now — has a great food value. It would be desirable to see a concentration process brought to perfection so that it might be mixed with brewers' grain for use in feeding animals.

When the vinasse is not used it is recommended to treat it by chemical reagents before mixing it with other waste water.

Purification of the whole of the waste water, with or without the vinasse may be obtained:

(a) By irrigation, especially over meadow land, upon a suitable soil, after neutralisation and the most thorough decanting possible; the quantity varies with the composition of the soil and the concentration of the effluent.

(b) By biological processes; the waste water, having been neutralised and thoroughly decanted, can in a suitable dilution be purified on percolating bacteria beds.

V. — Metal Trades

Metal trades include factories of the greatest variety; they can be divided into the following two classes from the point of view of trade effluents:

(1) Iron-works, foundries, etc., the refuse water from which, comparable to that from mines, is charged particularly with matter in suspension, sand, refuse of mineral ores and coke. It is sufficient to decant it through a series of tanks suitably arranged according to requirements.

(2) Works in which cleaning or scouring of metals, or alloys with acids is carried on. It seems to be less costly to treat the liquor of the first and second steepings for the recovery of iron and steel, together or separately, than to neutralise these waste waters before discharging them into a river, as it is indispensable they should be discharged. As this neutralisation should be done by washing water, an attempt should be made to reduce as much as possible the volume of water employed to this end.

When the refuse water contains copper, this metal can be displaced by iron when ferruginous acid water is obtained.

VI. — Mining Industries

In working coal mines waste water from three different sources has to be discharged:

(1) Saline water, containing more or less large amounts of chlorides, alkaline sulphates, and alkaline earth. It is only possible to decant the sand, clay and calcareous substances which it contains. There is no practical way of eliminating the salts; dilution is the
only method of rendering the effluent fit for discharge.

(2) **Acid ferruginous water**, charged with the products of the oxidation of iron pyrites. Its discharge into rivers renders the water not only unusable, for it damages more or less rapidly reservoirs, pumps and conduits, but the damage it causes extends to the destruction of quays and boats. The only process of treatment which appears actually practical is neutralisation of the waste water by barium hydrate; the sulphate of barium which is then formed has a market value which makes up for the cost.

(3) **Waste water** from washing coal which holds in solution saline matter and in suspension coal dust; an effort to remove the latter is made by thoroughly decanting.

The waste water from the working of metalliferous mines contains salts as well as particles of ore which, more or less soluble under certain conditions, cannot be poisonous, being present in very small quantities. Further, certain ores are embedded in silicious rocks which have to be pulverised. The particles of this rock, which are very light and sharp, are removed by the current of water used in washing and may do serious damage to fish.

In the waste water from silver mines are also found sulphates of iron and zinc; in that from copper mines soluble salts of this metal; in that from tin mines sulphides of arsenic or antimony; in that from iron ore mines, sulphuric acid and salts of iron; in that from lead and zinc mines, solid matter containing lead and sulphate of zinc.

In every case the decanting should be as perfect as possible, the metal salts ought to be decomposed and the oxides retained.

Rational use of combustible minerals should be preceded by the separation of products which they contain into gases, volatile products such as ammonia, benzol and tar, and coke. In certain industries where coal is used in its natural state, e.g. blast furnaces, arrangements have been adopted for the treatment of the waste gases. But these operations produce more often than not waste water, although certain processes have not this drawback.

These waste waters are charged with a large quantity of materials which are poisonous to fish and prejudicial, when in certain proportions, to the effective working of biological purification installations. When discharged into a river they often render impossible sterilisation by chlorine of water taken from the river on account of the smell and taste which develop.

A method of purification which will produce at a reasonable cost an effluent which can be discharged without danger into a water course is not yet known. However, the danger can be diminished either by treatment by means of lime and ferrous sulphate, or other reagents, or by bacterial oxidation on percolating beds. The large pit heaps which are found at collieries can be usefully employed for this work, i.e. for making percolating beds. Finally, recourse may be had to evaporation.

VII. — **Paper and Cardboard Industry**

This industry consists in making cellulose pulp which is then manufactured into the greatest diversity of shapes according to the use for which it is intended.

The making of cellulose from wood pulp produces waste water so heavily charged that it is necessary to dilute it with several thousand times its own volume of clean water in order to avoid too strong pollution. For this reason it is recommended that the factories be built by the sea or large estuaries. As a matter of fact no practical satisfactory means of purifying this waste water is known. It has been proposed to make use of it by means of very various processes.

Cellulose from textiles and esparto-grass, which is of the highest quality, is most often prepared with soda, which is worth recovering by evaporation and calcination of the lyes.

The lye-wash from the preparation of cellulose from straw is also highly charged; it can be purified after being mixed with all the waste water from the factory. It is decanted into large tanks and then distributed on percolating bacteria beds.

The majority of paper works prepare little or no pulp; most often they are content to bleach it and treat it, according to requirements, with colouring materials, size and filling.

Attention may here be drawn to two principal points in the purification of these waste waters; first, diminution in the volume of the water used in washing, and then retention by all possible means of fibres carried away by the washing. If these two precautions are carried out, purification may sometimes be unnecessary and may often be obtained by using percolating bacteria beds fed to a comparatively high degree.
The waste water from the manufacture of cardboard is generally distinguished by a unusual proportion of solid material. That from factories making the highest qualities can be treated in the same way as that from paper works. That from the making of inferior qualities, after suitable dilution, may be treated either like waste water from the making of cellulose from straw, or distributed after chemical clarification or at least neutralisation by free lime.

VIII. — Sugar Industry

Sugar refineries. — The waste waters from sugar refineries are of three kinds:

(1) Hot water only requiring to be cooled, which should be done by keeping this water separate from other waste water, when it can be used again.

(2) Muddy water from the transport and washing of beetroot. It is only comparatively slightly contaminated. Suitable decantation in a series of quite small tanks will produce an effluent which can be discharged, usually without causing trouble, into a water-course of average size, provided that it does not mix with fermentable water. Advantage may be gained in case of frequent re-use by treating with chemical reagents such as lime and ferric sulphate.

(3) Fermentable waste water. It is the most dangerous from the fact that it ferments. Three means of purification are open to the manufacturer: natural biological purification, artificial biological purification, and lastly chemical purification.

Natural biological purification by suitable distribution upon cultivated ground is the method most recommended, but local circumstances often prevent recourse to this method.

Artificial biological purification, when carried out with a good knowledge of the method, furnishes very satisfactory results. Trials, not very successful because indispensable conditions have not been complied with, should not a priori cause the method to be abandoned.

Chemical purification, however, if it is borne in mind that there is left in the effluent sugar which is fermentable, can in certain cases give satisfactory results. The water can also be used over again. It is necessary always to bear in mind that the dose of the reagent must be in proportion to the quantity of material to be precipitated, and that it should be neither below nor above what has been ascertained by trial. This implies constant testing in order to vary the charge according to the composition of the waste water.

Beet-sugar distilleries. — Although fermentable waste water may sometimes be negligible in amount, distilleries of beet-sugar should discharge the same effluent as sugar refineries, to which vinasse, the residue of the distillation, is added.

This vinasse contains very important fertilising elements, and an endeavour should be made to utilise them. The best method is suitable irrigation of land. It is always preferable to diminish or even to arrest the acidity of vinasse either by dilution or by fermentation.

When circumstances do not permit irrigation under normal conditions, different methods which have been proposed may be considered. Concentration and the process described by Muntz and Lainé (culture of moulds) should receive attention and deserve practical industrial trials. Artificial biological purification of diluted and fermented vinasse can give satisfactory results.

IX. — Textile Industries

The composition of the waste water in the textile industries varies considerably according to the raw material employed.

Vegetable textiles furnish waste water more or less charged with carbon products, but with very little nitrogenous material. Animal textiles, on the contrary, furnish waste water very rich in nitrogenous compounds, and, in the case of wool, considerable amounts of fatty matter.

Waste water from soaking flax can be purified by natural or artificial biological processes after having been decanted and neutralised. Chemical treatment, although imperfect, will be sufficient in certain cases.

Cotton, either raw or already finished, whether in the form of thread, cloth or waste, must be deprived of all matter which impregnates it so that it can be bleached. The lyes after the boiling down process are very injurious when discharged into rivers. It is necessary to treat them first by neutralising the free alkalis and then to eliminate the greatest part of the organic matter which they contain. Soda or its carbonate are recommended for use in place of lime, for it is possible to recover them and at the same time to
get rid of the most polluting portion of the waste water from this industry.

If all these waste waters are mixed the lyes must be discharged with the other unpolluted waste water so as to dilute them as equally as possible. The inter-reactions produce a certain precipitation which will be increased by ferric sulphate or iron-alum. The effluent thus clarified can be purified on percolating bacteria beds.

Raw wool is charged with an average of 60 per cent. of impurities, of which certain have a commercial value — the fats and potash.

A very great number of processes of purification of the waste water from the combing of wool have been recommended. That most employed is the separation of fatty acids by acidification of the lyes by a mineral acid, either sulphuric or hydrochloric. Precipitation and, at the same time, clarification of the waste water can be carried out by proper addition of a ferric salt; the fatty acids are then extracted from the precipitate. In certain factories the waste water from degreasing is treated separately, evaporated and the residue calcined in order to extract the potash.

Efforts have also been made to concentrate the waste water and to centrifuge it, so as to separate the particles of earth, the fats and the potash liquors.

A recent washing process based on a very simple principle, the process of E. Duhamel, of Roubaix, promises to be very advantageous for the manufacturer and to cause but little waste water.

The mixing of waste water from washing wool with the sewage water of a town causes purification of the sewage to be very difficult. So it is best to treat the waste water at the factory, or at least before it mixes with sewage water. This practice renders purification easier and more economical.

The waste water from scouring silk is also saponaceous, which enables it to be treated by adopting the processes of purification used for waste water from washing wool.

The making of artificial textiles produces waste water the composition of which is easy to discover and the dangerous substances of which can be neutralised with certainty.

The waste water from dyeing and printing thread and cloth contains variable amounts, and sometimes very considerable amounts, of organic and mineral compounds, which may even be poisonous for fish. Since the refuse waters from the various workshops have different reactions, it is recommended to collect them all in a tank of sufficient capacity. After having been neutralised, if required, the water is decanted and clarified by a chemical reagent. The effluent can be purified on percolating bacteria beds.

**LEGISLATION**

The laws laid down for the protection of the health and safety of workers, as well as those laid down for the protection of public health, provide the necessary measures for the treatment and discharge of waste waters.

Each factory should take the precautions necessary for preventing the diffusion of smells and disagreeable emanations from waste waters (see article "Odours").

The factory should construct drains, cisterns, tanks and pipes for the discharge of waste water, of impermeable materials, and should ensure that all joints, etc., are perfectly watertight so that the waste water does not contaminate underground water or the soil.

If waste water is discharged into a public or private sewer, it is necessary to interpose at the point of discharge an hydraulic interrupter which must be cleaned frequently.

Discharging of waste water into a water course or its distribution on land should be prohibited until after it has been submitted to sufficient purification to ensure it being harmless.

Hot water from boilers, etc., should not be discharged until it has been sufficiently cooled.

**BIBLIOGRAPHY**

Prof. E. Rolants (Lille).
Infectious Diseases

INTRODUCTION

Infectious and parasitic diseases may affect anyone, without distinction of age, sex or occupation. If only conditions favourable for infection exist. These diseases in general constitute, as it were, a generic risk which may be contrasted with the specific risk connected with certain infectious or parasitic diseases, where, in the case of special occupational processes and the disease in question, a connection may be established between the sickness and the work — a close connection resembling in every way that which exists between a lesion due to an occupational accident and the mechanical trauma which causes the lesion.

This specific risk is inherent, either to the occupation concerned, or to the kind of material under manipulation, or yet to the technique, or even to the environment. By way of example, there may be mentioned as belonging to this particular group of diseases, anthrax among tanners, and angstomiasis among miners and brick makers, for which, according to Borri, the specificity of the etiological connection between the work in question and the pathogenic agent must be admitted. And it is on this ground that such affections as actinomycosis, anthrax, malaria, rabies, extra-genital syphilis, glanders and tetanus require to be dealt with separately. An infectious disease should be considered as occupational whenever a right to compensation whenever the disease is contracted, or in consequence of, work. Hence there are conditions of place, time and work, which create the right to compensation, and confer on the disease concerned the medico-legal aspect of an accident.

Indeed, between a generic risk and a special risk, which may characterise an infection according to circumstances, there is an undefined zone, the boundaries of which are very difficult to indicate. With this reservation, it cannot be denied that, in the case of a person working in a hospital or laboratory contracting an infectious disease, or in the case of a workman exposed by the nature of his work to insect bites which transmit pathogenic germs, maybe of plague, yellow fever or malaria, the disease is contracted in a similar manner to an occupational accident. In any particular case the disease acquires a character which enables a claim for compensation to be made.

Experience has also shown that, when similar cases occur, such as plague among dockers, anthrax among tanners, or glanders among stable boys and veterinary surgeons, in the absence of any provisions concerning them in the texts of the laws regulating industrial accident insurance, in some countries, like Italy and Germany, medical assessors have compelled the magistrates to accept the principle that an infection which was produced during work should be considered as an industrial accident. The cyt-o-microbial struggle which occurs in the body as soon as a pathogenic agent has entered it through minute breaks in the continuity of the skin or mucous membranes, and the disorders this struggle causes in the tissues, have been considered by these experts as analogous to a traumatism with its sequelae; thanks to this very broad interpretation of one of the elements in the definition of an accident, a right to compensation has been successfully established. (See also the article "Occupational Diseases: Definition and Compensation").

Without entering into fuller details, there shall merely be enumerated below those infectious diseases which have been reported in various countries as having been, in some cases, considered as occupational in origin. A very brief summary only is given here, the reader being referred to fuller details to treatises on special pathology.

Akamushi disease. — This affection, which is still called "tsutsugamushi disease" or "Kaneda's disease," is a specific affection of agricultural labourers of Japan between July and October at the time of the floods. The disease is transmitted by an acarus (Akamushi). It is very much dreaded by the inhabitants, and when it rages only the poorest labourers will take the risk of exposing themselves in the flooded fields where it is contracted. Clinically the affection presents the appearance of typhus with a duration of one to three weeks; the mortality varies from 25 to 30 per cent.

Aspergillosis. — From time to time English weavers of cotton cloth suffer from epidemics of sharp febrile attacks, associated with a persistent asthmatic cough. Thick sputum, night sweats and loss of sleep at first may suggest tuberculosis; but absence from work brings complete recovery. Mallis, who in 1913 first described two outbreaks, pointed out that conditions favourable to the development of mildew on damp warp threads are present whenever the illness occurs. He ascribed the disease to infectious mildew spores, thrown into the air as the threads are woven on the loom; but the
exact mould concerned has not yet been isolated.

**Bacillus abortus. —** See “Mediterranean fever”.

**Bilharzia. —** According to recent researches, three distinct forms of bilharzia are now accepted: vesical bilharzia due to *Schistosoma (Dichotoma) Haematobia*, intestinal bilharzia due to *Schistosoma Mansoni*, and arterio-venous bilharzia due to *Schistosoma Japonica* (Katayama disease). Bilharzia occurs in the majority of cases through the skin, the parasite penetrating into the system in the form of cercarian larvae, after having passed through an intermediate host.

The disease, which is very common in warm climates, is spread by contact with dirty water, or by the excreta of persons suffering from bilharzia; it attacks Egyptian fellahs and women who obtain their water from “birkets” or pools situated near all the villages, and also workers on low-lying and marshy regions, or on rice fields, especially in Japan. (See also article “Occupational Diseases: Urogenital System”.)

**Blastomycoses.** — This designation covers illnesses caused by certain fungi which for a short period of their existence occur in the exclusive form of budding elements (Villemin). The state of knowledge at the present time concerning moulds does not permit any better classification of the various known fungi (Hammond).

The first case of human blastomycosis was described by Troisier and Achaile in 1893. Gilchrist in 1894 reported the first case of the cutaneous form. Since then observations have increased, and the blastomycoses known at the present time are grouped under the headings of “American blastomycoses”, which seem to be oidiomycoses, and blastomycoses properly so-called which are saccaromycoses.

The agent which causes the first appears always to be a parasite of the genus *Cryptococcus*. This form of blastomycosis is fairly common in America, where it attacks by preference men employed on agricultural work and in handling grain (Montgomery and Rickelit, 1901). Newton Evans in 1903 reported the case of a doctor who inoculated himself with the disease during an autopsy.

The affection is localised by preference on the skin and the lungs.

In 1924 Carter met with three cases of dermatitis, two of which followed directly on traumatism. He thinks that it is necessary to take account of this etiology in cases of dermatitis of occupational or traumatic origin.

Ravogli considers blastomycotic dermatitis as an occupational disease, due to handling animal products or to contact with animals affected with blastomycosis. Ravogli has collected several interesting cases, including two stable boys, a goat breeder, a shoemaker and a slaughterer.

In its chronic form the disease consists of an inflammatory process with an abundant production of spores and the formation of small cutaneous abscesses, with a tendency to ulceration and the formation of granulations. For a long time the lesion was regarded as cancer of the skin or as a warty tuberculosis. The condition occurs principally on the hands, face, limbs and scrotum.

The diagnosis is easy by microscopical investigation for the fungal elements. The development is slow, with a tendency to chronicity and to serious affections of the skin. After a cure, which is sometimes spontaneous, deep scars are left on the affected parts. Chronic cases, in which the viscera are involved, are less contagious than those affecting the skin.

In addition to direct contact it appears that the disease can be transmitted by the intermediary of insects (flies).

**Botriomycosis.** — At the present time botriomycosis is held to be caused by staphylococci which are able to become differentiated inside the body into clubbed forms (Magrour). The disease has been met with in veterinary surgeons who have been treating sick animals (Koch, 1897; Parascandolo, 1900), in gatherers of roses (Revillet, 1914; P. White). In this case the lesion has been found on the thumb and index finger of the right hand. This form of botriomycosis often seems to be due to the same agent as that got from animals (Habermann), and it is only from a clinical point of view that it presents any analogy. The last word on this, however, has not yet been spoken.

According to recent investigations, it is clear that a true human botriomycosis exists; it is, however, very rare, for up to the present only three cases have been met with (Kaiser and Gryns, Masson, Fumagalli).

**Butchers' pemphigus.** — This generalised disease has been described chiefly by American dermatologists among butchers and persons in contact with animal debris in the large centres of the food industry. The disease is usually serious and often fatal. Some writers have established a relation between this affection and aphthous ulceration and the meningococcus (Hofman and Dor, 1907; Parascandolo, 1900), in gatherers of roses (Revillet, 1914; P. White). In this case the lesion has been found on the thumb and index finger of the right hand. This form of botriomycosis often seems to be due to the same agent as that got from animals (Habermann), and it is only from a clinical point of view that it presents any analogy. The last word on this, however, has not yet been spoken.

According to recent investigations, it is clear that a true human botriomycosis exists; it is, however, very rare, for up to the present only three cases have been met with (Kaiser and Gryns, Masson, Fumagalli).

**Canadian pustulous dermatitis.** — This is a contagious affection due to a pseudobacillus tuberculosis, the so-called * acne bacillus* which can be transmitted to man, notably to persons who have charge of or look after sick horses (Galloway). It seems that this affection has been confused with the variola of the horse family.

**Cerebro-spinal meningitis.** — This disease is due to the meningococcus of Weichselbaum and to other microbes presenting the same morphological characteristics. It may appear in a sporadic form, but it usually assumes an epidemic form, which often confines itself to certain groups, being localised even to districts, houses or families. Bad sanitation, defective feeding, fatigue, overstrain and
Infectious Diseases

Climatic conditions are factors which favour the multiplication and virulence of the germ. The spread of the disease is often due to germ carriers. Some epidemics have been reported among mining and working populations (Germany, 1965, etc.). The disease constitutes an occupational risk for nursing staff attending to patients suffering from this disease.

Cholera. — This disease is endemic in India, especially in the regions of the delta of the Ganges; it made its first appearance in Europe in the sixteenth century.

Danger of infection is particularly great for doctors, nurses, sanitary inspectors and all those who are employed in treating and isolating cholera patients. The disease may also attack workers in scientific laboratories (Sata, 1927).

Cholera infection can be conveyed to a doctor's patients, by the intermediary of vibrio carriers, or by articles of food infected directly or indirectly by infected excreta. The disease was reported in 1923 among labourers at Vizagapatam (Madras).

Asiatic cholera is compensated in Queensland among hospital personnel, and in Yugoslavia.

Coccidiosis. — This parasitic affection is due to the presence of different kinds of coccidia which are found in the epithelial cells of the biliary canals and the intestinal glands. Cases of granuloma due to coccidia, beginning with pulmonary symptoms and spreading to the whole system, are known (S. Pulford and E. Larson, 1929).

Ravoli and other experts have reported cases occupational in origin. Timpano attributes to coccidia (Accleria Berleste, Leptus autumnalis) a form of cutaneous irritation, rhinitis and conjunctivitis met with among reed peelers (Arundo donax). It is true that cases of dermatitis due to oidiomycetes have been described under the name of coccidioses; these cases of dermatitis may be quite easily cured when the patient has been in contact with a sick animal.

The author thinks that this case was the first case of its kind.

See "Pustules", "Microsporosis" and "Trichophytoses".

Diphtheria. — This acute infectious disease, which is epidemic and contagious, is caused by the Klebs-Loeffler bacillus.

The bacillus is found in most cases in the pharynx, but may develop in any other region.

A doctor practising in an industrial town or populous centre is well acquainted with the peculiar gravity of the disease in case of overcrowding. During epidemics the number of germ carriers, which is considerable, facilitates the spread of the disease.

At the present time serum treatment has greatly diminished the mortality from diphtheria. Vaccination against the disease will make it still less common.

The persons who are most liable to contract the disease on account of their occupation are doctors and nurses, as well as, in certain occupations. This disease is compensated in Queensland when it attacks hospital personnel.
Dysenteries. — The term "dysentery" is applied to a well-characterised clinical syndrome, which includes amoebic and parasitic diseases, very diverse in origin, located in the intestines. There is generally a lesion of the mucous membrane of the colon and rectum which causes sanguineous stools.

For the purpose of this article it is sufficient to say that at the present time amoebic dysentery is recognised which presents an epidemic character and occurs in the temperate regions; it is due to the bacillus dysenteriae (Shiga and Flexner). A separate entity is the amoebic dysentery, which develops slowly, rages chiefly in tropical and sub-tropical regions and is due to entamoeba histolytica (tetragenae). This is the most common form, for amoebic dysentery claims certainly more than eight-tenths of the chronic cases. In other chronic cases the dysenteries are due to two other very extensively distributed organisms which are often found poor condition, exhausted, and congested of the glands, fever and pricking due to alcoholism.

Exanthematic typhus. — This acute disease shows itself in the form of a typhic condition and a characteristic rash, discreet at first, but rapidly becoming purpuric; it is accompanied by bloody effusions from the conjunctive and pharynx. The temperature is very high and often accompanied by delirium. The cause of the disease is an unknown virus transmitted by ectoparasites (lice). Typhus is compensated in Germany when it attacks sailors.

Favus. — This affection is caused by a fungus of the achorion genus (A. Schönlentin) which attacks the scalp, as well as the hairless parts and nails, giving rise to characteristic changes. In the scale when the parasite has reached its full development, formations occur which have a crusted appearance (scabs) with a sulphur yellow colour. The greatest part of these crusts is composed of masses of fungi; on hairless parts the presence of the parasite is manifested in the form of red patches covered with scales; on the nails are found thickenings, while the nail becomes opaque, brittle, irregular and of a greyish white colour.

Various kinds of favus which affect either animals can also be found in human beings. The clinical diagnosis does not as a rule present any difficulty; it is confirmed by microscopical search for the fungus in the crusts after they have first been treated with caustic potash (40 per cent.) or finally by cultures.

Gaseous oedema. — See "Septic vibrio".

Infections. — Common localised infections having as their starting point small abrasions of the skin or small injuries, are quite common in the course of manual labour. They are usually caused by staphylococi or streptococi. Although not serious so long as the trouble is localised, such infections may become particularly grave if they become general. (See "Septicaemia").

Infestous anaemia of the horse. — This affection, to which the name of "parasitic anaemia of the horse" has been wrongly given, is caused by a still unknown filtrable virus; it has been observed in a person who became infected during some laboratory researches on the disease. The symptoms consisted in intestinal disorders, cephalalgia, lumbar pains, wasting and anaemia. At the end of some
weeks the patient showed abdominal
herpes zoster, a rose rash and an inter-
mittent spotty fever oscillating about 39°C.
(Lührs).

Infectious jaundice (Weil's disease). — See "Spirochaetosis".

Influenza. — This infectious disease is
due to a coccobacillus isolated by Pfeiffer;
it is manifested clinically by fever, pains
in the back and limbs, joint pains, cephal-
algia and varying visceral disturbances.
Thus pulmonary and intestinal influenza
and influenzal meningitis are mentioned.
The working classes seem to be par-
ticularly affected during an epidemic,
and usually the pulmonary forms pre-
dominate. Working women are attacked
with more serious symptoms than men,
especially in the manufacture of tobacco
(Tedeschi). Moreover, when working in
fumes show a certain immunity against
nasal and respiratory catarrhs in general.
Thus, A. Gregor found that workers in
cordite factories, gas works and tin mines,
exposed to fumes, were affected much less
seriously than workers in the same kind
of work not exposed to fumes, and than
soldiers and sailors. On the other hand,
E. J. Ball thinks that fumes containing
sulphocyanide favour the protection of the
workers. Further, Frank Shuflebotham
found that it was chiefly men employed
on work in which fumes of sulphurised
hydrogen, chloropicrine, chlorine and mus-
tard gas (dichlorelthyl sulphide) were
generated who were protected against influenzal
infection. Walker has described
a case of infection in a laboratory due
to the coccobacillus of Pfeiffer: the symp-
toms consisted in rhinitis, conjunctivitis
and bronchitis without fever.

Lambliosis. — A disease due to the
Lambia intestinalis, a parasite of the
order of polymastigia which has four to
eight flagellae. Some cases of intestinal
infection in miners have been observed in
Germany (Teitge).

Leishmanioises. — These are diseases
due to protozoa (Leishmania) which are
grouped in two categories: those localised
to the viscera, which lead to infantile
splenic anaemia and especially to Indian
Kala azar; and those whose localisation is
cutaneous and muco-cutaneous which lead
to Kala azar; and those whose localisation is
splenic anaemia and especially to Indian
measles. — This infectious disease is
due to a parasite of the muconine order
(Lichthemia Italice), isolated in 1913 by
Perin in theexpectoration of a country-
woman, who succumbed to the disease.
In 1923 Perin and Ricci again found the
same parasite in a peasant who showed as
clinical symptoms, cough, hemoptysis
and asthma. Lichthemia has also been
found on maize, in manure and in the
dust of the harvest.

Marsh fever. — Still described under
the name of mud fever this disease
caused in 1928 a small epidemic in the
flooded regions of the Oder, where the
same infection had been previously ob-
served. The disease affected chiefly young
persons of 14 to 25 years who had been
working in flooded areas. Clinically, it
shows itself by premonitory fatigue, fol-
lowed by violent cephalalgia, high tem-
perature, stiffness in the back and limbs,
anorexia and tremors. Vertigo, muscular
pains, rachialgia and often abdominal
pains may also be present. Objectively,
conjunctivitis and congestion of the face
are found. The temperature may reach
40°C; it remains so for five to seven
days and is accompanied by intense
sweating and varying exanthems.

The etiology of the disease remains
obscure and its diagnosis is often confused
with influenza and dengue. Prognosis is
usually good. The number of cases ob-
served up to the present time exceeds a
hundred (Werner).

Measles is an infectious disease charac-
terised by a rash which is preceded by
an ocúló-nasal catarrh. Infection can
only occur directly. The disease itself is
comparatively benign in children, but
may assume at the onset a malignant
character in adults. From the occupa-
tional point of view it is only of impor-
tance as regards persons employed in
hospitals or who come directly in contact
with the patients. This disease is com-
pensated in Queensland when it attacks
hospital personnel

Mediterranean fever. — This infectious
disease is also known as "undulant fever"; it is common to man and some
animals (goats especially); it is endemo-
epidemic in the basin of the Mediterranean
from whence comes its name, and is due
to Micrococcus melitensis Bruce. In man
it is characterised clinically by copious
sweats, persistent pains and especially by
successive rises of temperature of long
duration (undulant fever). It is found
fairly often among goat-keepers and persons who come in constant contact with goats or sheep (Imbert); and it can be easily transmitted in the case of wandering herds not subject to adequate sanitary supervision. For this reason France decided in 1923 to bring into force a series of protective measures against the spread of the disease. Imbert in a thesis, published in 1938, collected 70 cases in the Ardèche, in half of which contagion by simple contact was the source of the disease; he shows how liable butchers are to undulant fever (4 cases).

At the present time the question of identity between the agent of human undulant fever and the bacillus abortus (bacillus of Bang), which causes epizootic diseases among bovines, is under discussion. Recently some authorities have expressed the opinion that there is only one and the same agent, which in passing from man to the animal and vice versa presents its essential specific qualities, though subject to certain biological changes. The practical importance of the problem is obvious. For a long time it was believed that undulant fever was only propagated by goats; but it has since been found that it may also occur in sheep, horses, dogs, rats and even cows. Thus the possibility must be allowed of infection by means of milk and dairy products; moreover, such infection has been confirmed in carefully controlled cases.

A case of laboratory infection due to the micrococcus of undulant fever has been reported by Professor Carbone, of Parma.

Microsporosis. — This affection of the smooth parts and the hair is caused by various kinds of the microsporon genus and notably that of M. Audouini in the case of man. The disease can be transmitted by various animals, such as the dog, cat and horse, in which microsporases are quite common. Transmission from man to man may occur as with other dermatophytes.

Mumps is an infectious disease characterised by inflammation of the salivary glands and particularly of the parotids. It is included in the list of occupational diseases in Queensland when it attacks the personnel of hospitals.

Noma. — The affection is caused by a necrosing bacillus which has been identified with the bacillus of diphtheria of calves. Clinically, it causes the formation of an abscess and deep ulceration. Jensen has reported some cases of noma as affecting persons employed in laboratories.

Oriental sore. — This affection, which is still known under the names of "Aleppo boil", "Cutaneous Leishmaniasis" or "Biskra boil", takes the form of a parasitic skin granuloma produced by Leishmania tropica or Leishmania farcibercolata. After a somewhat variable period of incubation it appears on uncovered parts of the skin as a pruriginous papule, surrounded by a hyperaemic areola which opens, forming generally a single ulcer with infiltrated edges and a violet red fungating base.

Certain species of mosquitoes or bugs (Cimex lectularius) are regarded as the agents of transmission. Two autochthonous cases of oriental sore have been reported in France, in 1930 and 1936, among workers at the ports.

Oroya fever. — See "Peruvian wart".

Pernicious anæmia of the quebradas (ravines). — See "Peruvian wart".

Peruvian wart. — This infectious disease, still known under the name of "Oroya fever", is characterised by fever, marked anæmia and a warty cutaneous eruption. The disease only occurs in some regions of the Cordilleras in the Andes.

Oroya fever in 1870 attacked the workmen employed in constructing a railway between Lima and Oroya. Further, all the workmen employed in making the railway across the Andes contracted Peruvian wart. In 50 per cent. of the cases the disease was fatal (Bourse). Peruvian doctors regard Oroya fever and Peruvian wart as two manifestations of one and the same morbid condition. Experimental proof of this fact was established in 1885 when a medical student, Daniel Carrion, a native of a locality where the disease is endemic, inoculated himself with the wart and became ill twenty-three days after with Oroya fever, from which he died at the end of two weeks. However, in 1913 the Strong mission decided on the duality of the two diseases, thus distinguishing a febrile and malignant form which is generally fatal (Oroya fever) and an eruptive form which has a benign character (Peruvian wart). As a matter of fact, the geographical distribution of the two diseases is not always the same; and there are places where only one or other of the affections is met with. Oroya fever, known also under the name of "pernicious anæmia of the Quebradas", is due to a microbe which has been found in the blood of patients, and recovered by observers in the tissue of the warts. The pathological agent is transmitted by an insect of the blood-sucking genus (P. verrucarum, P. nuyuchii).

Plague is an epidemic disease transmissible directly to man or by the intermediaiy of animals (rodents, ectoparasites), due to the bacillus of Yersin; it is characterised by a typhoid state which rapidly becomes serious. The appearance of buboes, petechiae and pulmonary signs constitute very grave complications which are especially contagious and fatal.

The transmission of plague to a distance takes place on land by rats and fleas, assisted by the increase in the number of roads and railways. On the other hand, in maritime conditions the chief transmitting agents are rats which infest grain-carrying ships. A man during the incubation period of plague, or as a carrier of infected fleas, may also convey the disease to a distance.
Direct contagion, except in the case of the paralytic form, is rare. Contagion of human origin occurs usually through underclothing and clothes which have belonged to a patient, although the bacillus is not at all resistant to light and dryness. There are several cases recorded of plague attacking doctors, either during epidemics or in laboratories during research work. Certain occupational classes are very much exposed to the contagion, notably transport workers and especially dockers, seamen and railway workers. Among other occupations should be mentioned: hunters, for example, tarabagan hunters in the Mongolian steppes; rag sorters, among whom epidemics occurred in 1913 at St. Barnabas' cardboard factory at Marseilles, in 1916 at Bristol, and in 1920 at Paris; in Manchuria some coolies have been infected by their donkeys (shibayama). At Sargo a dyeworks was infected on two different occasions, in 1906 and 1914, plague having been brought in by rats hidden in boxes containing old dresses for cleaning or dyeing.

In well-managed hospitals the risk of infection of the medical and nursing staffs is extremely rare, as is known from experience gained in India (Hankin). That does not imply any harmlessness for the virus, since frequent cases of infection due to hands infected by pus from a recent bubo, from pricks during autopsies and from contaminations from excreta, are on record. Epidemics are even known to have started from infection in laboratories, though this has not often happened (Vienna, 1893; Preston, 1910; Ruisseau near Algiers, 1912; Tangiers, 1914, etc.). In the pneumonic form of plague enormous quantities of bacilli are scattered into the surrounding air by the patient during coughing. Plague is compensated by the Governments of Yugoslavia and Japan if contracted during the handling of rags, hair and skins, and by Queensland for hospital personnel.

Psittacosis. This disease which is still called "parrots' typhus" (Peter) was recognised for the first time in France in 1892 during an outbreak which occurred among parakeets imported from Brazil. It was transmitted to some persons who conveyed or had charge of the birds. It was Nocard who first isolated, in 1892, the bacillus which bears his name, and called the disease "psittacosis". It is believed that this bacillus belongs to the B. paratyphoid group; Perry (1920) found it to be identical to the B. aertrycke (Mutton), and to the B. typhi murium. It has now become classified in the Salmonella group, whilst other experts consider it to be a virus capable of filtration, opening the way to other germs, and especially to streptococci, to the bacillus of Nocard, etc. The disease recalls the clinical picture of typhoid fever, and most of the symptoms of atypical pneumonia. Coughing is fairly frequent. The mortality rate is very high. A fatal case has been reported (1930) in the United States as occurring to a laboratory assistant engaged in looking after parakeets. Eleven laboratory assistants in the Federal Hygiene Service have been attacked by psittacosis during research work.

Rabies. This disease, which is peculiar to the dog, wolf, and other animals (foxes, cats, the equine species, goats, pigs, etc.) may be transmitted to man by bites, by licking of the apparently healthy mucous membrane, or by soiling of wounds with foam from the mouth. According to Levaditi and his collaborators, the rabies parasite is a microspore or a parasite belonging to a similar group. The bodies which Negri succeeded in demonstrating in the nervous cells, especially on the limb (hippocampus), are said to constitute the pan-sporoblastic phase of its cycle of development, a phase which is lacking in the fixed virus. The occupational risk is great for all those who have frequent opportunity of living close to animals susceptible to the disease: hunters, breeders, owners of dogs, stable boys, cowherds, veterinary surgeons, carters, employees in furriers' workrooms, sailors, etc. Though the rabies virus is delicate, without possibility of conservation except in the patient, it is also capable of becoming attached to inanimate objects and polluting these dangerously during an appreciable time, and by way of these coming in contact with the tissue and giving rise to the disease. In this way are explained several cases, some of which have even been quoted by ancient writers (Caesium Aurelianus, for instance) and nearer our time by Porta, Enaux, and Chaussie (1795), Barsley, Ricchole (1893), Remigler (1906), Engel, Koevaloff (1923), Krauss, Gerlach and Schweinburg, etc., cases which prove the possibility of contagion sometimes of occupational origin, quite apart from infection due to bites.

In man the disease commences by a period of incubation lasting from fifteen to sixty days, sometimes even longer, with a change in the patient's humour, which is variable, anxious, with phenomena of insensibility, but more often of hyperaesthesia, at the seat of the bite. There follows a slight increase of temperature, with more and more abundant flow of saliva, as well as increasing cramp on swallowing, accompanied by respiratory trouble. The anxious state gets worse. The muscles of the trunk and of the limbs are affected by cramps caused by the least sensory stimulus. There is loss of consciousness except for short intervals of tranquillity. Death occurs as a result of paralysis, with symptoms of cardiac weakness and marked fever.

The anti-rabies vaccination of Pasteur is very well known, and its practical value is so much the greater the earlier it is applied. In the case of individuals bitten by a mad dog and treated by vaccination, mortality has fallen from between 30 and 40 to about 0.5 to 1.5 per cent.
Rabies is subject to compulsory notification as an occupational disease in the State of Illinois.

Rat bite fever. — See "Sodoku".

Recurrent fever. — A disease known as recurrent fever, and also under the name of "recurrent typhus", is due to a spirochaete (S. Obermeyeri. S. Duttoni, S. lutea, S. Novyi, S. Carteri) which manifests itself by an attack of continued fever often followed by one or several relapses. It is transmitted to man by means of parasitic insects which seem to be of different kinds according to the different varieties of recurrent fever.

A case of laboratory infection by the conjunctiva was reported in Russia in 1928 at the medical clinic of Kazan (Ivanowa).

Rheumatisms. — Under the name of rheumatism are grouped joint affections, and muscular and nervous conditions which very often affect the working population. It has been shown that acute polyarticular rheumatism is an infectious disease. The germ, however, has not yet been isolated. On the other hand, in forms of chronic rheumatism an important part is played by the influence of tuberculosis. Generally hard physical work, with exposure to bad weather conditions, draughts, wind, rain, dampness, and high temperatures, is a predominating factor for rheumatism. As a matter of fact this affection is often met with in bakers, stokers, laundry women and land-workers, and among the last named chiefly in the form of lumbago. The clinical forms vary according to the position of the pains. Rheumatism of the shoulders (Omalgia rheumatica), sciatica, muscular rheumatism and chronic arthritis deformans are all recognised. Rheumatism in the acute febrile form is especially dangerous for the heart.

According to the Minister of Health of Great Britain, there are registered annually in England and Wales among persons insured against sickness, 90,000 cases of lumbago, 22,000 cases of sciatica and 56,000 cases of muscular rheumatism; more than 50,000 insured women are each year victims of these diseases. In Great Britain it is estimated that rheumatism is responsible for 80 per cent. of deaths due to diseases of the heart among young persons below twenty years of age.

It is generally considered that rheumatism is favoured by the bad social conditions under which poor children live. It is in consequence proposed to subject to close supervision all children under fourteen years, it having been found that very often the disease begins in early infancy.

Some idea of the importance and extent of rheumatism among workers may be obtained when it is considered that in Great Britain the disease in 1927 caused a loss of 5,500,000 working weeks and represented a charge of 5 million pounds sterling for the budget of the national health insurance. The same hard, for this same period a sum of 12 million pounds sterling represented the loss of wages sustained by the insured sick persons.

Rocky Mountains spotted fever. — This affection, which is still known under the name of "tick fever", is an infectious disease caused by unknown germs and transmitted by the Dermacentor andersoni Banks, an acarus of the ixodide family. The disease begins by cephalalgia and articular pains. The incubation period is from one to eleven days. The fever, which is remittent, reaches at the end of ten to twelve days 39.5° to 40° C., and falls between the fourteenth and eighteenth day. There is at the same time an acceleration of the pulse to 110 up to 140, and of respiration to 25 up to 50 and even 60 respirations a minute. The predominant symptom is a rash which commences at the wrist and ankle and extends to the forehead, back, chest, and then to the abdomen. The rash may become confluent and form petechiae. The differential diagnosis is difficult on its appearance from a typhus rash. The disease has been observed among forest workers in the Rocky Mountains, especially in the States of Montana and Idaho.

Doctors and laboratory workers have also been among the victims of tick fever. Up to the present 4 cases have been reported, of which the most recent, in 1928, occurred in one of Hamilton's laboratory assistants who contracted a fatal illness from handling the virus.

Rouget is an infectious disease giving rise to outbreaks in swine and transmissible to man. According to Arkwright (1918), cases of rouget in man are actually rare. It is not even certain that all the cases described up to now have been accurately diagnosed. In the last half of the nineteenth century several cases of stomatitis were attributed to rouget, at a time when this disease was raging among the herds. Most of the cases were due to taking milk. In some other cases it was possible to establish an epidemiological origin for the infection, such as contact with diseased animals or butchering. However that may be, the question has not been cleared up and the general opinion is that it is not rouget, but angina and fever due to streptococci or to other bacteria transmitted by a mammitis of cows. On the other hand, secondary infections occurring in animals attacked with aphthous fever have been suspected.

At the present time the identity of this affection with orysipeloid is almost generally admitted (see "Erysipelae").

Scarlet fever. — This infectious epidemic disease occurs chiefly among children. The symptoms are sore throat, enlargement of the lymphatic glands, disorders of the circulatory and nervous systems, with a rise of temperature to 40° C. and more, and a red rash which has given to the disease its name. In serious cases scarlet fever is complicated by nephritis and various inflammations of organs, due to secondary infections.
The disease usually runs its course in two or three weeks, after which desquamation of the skin commences. Two cases of laboratory infection were reported by Moltke and Poulsen in 1929. Among adults scarlet fever is an occupational risk for the personnel of infectious hospitals, for rag sorters, and in general for every person in contact with patients with yellow fever, or with rats, due to the disease called "rat bite fever". Septic oedema is met with in agricultural infections, and is also quite common, especially in Japan, doctors and in particular all laboratory workers, just as all who come in contact with rats, may be infected by the spirochaete of haemorrhagic jaundice. The supply of virus may come either from man in the case of typhus, or from an animal, such as the rat for sodoku and haemorrhagic jaundice. It is almost certain that cases formerly diagnosed as infective jaundice, febrile jaundice, jaundice fever or relapsing jaundice were really cases of haemorrhagic spirochaetal jaundice. Septicemia, pyaemia. — Under this heading are now understood serious morbid conditions characterised by the presence of microbes in the blood. In consequence, one may say that there are as many varieties of septicaemia as there are pathogenic micro-organisms capable of passing into the blood and of developing there. The penetration of microorganisms into the blood takes place under the most varied conditions: pricks, wounds or other injuries which are sometimes quite negligible in themselves. Any infected focus, whether a whitlow, abscess, phlegmons, chilblains, or certain diseases, such as erysipelas or pneumonia, whether suppurating or not, may cause a septicaemia. Septic pyaemia presents a collection of ordinary symptoms: shivering, fever, sweating, prostration and secondary deposits. It is sufficient to say that septic-pyaemia from streptococcic infection is the most common, for this microbe exists in the state of a saprophyte on the mucous membranes and possesses a great aptitude for growing in the human blood. Septicaemia from staphylococcic infection is also quite common, especially as an infection secondary to a staphylococcic lesion of the skin where this microbe is found in the saprophytic state.

Septic vibrio. — The septicaemia of septic vibrio which is accompanied by septic oedema is met with in agricultural workers who handle manure (Antonelli). (See article "Agricultural Labourers").

Sodoku. — Still known under the name of "rat bite fever", this disease, which is due to a spirochaete called by Noguchi Spiroplasma Sodoku, is characterised by shiverings, fever, a generalised eruption and inflammatory appearances at the site of the bite. In the case of a bitten finger, this is the most common, especially as an infection secondary to a staphyloccic lesion of the skin where this microbe is found in the saprophytic state. The course of the disease varies from three days to three, four and even more weeks. An abortive form has been described, also a form confined to the region of the bite, and a nervous and a renal form.

Spirochaetosis. — This is a group of acute diseases caused by pathological spirochaetes; it includes recurrent typhus, leper-haemorrhagic spirochaetosis, trench fever, sodoku, and, according to some authorities, yellow fever, which Noguchi attributes to spirochaetes (leptospira icteroides). The characteristic feature of acute spirochaetoses lies in the temperature chart, the presence of jaundice and the absence of direct contagion from man to man. Transmission occurs by the intermediary of an ectoparasite (the louse for recurrent typhus) or mosquito (the stegomyia for yellow fever). The supply of virus may come either from man in the case of typhus, or from an animal, such as the rat for sodoku and haemorrhagic jaundice.

Sporomycosis. — Under this name there was described, in 1928 a benign affection occurring in summer in persons in perfect health, running a course of some weeks and clearing up when the patients had been removed from the infected locality. Clinically symptoms of tracheo-bronchitis, digestive disorders, asthenia, myalgia and wasting were found. The Aspergillus fumigatus and Mucor mucedo were regarded as the cause of the disease. The symptoms commenced as early as the month of May and attacked chiefly men who were sweeping up grain (Pasteur Vallery-Radot and Paul Giraud).

Sporotrichosis. — This affection is a mycosis common to man and animals, due to a fungus known as Sporotrichum
Beurnmanni. For a long time this infection was confounded with syphilis and tuberculosis, its clinical character having been defined only in 1909. The parasite, which was isolated and cultivated in 1905, is very widespread in nature: it is found in the saprophytic state on equiseta and on oats. It develops spontaneously in such mammals as dogs, horses, and rats, and in insects, so that all these intermediaries may serve to transmit the disease to man. Infection may occur at the site of an accidental injury, even though quite minute, or by the digestive organs, or even through the healthy skin or at the junction of the bulbar and palpebral conjunctiva. Accidental infections in the laboratory are frequent.

The disease attacks agricultural workers, sellers of grain, fruit, flowers and vegetables, and men employed in transport work, drivers, stable boys and veterinary surgeons. The disease has been found in almost every country, the frequency varying from one place to another.

Trichophytosis. — This group of skin affections which attacks the epidermis, hair or nails, is due to various kinds of fungi of the Trichophyton genus. The trichophytosis caused by the *trichophyton cutaneum* of Breslau is characterised by an eruption of squamous erythematous or vesiculo-erythematous patches which are pruriginous and are situated in the inguinal, ano-vaginal, axillary and mammary regions. The disease is caused by an agent as yet unknown; it occurs amongst cattle where it is not known in other parts of the world. Out of 614 cases observed, 20 ended fatally. Numerous cases of tularaemia were caused in 1928 in a village in the Urals by the water-rat, which is hunted for its skin. The Health Service of the Ural district has published a notice containing hygienic and preventive recommendations for hunters of water-rats.

The symptoms appear forty-eight hours after infection, which most often occurs from a bite; they consist of fever and pains in the vicinity of the glands to which the bitten area is drained. A marked affection of the glands characterised by great swelling and violent pain, passes on to suppuration. The duration of the disease varies from three to six weeks, with a feverish condition like that of septicaemia. Convalescence is slow. A form complicated by conjunctivitis and a typhoid form have been described. The occupations in which the disease has been observed are: cooks, gamekeepers, housekeepers, market-stall keepers, and, in general, those who skin and cut up rabbits when preparing bait for fish or coyotes, or food for foxes, owls or pigs.

Typhoid fever. — Under this head are included all conditions impairing the activity of the subject, even temporarily, in which the presence of agents of the typhoid group are found by laboratory tests (Lenglet and Ayrignac). To this group belong the typhoid bacilli properly so called (Bac. of Eberth, *Paratyphoid bacillus A*, *Paratyphoid bacillus B*), and the *Salmonellosis bacilli* which can only be distinguished from each other by secondary clinical and bacteriological characteristics.

The infection generally occurs by ingestion, and only occasionally by the respiratory passages. Fatigue and defective nutrition explain the intensity and gravity of typhoid conditions, especially in tropical countries.

In 1929 Achard reported the results of his observations relative to a woman employed in a laboratory in sealing
capsules of anti-typhoid T.A.B. vaccine, which, in error, had not been sterilised. Her fingers were soiled, and even her face, by projections of the microbic emulsion. She developed ordinary typhoid fever after a very short period of incubation. Achard also insists on the frequency of contagion due to dirty hands (care in regard to manipulation of soiled basins, sheets, shirts, etc.) amongst nurses and doctors, etc. Perspiration of the hands probably favours numerous cases of indirect contamination.

Dissemination of the infectious agent by various forms of organic matter and by such things as water, food, soil, clothes and underclothing, in which it is preserved for months, explains the virulence of typhoid bacilli, after periods more or less prolonged. Damp air, dust and flies may convey the bacilli. Carriers of the bacilli play an important part in the transmission of the disease; and the danger is especially great in the case of persons employed in the manufacture of food products or in the preparation of food, and butchers, dairymen, pork butchers, gardeners and cooks. Infection by excreta from patients is by far the most common source; and the chief vehicle is the water supply which should always be suspected in any epidemic of a serious nature. Next to water, soil which preserves the bacilli brought to it by manure, excreta which foul it, the hands and articles of persons who have been in contact with patients or carriers of bacilli, are means for spreading the disease. The disease is compensated in Queensland when it attacks hospital personnel.

Preventive vaccination should be compulsory for every worker called on to handle live or dead typhoid germs (Achard).

Vaccinia is a disease which is common among bovines and members of the horse family, where it takes the form of a localised affection which is usually benign. It is from these animals that man may become infected. Among swine and goats, the disease is more dangerous. The infection attacks horse keepers, stable boys, agricultural labourers and veterinary surgeons. Many cases of vaccinia are known to have occurred in men, which have been transmitted from cows. The patient presents vesicles and pustules, and sometimes localised nodules, in the affected skin region. Ran and De Jong have described a form of vaccinia localised in the ear and on the external auditory meatus.

During an epidemic of vaccinia in 1909, out of 21 milkers, 22 were infected, although most of them had been vaccinated during infancy. Small epidemics are met with among farm labourers which affect from ten to twenty persons (Tryb). Some cases known under the name of "Manké" have been confused with vaccinia; they are regarded now as eczema. Typical cases of vaccinia are rare nowadays for vaccination has certainly diminished the frequency of the disease.

Variola or smallpox. — This disease which in the old days used to rage in epidemic form in every country, has become more and more rare since general vaccination of the population. Danger of infection, however, exists when merchandise infected by variola is imported into industrial regions which have been hitherto exempt. Thus in France in 1925 some cases of infection were reported in four departments with several deaths and threats of serious epidemics (Camus). Apart from vaccination, prevention of the spread of the disease should be ensured by careful disinfection of merchandise liable to transmit the infection.

This disease is compensated in Queensland when it attacks hospital personnel.

Warts are papillomatous excrescences of the skin common in domestic and wild animals, fish and birds. In spite of the positive result of transplantation experiments and of transmission by contact, the natural infection of man by an animal is quite rare. Cases of infection by foxers, transmitted from foxes, are recorded.

Yellow fever. — The infectious disease known as yellow fever runs a rapid course; it is caused by a virus, the nature of which has not yet been determined, but it seems to belong to the spirochaete genus. The virus carrying agent is a mosquito of the Stegomyia family (S. fasciata or S. Calopus). The disease attacks chiefly agricultural workers who, apart from vaccination, prevention of the spread of the disease is compensated in Queensland.

This disease is compensated by the Government of Yugoslavia.

LEGISLATION

In Germany, since February 1929, "Infectious diseases" have been compensated when they attack the personnel: of hospitals, maternity homes and other similar institutions which take in persons for treatment, as well as general and public or private associations for social
aid; of the public health service; of laboratories for research and scientific experiments whether for natural science or medicine. Infectious diseases which are characteristic of tropical and sub-tropical countries, viz. malaria, dysentery, yellow fever, sleeping sickness, dengue, plague, undulant fever, framboesa and anktylosomiasis, are compensated when the latter when it attack seamen in the merchant service (not those on inland waterways).

These diseases are compensated in Hungary when they attack agricultural labourers; in Queensland (smallpox, typhoid fever, diphtheria, bubonic plague, measles, mumps, scarlet fever, when they attack hospital personnel); in Western Australia when they attack sanitary officials; in the State of Ohio when they are a complication of local lesions caused by oils, lubricants, dust or liquids; in Austria since 1928, when they occur among the personnel of scientific laboratories.

In Lithuania and Yugoslavia, compensation is granted for epidemic and tropical diseases in the mercantile marine.

Septicaemia is compensated in the States of Victoria and Queensland (in the latter when it attacks persons employed in handling meat and animal products, in carding and sorting wool, in handling skins and hides, wools, horsehair, hair, hog bristles or carcases of animals).

In some countries certain cases of infection, such as anthrax and plague, are considered as accidents, so that the actual tendency, as for example in Italy, is to regard sections of an occupational origin as industrial accidents and to compensate them accordingly.

**IODINE**

**Iodine**

**CHEMICAL PROPERTIES**

Iodine (symbol I), discovered in 1812 by Courtois, is a product widely disseminated in nature in combination with other substances and often accompanied by a compound of chlorine and bromine. It is likewise found in the state of iodides and iodates (of mercury, silver and lead), in certain ores, in Chilian nitre (sodium nitrate), in certain mineral waters (iodides of magnesium and sodium), especially in sea water (0.002 grm. per litre), whence it passes into certain types of plants, e.g. seaweed (*Fucus vesiculosus*, kelp, lamnaria), and certain marine animals, e.g. sponges and mollusks.

In the pure state, iodine occurs in the form of large rhombic plates of a blackish violet colour, with a metallic and a peculiar smell which at 114° boils in water, and the sodium and potassium chlorides, which is highly irritant and which, like its crystals, dye the skin and organic substances dark yellow. The fumes become recondensed without passing into a liquid state, and are sublimated in bright black crystals. It is very slightly soluble in water (1 part per 3,000); it dissolves easily in an aqueous solution of iodine of potassium, in alcohol, ether, chloroform, carbon disulphide (which dissolves 33 per cent. of it), etc. Used with starch, typical violet coloration is obtained, which disappears when subjected to heat.

Iodine is very much used in the preparation of alkaline and organic iodides of certain organic colours (violet and green iodine, tetraiodofluorescin), photographic preparations, in chemical laboratories, in medicine, etc.

In combination with a solution of ammonia, and in part with a solution of salts of ammonium, iodine may give rise to explosion. The product known as "brom-iodine", which is very much used in the photographic industry, has a highly irritant action.

**INDUSTRIAL PROCESSES**

The treatment of seaweed (kelp) still followed in Great Britain, France, Japan, etc., for a long time constituted the sole means of preparing iodine. The seaweed is dried in the sun or calcined in order to obtain the "sodas"; washing in water, followed by concentration of the liquors obtained and calcination, also furnishes a means of obtaining the "sodas" while conserving the organic substances contained in the seaweed.

The "sodas" or "ash" are again placed in water, and the sodium and potassium chlorides, as well as the soluble salts, are thus separated (sulphates, alkalines, carbonates). The mother liquor is treated by sulphuric acid, which decomposes the sulphide. Sulphur dioxide and sulphuretted hydrogen are given off, with formation of a precipitate of sulphur which is recuperated. The mother liquors, rich in iodides are thereafter distilled in the presence of manganese dioxide and sulphuric acid. Various processes are utilised. In accordance with one of these methods, the acidified mother liquor is distilled, recovered, condensed, and then manganese dioxide is introduced gradually up to the point at which the reddish violet fumes liberat-
iodine is recovered in the form of crusts, and the iodosides obtained as a second product are treated with chlorine (in the form of potassium chlorate and hydrochloric acid in accurately calculated quantities). The iodine separates out and is obtained as a solid on the surface, or in the bottom, of the recipient.

Another method consists in drying the iodoside solutions, which are then mixed with water and treated with sulphuric acid or potassium bichromate.

A third method finally utilises treatment of the mother liquors with copper sulphate or sulphate of iron in order to form copper iodoside, from which the iodine is ultimately extracted by distillation with sulphuric acid and oxide of iron.

Incineration of the seaweed may be avoided by distilling it directly in a retort.

In South America the iodine is extracted from crude sodium nitrate, the mother liquors coming from the refining of the nitre (with 0.5 per cent. of iodosides) being treated with bisulphate of soda or a solution of sulphur dioxide. The iodosides separate out in a solid mass. The iodosides are decomposed by the addition of a little water. The impure iodine (80 to 85 per cent.) is recovered and filtered.

Iodine may finally be extracted from the mother liquors of Stassfurt salts, or from iodosides by electrolytic process.

Crude iodine is purified by sublimation, which is effected in an earthen retort heated to a moderate degree in a sand bath. The fumes are recovered in a large earthen receptacle with a double bottom for separating the distillation water. The iodine is sublimated a second time to eliminate small traces of chlorine, of bromine and of water which it may still contain.

Amongst the compounds of iodine, mention is restricted to the following:

Methyl iodoside (CH₃I), prepared like ethyl iodoside with methyl alcohol, phosphorous and iodine, is a liquid with a density of 2.293, which boils at 45° C.; with much water at 100° C. It decomposes into HI and methyl alcohol. It is used chiefly in the preparation of methylated aniline colours.

Ethyl iodoside (C₂H₅I) is prepared by causing red phosphorus to be digested with absolute alcohol to which iodine is gradually added. It is heated and distilled in an air-bath, it is washed with dilute alcohol, then with water, and then dried with CaCl₂. It boils at 72.3° C. Ethyl iodoside decomposes slowly when exposed to light.

Allyl iodoside is similar, and is constituted like allyl bromide and allyl chloride.

Ethylene iodoside, similar to ethylene bromide, is distinctly toxic. It gives rise to cerebral troubles, with a sensation of violent oppression.

Cyanogen iodoside has been studied by Goldfarb (1891). It was formerly used as an anti-parasite for cattle.

Nitrogen iodoside is extremely explosive even on the slightest friction.

Iodine trichloride is very little used and is highly caustic.

For lead iodoside, see article, "Lead, Compounds of".

Iodoform or triiodomethane (CH₃I₃), discovered in 1822 by Serullas, is prepared by heating ethyl alcohol or acetone with iodine and the amount of alkaline hydrate or carbonate necessary for decolorising the iodine. Efforts are at present being made to discover a practical means of effecting this by electrolytic process.

**Pathology**

Iodine exercises an action which is similar to, though less intense than, that of bromine and chlorine. Inhalation of its fumes may cause, besides a local irritant and caustic action, acute or chronic poisoning. This action may, however, occur also as the result of ingestion of iodine (dust) or, more frequently, of its salts in the course of their manufacture or of their use. The contact with the skin of an aqueous solution of iodine and its salts may also, in the long run, lead to absorption of the product, especially if the skin is not injured.

When it exercises a general action on the system, iodine may give rise to methaemoglobinaemia, often accompanied by methaemoglobinuria (Lowy). Acute symptoms are represented, according to Ascher, by excitement, nervous manifestations, irritation of the mucous membrane. Two serious cases, one of which was fatal, have been reported by Schuler (1890-1891) in a Swiss factory for the manufacture of organic compounds of iodine. In the fatal case, the victim suffered from vomiting, diarrhoea, serious cerebral trouble, vertigo, double vision, dysuria and collapse.

Certain injuries met with among workers engaged in the preparation of iodine are due to chlorine and other products utilised in course of its manufacture.

On the skin, iodine gives rise to yellowish brown staining and in the long run to irritation due to its well-known vesicating action which, accord-
ing to the research engaged in on himself by Matt (1888), a pupil of Lehmann, is said to be still more marked than that due to chlorine or bromine. The skin becomes dry and peels off in strips. Oppenheim reports cases of dermatitis of endogenous origin in the form of vesicles, and bilateral, toxic dermocystosis and impetiginous eczema of the face, with acne and folliculitis. Zanker, Sabouraud, Prosser White and others have drawn attention to cases of dermatitis due to iodine among photographers and members of hospital staffs (doctors, nurses).

On the mucous membrane, the iodine exercises an irritant and caustic action: at the level of the eyes the fumes cause watering of the eyes with a burning sensation, inflammation of the blood vessels, and sometimes blepharitis and, in the case of concentrated fumes, opacity of the cornea. As regards the nasal mucous membrane, there have been reported rhinitis and, as regards the buccal mucous membrane, catarrhal stomatitis, with salivation and a tendency to ulceration. The teeth become tinged with yellow. Chevallier (1842) noted irritation of the upper respiratory passages, and a chronic case of pharyngitis. There has also been quoted a case of cramp of the glottis. Ascher, finally, has reported cases of irritation of the gastric mucous membrane, even to the point of laceration.

The organic compounds of iodine have given rise to several cases of very serious injury, for besides the irritant action similar to that of alkaline chlorides, they possess a narcotic effect which recalls that of methyl bromide. In 1891 Meine, of Basle, reported three cases of poisoning by methyl iodide. Grandhomme (1893) noted in a factory of Hochst-on-Maine, six cases — some of which were serious — of poisoning due to the same product amongst workers who were engaged in preparing anti-pyre. Jaquet (1901) has described another case of poisoning by methyl iodide, and mention should also be made here of the cases of Schuler, referred to above.

In the cases studied, the methyl iodide had given rise to nervous phenomena characterised by very accentuated psychical excitement, followed by narcosis. The patients complained of derangement of vision, of discomfort and vertigo. They had slow pulse and retarded cardiac activity, derangement of the sensory organs, an absence of the reflexes of the conjunctiva, etc. (Lewin, Guillery, etc.). Zangger recalls that ethyl iodide may cause paralysis (since it is a question of a neurotropic poison) and that methyl iodide may give rise to phenomena similar to those produced by nitrous gas, etc.

The injuries caused by iodoform are exclusively limited to dermatitis. There has been described a type of eczema ("greenish and chronic itch") with violent irritation. In the case of a doctor, manipulation of iodoform gauze caused a lesion followed by a papular and eczematous rash on the back of the fingers and of the hand (Hartzell, 1917).

In general, the palm of the hand is not attacked. On the back of the hand and on the fingers, there form, on the contrary, vesicles which become covered with a crust. When this falls, the lesion is constituted by fissures or painful rhagades, with thickening of the surrounding skin.

Another case of special susceptibility has been related by Bruno Bloch (1912). It was, according to this expert, an instance of hyper-sensibility of the skin in regard to the methyl group rather than hyper-sensibility in regard to iodine. The mucous membrane is said to be free from this hyper-sensibility.

**HYGIENE**

The hygiene measures indicated are those provided for all chemical operations involving liberation of toxic fumes: processes in closed receptacles or, in certain cases, with effective ventilation (accompanied by natural recovery of the fumes containing the product). In the Swiss factory where two serious cases of poisoning occurred due to organic compounds of iodine, medical examination of the workers every three days, with analysis for detection of iodine in the urine, was instituted. In positive cases, the worker was sent to another department of the factory. Cleaning of the hands stained with the product was effected with an alcohol and soda solution.

**LEGISLATION**

The measures come within those provided for the chemical industries. Legislation accords compensation for injury due to iodine, ethyl and methyl iodide in Switzerland. It is possible that compensation for cases of dermatitis (due to liquids, for instance) may cover also dermatitis caused by iodine and its compounds, where these disease forms have been included in the list of diseases subject to compensation without an accompanying list of the industries affected by the law in question (see article "Occupational Diseases: Definition and Compensation").
Iron, Pig Iron and Steel Industries

In siderurgy the products are classified successively into "irons", "steels" and "pig irons" according to their increasing content of carbon.

Iron, also called "soft iron", is theoretically free from carbon. Steel contains varying quantities of carbon, but not exceeding 1.50 per cent. Pig iron generally contains more than 2 per cent. of carbon.

The differentiation of iron and steel is often difficult if regard is had only to the carbon present. In ordinary language, steel is the metal obtained by fusion, and iron by welding the mass when in a pasty condition.

The "special pig irons" and the "special steels" are alloys of iron with metals such as nickel, chromium, manganese, silicon, tungsten, etc.

Iron ores are either oxides or carbonates, sometimes also iron pyrites (sulphides) oxidised by roasting to extract the sulphur. The ore is rarely pure. Mingled with it are clayey or calcareous substances, to eliminate which fluxes of varying kind are added according to the nature of the ore, calcium carbonate or dolomite (limestone) if clay predominates: siliceous matters (clays) if the ore is calcareous. Slag is the gangue which has undergone fusion.

The production of pig iron and steel in the most important countries is as follows (monthly mean in thousands of metric tons):

Industrial Processes

Preparation of the minerals.— Some ores are washed to get rid of adhering earth. Others are broken up either with a hammer or mechanical crusher. Others again undergo a roasting process which frees them of sulphur and arsenic.

The mixture of ore and flux is appropriately called "the fusion bed".

Principle underlying the manufacture.— Reduction of iron oxide by means of carbon monoxide given off by the fuel used: Fe₂O₃ + 3 CO = 2 Fe + 3 CO₂. In the old process (Catalan) the temperature never became high enough to fuse the metal and ore nor to make the carbon combine with the iron. The mass remained in a pasty state and a "soft iron" was obtained after removal of the dross with the hammer. In modern processes the blast furnace is used.

The blast furnace is a lofty erection (15 to 20 metres and more), of which a cross section looks like two cones superposed on their wide bases. It is lined inside with very refractory bricks and the outside masonry is strengthened with iron hoops. The essential parts of a blast furnace from above downwards are: the mouth, the shaft, the belly, the boshes, the hearth, the crucible.

It is set going in the following way: heating up of the structure from a hearth, the base of which is made of dry wood and shavings with coke on top as far as to the mouth. When the heat is sufficient, successive layers of coke and ore are charged in through the mouth, diminishing gradually the proportion of coke until the necessary proportion for normal working is obtained. From then onwards coke and ore are charged alternately; working is not stopped except when repairs are necessary.

The molten metal and slag lie superposed in the crucible according to their density. When the crucible is full of pig iron the furnace is tapped by making an opening in the lower part. The iron, as the case may be, is run into ladles placed on wagons or into sand channels where it solidifies, to be subsequently broken up into pieces known as pigs. Tapping of the slag is done from time to time from an opening situated in the upper part of
the crucible and received into cold water which breaks it up into granules.

Normal working of a blast furnace is only possible thanks to the insufflation into the mass of considerable quantities of air to furnish the oxygen necessary for the reactions. This air, driven by a blowing machine, enters at the lower part of the hearth and rises up towards the mouth.

The principal chemical changes taking place in a blast furnace are as follows: at the point of entry of the tuyers into the hearth and lower part of the boshes (temperature of fusion: reddish white) CO is formed by the burning of the coke (C+O₂=CO₂).

At the upper part of the boshes (bright red) decomposition of the limestone into lime and carbonic acid gas takes place (CaCO₃=CaO+CO₂) (formation of slag).

At the bottom of the shaft (bright red) conversion of carbonic acid gas into carbon monoxide: CO₂+C=2 CO.

In the middle part of the shaft (red) reduction of the ore by carbon monoxide: Fe₂O₃+3 CO=3 CO₂. Further, part of the ore is reduced under the combined action of the carbon and hydrogen derived from the decomposition of the steam. In the upper part of the shaft (dull red) part of the carbonic acid gas breaks up to form carbon dioxide and carbon: 2 CO=CO₂+C. It should be noted that in the hearth near the tuyers cyanides are sometimes formed by the action of nitrogen which are partly, varying with the more or less good working of the blast furnace, the quality of the ore and fuel, etc. On the average the proportions of the different gases making up the mixture are as follows:

<table>

These gases have a high temperature and considerable value for fuel purposes. This is why they are now caught in the upper part of the blast furnace and utilised in regenerative furnaces.

Recovery. — Originally the gases captured near the mouth were used exclusively in the recuperators. The way in which the recuperators work is as follows. The gases — more or less freed, during their passage through the downcomers, of the dust which they bring with them — are mixed with outside air and enter into combustion in firebrick checkered baffle chambers within which they circulate before reaching the chimney stack. When the walls of these checkered chambers have reached a high enough temperature, the stream of gas is stopped and a current set up in the opposite direction so as to drive the heated air towards the tuyers feeding the blast furnaces.

This alternation requires, therefore, at least two recuperators per blast furnace. There are different types, the commonest being the "Cowper" and the "Whitwell".

The utilisation and purification of the blast furnace gases has been more and more perfected in recent years. A part only of these gases is used for heating the recuperators and steam boilers. The other part, used for driving the gas motors, requires more thorough purification.

First purification. — After the heaviest dust has been deposited in the downcomers, the gas passes through apparatus with a view to cooling it by contact with finely divided water, either in the form of rain (Zschocke apparatus) or in the form of humidifiers made of wire gauze (Bian apparatus). Centrifugal fans then free the gas of the dust rendered heavy by the water. In this state the gas is sent to the "Cowper" recuperator and to the boilers. It still contains from 0.3 to 0.5 grm. of dust per cubic metre.

Second purification. — The part of the gas intended for driving motors undergoes a second purification. Theissen's apparatus, which is that most used, depends on rapidly rotating paddies setting up a contrary movement of air. The humidified dust, thus rendered more heavy, is thrown against the walls of the apparatus and carried away by a current of water. The gas then passes to an apparatus for separating the water and from there to the motors which it has to drive. It then contains from 0.005 to 0.02 grm. of solid matter per cubic metre.

All this makes it easy to understand how the gas pipes have become longer and longer, and have also had their joints, valves, manholes, safety valves in case of explosion — that is when escapes take place — multiplied.

The piping requires periodical cleaning. Generally, those situated in front of the point where the initial purification takes place ought to be cleaned every three months. The pipes behind it are cleaned every six months or once
a year. The gas pipes, after the second purification, may be left for two or three years without cleaning.

The product of the blast furnace is pig iron: grey pig or cast pig iron in which the carbon is in a free state; white pig or refined pig iron intended for the manufacture of iron and steel, and in which the carbon is principally in combination with the metal.

Manufacture of Iron

Principle. — Decarburation as complete as possible of the pig iron with elimination of the largest amount of foreign matters: silicon, manganese, phosphorus, etc.

In the Conet process (shallow hearth furnace), the pig iron is placed in a very refractory crucible on wood charcoal, the combustion of which is activated by the draught from a tuyer. The oxide of iron formed burns a part of the carbon, silicon and phosphorus, with the formation of very fusible silicates and phosphates. The iron, partially decarbonised, less fusible than pig iron, forms a spongy mass (bloom) which is hammered to get rid of the slag.

Puddling. — This is done in a reverberatory furnace at very high temperature.

The pig iron, with the dross and waste very rich in oxides of iron or sometimes of basic products (lime), is melted on the floor of the furnace and continually stirred with a rabble. Dross is formed which floats on the surface and is removed. Little by little the melted mass is purified and tends to solidify in a soft spongy mass which the workman fashions in “blooms” of about 50 kilos.

There are various kinds of mechanical furnaces which take the place of puddling by hand.

Shingling. — These blooms are immediately subjected to the action of a shingling hammer which drives out the still liquid slag and gives the necessary cohesion to the iron.

Manufacture of Steel

Steel is obtained either by carbonising the refined iron or in partially decarbonising the pig iron. Various processes are used.

By puddling. — This does not differ from the process described for the production of iron except in the fact that the process is stopped before total decarbonisation.

By the Bessemer process. — The liquid pig iron coming from the cupola, or mixers of the pig iron, is run into a crucible of very large size (converter) where it is subjected to intense agitation under the action of compressed air introduced at the bottom of the apparatus by several tuyers. The receptacle of thick sheet iron is lined inside with refractory bricks. It can be given a rotary movement around a horizontal axis resting on two trunnions. It is by one of these that the air pene-

![Bessemer Process Diagram]

I. Mouth; II. Shaft; III. Boshes; IV. Crucible; P. Lateral pipe for gas supply.
carbon with abundant production of oxide of carbon (flame period) — the longest period; combustion of the iron with production of red fumes of oxide (period of fume) — the shortest possible.

At the last moment before tapping a certain quantity of manganese iron is added, of which the content in manganese varies with the kind of steel it is desired to obtain.

By the Thomas process. — Certain ores (minette-coltic iron ore) containing considerable quantities of phosphorus compounds can only yield, by the Bessemer process, steels containing phosphorus in injurious amount. Hence varies with the kind of steel it is desired to obtain.

By the Bessemer process. — Certain ores (minette-coltic iron ore) containing considerable quantities of phosphorus compounds can only yield, by the Bessemer process, steels containing phosphorus in injurious amount. This is due to the silica in the refractory lining, which, reacting on the phosphates formed during oxidation, decomposes them as they are made and prevents their elimination. In the Thomas process the acid lining (silicic anhydride) is replaced by a basic lining composed of a double carbonate of lime and magnesia (dolomite). Further, in this process, a certain quantity of lime is added to the charge in the converter in order to obtain a highly carbonaceous slag. (See article "Basic Slag").

The way in which the Thomas converter works does not appear to differ much from the Bessemer: the period of sparks is shorter, and after the flame period some minutes elapse (after blow) before the fume period. Lastly the bath has to be cleaned before tapping and the addition of manganese pig iron.

By the Martin-Siemens process. — The Martin-Siemens furnaces are reverberatory furnaces with low roofs. They are heated by gas from producers and have recuperators. Their function essentially is to decarbonise and purify the pig iron by melting at a high temperature (1,800°) with old iron and steel (scrap). During refining, which lasts some hours, cleaning takes place from time to time by removing from the furnace, by means of special rabbles, part of the dross which covers the molten metal. Towards the end of the process, ferro-silicon-manganese is added. Tapping is done through a tapping hole situated at the lowest part of the floor of the furnace into a mechanically carried ladle.

Mechanical means of charging exist for the Martin-Siemens furnace. Many modifications have been made in the Martin-Siemens furnace; the principal are directed either to continuous working (Talbot or Martin continuous process), or the division of the operation into two successive steps (Bertrand-Thiel process), or lastly, the rocking movement imparted to the floor of the furnace at the moment of tapping.

Process of crucible steel. — This process is reserved for steels which require to be of exceptional quality. A crucible furnace is in principle a regenerator furnace of the Martin-Siemens type with a recuperator chamber and is generally heated by produced gas. Each crucible with its charge (of 30 to 40 kg.) prepared beforehand is covered before it is laid on the floor of the furnace where refining by fusing and removal of the dross is carried out. After refining, the crucibles are withdrawn from the furnace through an opening in the roof, either by hand by means of special tongs or more usually mechanically. Tapping follows.

Steel made by the cementation process. — The principle of the process is a carbonisation in which the carbon, derived from an external source, penetrates slowly (8 to 20 days) into the metal kept at a red heat, but without being melted. This operation consists essentially in heating wrought iron bars bedded in the carbonising substance (for example, wood charcoal) in more or less fine powder (cement) in special chambers. The top of the chambers is covered with a layer of sand which is an obstacle to oxidation.

Electrical blast furnaces. — Reduction of the ore in an electrical furnace yields a pig iron prepared at a very high temperature (3,000 to 3,500° C.).

Electrical melting and refining furnaces may be classified according to the arrangement of the electrical connections into furnaces with conducting and non-conducting floors.

Furnaces with a non-conducting floor have but a poor electrical yield, giving a very troublesome bath, and are in consequence little used. Furnaces with a conducting floor are very delicate and their advantages are much discussed.

Furnaces with non-conducting floors and carbon or graphite electrodes can heat the charge either indirectly by arc (Stassano, Rennerfelt) or directly from electrodes to the metal or to the slag.

Special steels. — The manufacture of special steels is generally done at the moment of refining. For nickel steel this metal is usually added in the Martin furnace before the addition of the manganese pig iron. It is the same with silicon steel by the addition of ferrosilicon. Chrome steels, tungsten, and molybdenum steels are made in the crucible. Steels with a high proportion
of manganese are made by preference in the electric furnace.

**Manufacture of Pig Iron.**

What is called pig iron of the second melting is pig iron produced in the blast furnace and remelted either in crucibles or reverberatory furnaces, or more often in a special apparatus called a cupola.

**Cupola.** — The cupola is a deep structure of refractory masonry slightly widened from below upwards. At its lower part are two tapping holes for the pig (iron and slag) as well as tuyers for introducing air. The pig iron is charged in with the coke and lime. The lime is added to yield a fusible slag. "Scrap" iron in greater or less quantity is often added according to the kind of pig iron that it is desired to obtain.

The molten pig iron is generally received into ladles carried by hand and run into moulds either of sand or iron.

**Casting.** — Except in the case of objects manufactured in series which are run into permanent moulds, other objects — in iron — are moulded on wooden patterns by means of a more or less powdery and plastic mixture made of clayey sand with organic matter added: straw, horse dung, etc. The moulds, when ready, are left to dry where they are or are carried to the dryer before casting.

Special alloys with iron are made such as the ferrosilicous, ferromanganese, ferrochrome, etc.

After casting is finished, the iron articles are usually subjected to a process for freeing them of sand and trimming. Freeing from sand is done either by hand by means of a metal brush or mechanically. Mining is done either by cutting or grinding.

As a final operation, the moulds are destroyed and the sand distributed.

**Sources of Danger.**

Among the numerous sources of danger for iron and steel workers are: the heavy work in almost all phases of the manufacture, the excessive heat and the action of radiant heat, especially in front of certain types of furnaces; abrupt changes in temperature; discharge of hot solid particles or splashes of molten metal; dust in general and, according to the type of work, dusts with special risk attaching to them (sand, flour, starch, etc.); gases such as carbon monoxide, carbon dioxide, sulphur compounds, cyanogen, toxic lead fumes, mercury vapour, etc., and especially the gases at the blast furnaces.

Perhaps it would be well to emphasise the most important of these sources of danger:

The crushing of the ores, their charging and discharging, and generally all the preliminary operations giving rise to the production of quantities of dust. (See article "Dusts, Fumes and Smoke").

Mention only need be made of the discharge of sulphur dioxide in the roasting of iron pyrites which is irritating to the respiratory tract.

**Fig. 15.** Bessemer converter (vertical section) (according to Carre).
In American steel works the composition of this gas is said to be as follows: carbon monoxide 26 per cent., carbon dioxide 11.12, hydrogen 3.5, nitrogen 57, acetylene 0.3, methane 1, oxygen 0.2. The gas also contains arsenuretted hydrogen, sulphur dioxide, hydrocyanic acid, stibine, etc. The most dangerous places on the route run by the gas during the different phases of manufacture are shown in fig. 16 (after Rober and Hayhurst).

Engel, of Cleveland, has recently (1925) made enquiry into cases of poisoning by blast furnace gases which, according to this expert, are very frequent among those employed in steel works. The gases are inodorous, of sweetish taste, and present a greyish fume. The gases analysed by Engel contained 25 per cent, of carbon monoxide, 12 per cent, of carbon dioxide, 6 per cent, oxygen, 55 per cent, of nitrogen, and 2 per cent, of hydrogen. In the past twenty-five years he had treated 1,200 gassed workers without one fatal case or serious consequences. All the cases were acute, none chronic. Several times the same workman had been affected. When a fatal issue had occurred, it always took place at the spot where the poisoning occurred.

Under the influence of the wind, carbon monoxide escaping accidentally from apparatus can be conveyed for quite remarkable distances and then produce fatal asphyxia.

Researches made in collaboration between a mining engineer in Belgium and a medical inspector of factories showed that wet mud in the flues contained hardly any CO, but it was not so with dry dust which retains, by physical absorption and by mechanical hold, dangerous quantities of the poisonous gas. On the other hand, these muds and dusts, which give off very unpleasant smells, are said by some enquirers to contain appreciable quantities of cyanides.

On the subject poisoning other than that due to carbon monoxide, it should be remembered that cases from arsenuretted hydrogen have been described. Cyanogen compounds also can be generated under certain circumstances.

The use of cyanides in the operations of cementation ought also to be mistrusted.

Further, when the slag is tapped as it undergoes granulation, noticeable discharges of sulphur sated hydrogen gas have been observed without reckoning on the fact that the flow of slag is sometimes aided by the use of fluorides. In certain steel works, use of seawater to quench the incandescent coke gives off hydrochloric acid fumes (Elba, Italy).

From a hygienic point of view the addition of nickel, chrome, wolfram, etc., to obtain the special steels has no great importance. On the other hand, the preparation and wrongful manipulation of iron containing silicon is a cause of very serious injury to the workmen who manufacture it (see also article "Ferrosilicon").

Ferrosilicon is obtained by melting a mixture of iron ore, quartz, coke, and lime at a very high temperature in an electric furnace. The silicic acid and the iron ore are reduced by the carbon to silicon and iron respectively so that ferrosilicon is formed, of which the content in silicon may reach 80 per cent. The phosphorus and arsenic combine with the calcium. The silicon given off in the form of vapour becomes oxidised into silicic acid once it is free in the air, and it is this which is harmful to the workers. The preparation of special steels has also been the cause of manganese poisoning.

A danger happily becoming rare, in blast furnace work is that from
explosion. Another, and very common, danger is that resulting from burns in iron and steel manufacture, especially frequent at the time of tapping.

What has been said on the subject of accidents to be feared from carbon monoxide has equal force, mutatis mutandis, in the work at, and repair of, all furnaces and hearths used in siderurgy.

The workmen in charge of all kinds of converters and other apparatus for the refining of steel up to its treatment of converters and other apparatus for siderurgy. — 19.6 to 43.5. These figures greatly increase at the moment of cleaning the castings (up to 115.2 mg.) and trimming the moulds. In this department dust (coming mainly from the chimneys) and smoke (0.15 mg. to 0.25 mg. per cubic metre) even up to the roof is a characteristic phenomenon.

Four cases of subacute and chronic mercurial poisoning with one death were reported by Jordan and Barrows, in 1924, among workers at high frequency furnaces. The mercury vapour escaped from the converters and the content of mercury in the surrounding air was about 0.7 mg. per cubic metre. Another cause of mercurial poisoning is the frequent cleaning of the mercury and repairs to the discharge pipe. New models may remove this danger altogether.

Among the compounds of iron, ferrocyanide, a liquid cherry red in colour and extremely volatile, is said by some writers to be as toxic as nickel carbonyl. It was recently (1925) proposed to substitute this for lead tetraethyl. Sanchez-Girona, of Madrid, was inclined to attribute the anaemia noted in metallurgists (1922) to the presence of sulphate of iron in the blood.

Finally, the crushing and bagging of the slag is often accompanied by evolution of much very fine and penetrating dust. When it is a question of basic slag coming from dephosphorisation (Thomas slag) pneumonoconioses set up from this dust are particularly to be feared (see article "Basic Slag").

In foundries, especially where large pieces are cast, the moulds are sometimes dried by means of big braziers or wood or coke fires. The gases given off when they are burnt and the volatile evil-smelling matters emitted from the moulds reach the sheds and sometimes make the men ill.

For the rest, the drying rooms for the moulds in foundries are rarely equipped with the necessary hygienic requirements. When tapping takes place injurious fumes are generally given off. This is why in cleaning the flues immense quantities of vapour, gas and smoke are emitted from the combustion of the organic matters entering into the composition of the foundry moulds are generally, in addition to
siliceous matter which constitutes the basis (about 80 per cent.), various organic substances: oats, straw, starch, horse dung, etc.

Another danger in the foundry is that of burns; either from sparks or accidental spilling of the metal when done by hand.

Two causes of ill-health, which are frequently found in foundries, must be mentioned.

The first is that of the sand dust used in making the moulds. This is especially noticeable in distributing the sand after pouring and cleaning the moulds either by a brush or sand blast.

The second cause is that of trimming and glazing the pieces of pig iron. These operations, when done with very hard wheels (emery) are accompanied by the production of particularly injurious dust, of fine particles of metal, and of the abrasives. The action of these dusts on the respiratory tract has received the name of "industrial siderosis" (see article "Industrial Diseases: Respiratory Tract").

Further, cutting and trimming castings is one of the most dangerous operations for the eyes in view of the projection of metallic particles. Analysis of the air of iron foundries in Russia has shown that the most poisonous element present is carbon monoxide: 0.90 to 1 mg. per litre; in one case hydrocyanic acid gas (0.08 mg. per litre) besides sulphur dioxide was found (Grodzwski). In the course of another enquiry by Brujewitsch in Russian steel works, the amount of carbon monoxide were found to be very small and of no practical importance; but on the other hand, in the foundry and casting departments as much as 0.01 per cent. and even more carbon monoxide might be found.

STATISTICS

Most writers agree in considering that work in iron and steel has a prejudicial effect on the health. It is, however, necessary to bear in mind the different occupations in the industry.

According to the statistics of the Sickness Insurance Society of Leipzig, the duration of the illnesses among iron founders was as follow (figures compared with the number of days relating to 100 workmen in every profession per year equated to 1): cases of sickness, 1.5; cases of death, 0.9; sick days, 1.4; infectious diseases, 1.2; of which tuberculosis equalled 0.9; nervous diseases, 1; respiratory diseases, 1.1; circulatory diseases, 1.1; digestive diseases, 1.4; skin diseases, 1.2; diseases of the locomotor system, 1.4; external maladies, 2.3; accidents, 2.7

The comparative mortality figures of the Registrar-General in Great Britain for the years 1910-1912 for iron and steel workers and all occupied and retired males were as follows:

<table>
<thead>
<tr>
<th></th>
<th>Respiratory diseases, non-tubercular</th>
<th>Bronchitis</th>
<th>Bronchitis</th>

According to enquiries made by Vernon, blast furnace workers had on an average two days' sickness per year more than other steel workers; among the older workmen (forty-nine to sixty-nine years of age) the morbidity was twice as high as among the others. Respiratory and rheumatic affections came first. The mortality rate was also higher among this group than in the other classes of steel workers.

The same expert brought out also that there was about a 1 per cent. turnover among young metal and machine workers in England and 3 per cent. among the older men. Data furnished by the Iron and Steel and Kindred Trades Association, numbering in 1911 587,000 workmen, showed 537 deaths for the period 1910-1912, which corresponds to 6 per cent. The mortality from respiratory non-tubercular diseases was 65 per cent. higher than that for all males; the mortality for diseases of the circulatory system exceeds the average by 5 per cent., while that from tuberculosis is below the average by 8 per cent., that from accidents by 16 per cent., and that from "other causes" by 7 per cent. It must, however, be observed that the turnover of workmen and the change of occupation in the same factory modify the statistics at every moment and make them very obscure.

These statistics confirm the phenomenon already stated that work in steel works predisposes especially to acute respiratory maladies and in particular to pneumonia. Very hard work predisposes also to disease of the heart and blood vessels.

Vernon and Rusher, examining the sickness certificates of the Iron and Steel and Kindred Trades Association for a period of six years, were able to obtain separate figures for each occupational class. Expressed as comparative figures the mortality was 968 for casters of steel and pit workers, 790 for the puddlers, 715 for workmen charged with control of the valves and machines, 528 for workmen manufacturing white cast iron, 748 for other workmen and 723 for workers in all industries. Mortality from respiratory diseases was very high in the case of steel casters, rollermen and puddlers. The first group showed also a high mortality rate for diseases of the circulatory system.
The same figures are obtained when the morbidity data are analysed. Here again, the same classes of workers present high figures for respiratory diseases and rheumatism and the steel casters and puddlers again stand first.

According to Hope and Hanna, the number of days of incapacity for sickness per year come to 12.6 for steel workers, as against 11.9 for iron founders, and 10.2 for agricultural labourers.

An enquiry by Hayhurst, extending over a period of three years (1911-1913) in the different departments of a steel works in which the highest turnover never exceeded 15 per cent. of the total workers, revealed the following average annual values for the morbidity of the personnel employed:

<table>

</table>

It should be added that this enquiry was made at a very well-managed factory employing 5,602 workmen. The certificates analysed were those the workmen sent to the Mutual Insurance Society, which excluded from benefit those suffering from venereal diseases and accident.

Hayhurst found that 1,444 calls for benefit were made for illness lasting more than five days; which made an annual average of 7.2 per cent. The maladies for which the calls were made worked out as follows: respiratory diseases, 39; digestive diseases, 26; infectious diseases, 16; diseases of the joints (rheumatism and lumbo-go especially), 18; nervous diseases (especially sciatica, neuralgia, neuritis, neurasthenia), 79; diseases of the skin, 65; circulatory diseases, 63; urinary diseases (especially nephritis), 45; strains (especially hernia, heat stroke, etc.), 41; auto-intoxication and diabetes, 27; chronic maladies, 18; sense organs, 17; tumours, 11.

An enquiry made by the Mines Department as to cases of asphyxia from gas in 1918 showed 120 cases, most of them fatal, and distributed as follows: gas flues, 6; shaft furnace, 1; blast furnace (throat), 17; hot blast, 4; cleaning the boilers, 4; gas outside the boilers, 3; flies, 34; gas washing, 12; etc. The flues and piping generally are thus shown to be the most frequent place for poisoning to occur.

In the United States, from 1912 to 1923, in three works of the Illinois Steel Company employing 1,178 persons in a certain group of processes (blast furnaces, boilers, etc.), there occurred an annual average (from 1917 to 1920) of 71 severe cases of poisoning by carbon monoxide, 271 slight cases requiring medical attention, and an ill-defined number of very slight cases not requiring medical attention. These figures at any rate are lower than those shown in English statistics.

In another American works the average annual number of cases of sickness was 13.4 per cent. among the blast furnace workers as compared with 7.9 for workers in other sections.

An enquiry made by Brundage in a town in Pennsylvania in 1919 brought out the fact that influenza and pneumonia caused 50 per cent. of the sickness among metal workers. If to these are added the other respiratory diseases (bronchitis, pleurisy, tuberculosis, etc.) the percentage rises to 61. High incidence is shown, too, of statistics of cases of poisoning from carbon monoxide in blast furnace gas are given in the report of the Medical Inspector of Factories: 1917, 22 (6 fatal); 1918, 17 (2); 1919, 33 (6); 1920, 26 (5); 1921, 18 (3); 1922, 28 (4); 1923, 21 (4); 1924, 24 (1); 1925, 25 (6); 1926, 9.
hernia and infectious diseases. Rheumatism, however, is less frequent than in Great Britain.

Analysis of 4,014 accidents occurring in the course of four years (1903-1906) in the steel works at Sestri Ponente (Italy) enabled Peri to draw a series of conclusions which are still of theoretical and practical interest at the present time.

As regards their consequences the accidents could be distributed as follows: for every 1,000 accidents 979.8 were attended by total temporary invalidity; 18.9 with total temporary and partial permanent invalidity; 12.9 were fatal.

The parts of the body affected were: the head in 545. out of 1,000, in 57.5 the trunk, in 58.3 the upper limbs, in 286.7 the lower, in 54.3 the eyes, in 21.4 other parts of the body.

The accidents to symmetrical limbs and organs were distributed thus: 11.9 per 1,000 bilaterally, 543.5 the right and 444.5 the left side.

The course taken by the injury depended essentially on opportune intervention, timely operation, antiseptic treatment, daily care of the wounded part, and care taken to avoid the consequences of accidents.

The duration of incapacity from work was less than a week in 714.3 cases out of 1,000, less than a fortnight in 201.4, less than a month in 451.2, less than two months in 56.3, less than three months in 18, and more than this in 7.6 cases.

It should be remembered that in certain departments of the works where the frequency of accidents is high, this can be explained by the fact that workmen absent from illness, accident, etc., have to be replaced, so that the number of persons exposed to the risk of accident is higher than the number reckoned unless this fact is borne in mind. Further, the same workman may be the victim of several accidents. Lastly, the requirements of the industry sometimes demand an increase in the number of workmen.

Accidents were more frequent on the night shift. The actual number of accidents was almost the same as that during the day, but the number of workmen employed at night is reduced, so that the percentage affected is higher.

The frequency of accidents has been shown to be greater in the hottest months, when the workmen are obliged to work at excessive temperatures.

The number of accidents was highest on Monday or the first day of work. It was generally followed by a fall on the succeeding day or Tuesday; but the curve rose again except on the Friday (for reasons as yet unknown). This phenomenon is but a further confirmation of the curve made out by other investigations (Imbert, Pieracini and Maffei, etc.).

Peri also proved (were it necessary) that manual work causes a greater number of accidents than machine work.

The group "35-50 years" comprises the majority of unskilled labourers, the workmen in the steel works and the departments where the risk of accident is greatest; the group "51-70" is very small, and comprises the workers who are least exposed to accidents as well as being the most skilful in the avoidance of accidents.

The frequency of accident according to duration of employment in the works was:

- Per 1,000 workmen employed less than one month, 14.9; for six months, 262.8; for one year, 248.3; for one to three years, 292.4; for three to five years, 98.6; for five to seven years, 88.8; for seven to nine years, 32.1; for nine to ten years, 12.9; more than ten years, 28.4.

An investigation was made in Sweden in 1911 among iron and steel workers at Eskilstuna, where out of 57,000 inhabitants 4,000 to 5,000 are employed in the industry in question. It related to 4,233 persons, of whom 310 were women. Open cases of tuberculosis numbered 78, suspicious cases 34, tuberculosis of other organs 26. The 9 cases noted in women related to persons engaged in packing, polishing or enameling.

In men incidence was highest among the grinders of edged tools (about five times more than among other workers); it was very rare among the casters (only 1 case among 214 employed); it was rare also among the glazers with emery wheels (5 cases among 240 employed).

In 1912 an enquiry was made among 2,000 persons, of whom 1,021 were women, employed at the surface mines of Kiruna. The number of cases of tuberculosis showed 64 open, 30 suspicious and 345 affecting the glands (17.2 per 100 examined). Among the 485 adult men examined no difference was found in the various categories of workmen as regards tuberculosis. The higher percentage among women is explained by the fact that while a medical certificate is demanded for the workers, nothing prevents sound workers from bringing the tuberculous members of their family into the work in the diggings.

Pathology

The pathology of the workers in this industry is subject to the following factors: arduous fatiguing labour, dusty and hot atmosphere, etc. Naturally these conditions are not the same.
everywhere, but still at the present time bad hygienic conditions are very often found in these industries.

The radiant heat, the high temperature, and the failure of adequate ventilation favour the occurrence of quite a series of illnesses, which are more frequent in steel works and foundries than in engineering works. Specially characteristic are muscular cramps, heat stroke, anaemia, digestive troubles, precocious senile decay among persons employed a long time in the industry (Hayhurst).

The conditions of the industry demand excessive muscular work and the strain is said to be the cause of hernia and arteriosclerosis localised chiefly in the upper limbs.

Respiratory affections take the form of bronchitis, asthma, pneumonia and tuberculosis. The lesions of the respiratory tract deserve detailed examination: pneumonia due to basic slag and pulmonary siderosis.

Grinding basic slag used formerly to give rise to enormous quantities of dust in which the phosphoric acid was combined with the lime and iron. The pneumonia was attributed to the caustic action of the lime. According to Ehrhardt, in 1887-1889 a half or a quarter of the workmen in the factory were affected by the disease and some two, three or even more times in the course of the year.

The pneumonia is acute, rarely catarrhal and often complicated with pleurisy: 25 per cent. of the cases prove fatal. Enderlen (1892) demonstrated the presence of the pneumococcus. The hygienic conditions in this work have been greatly improved, but in 1908-1909 20 fatal cases of pneumonia were reported from four works employing 420 workers. Since then technical improvements have still further lessened the dust in basic slag grinding, and since then these accidents have been greatly reduced in number. Among the methods employed mention should be made of granulation of the basic slag by means of a water spray. This prevents the dust, it is true, but causes some evolution of sulphured hydrogen gas, so that good ventilation is needed.

Opitz (1920) studied the pneumonia due to basic slag and considered it not to be a specific inflammation of the lungs. The mechanical and chemical action of the dust only prepares the ground for the morbid agents. In a German factory the mortality from pneumonia was 28 per cent.; after prophylactic measures had been taken, this fell to 1.2 per cent. — a figure twenty times higher than that in other industries. Sixty German factories, employing 2,500 workmen, had a mortality of 35 workmen per year. During the war women replaced men to the extent of 20 per cent. of the total and, apart from influenza, diseases of the respiratory tract affected 36.8 per cent. of the women and 27.9 of the men (see article "Basic Slag").

Iron (oxide) dust sets up a pneumonoconiosis known under the name of siderosis. According to the composition of the iron the pulmonary lesion is more or less serious. Thus, for example, if it is a question of oxide of iron, especially sclerosis and very rarely tuberculosis of the lungs are said to occur. On the other hand, if the dust is ferric oxide or contains phosphorus,
the lesion is said to be more serious and the mortality from tuberculosis very high.

Pneumoconiosis among ironstone miners in Cumberland was studied in 1918 by Collis and in 1925 was the subject of an address by Sir Kenneth Goadby. In 1925-1926 Cronin again took up the clinical study of this lesion among 100 ironstone miners of Cumberland and North Lancashire. The dust from the ore contained 12.66 to 13.62 per cent. of silica, 2.02 to 2.38 lime, and iron in the form of sesquioxide and traces of phosphorus (0.0067). Clinical examination showed the existence of generalised pulmonary trouble in both lungs situated principally at the apices, but which does not resemble asthma, bronchitis or pneumonia. The complex symptomatology observed is quite different from that of silicosis.

Pulmonary siderosis has been closely studied by Hoek and Denet-Kravitz; but their findings can be best analysed when dealing with dust diseases (see article "Occupational Diseases: Respiratory System").

Dust, heat, handling of hot substances, etc., set up more or less severe lesions of the skin: burns, callosities, eczema, etc. Peri in 1910 described cutaneous lesions on the hands of young workers who prepare the pine ropes used in the casting of cast iron pipes. These are made with the shavings of Pinus maritima produced by machinery. The lesion, situated particularly on the palm and fingers of the right hand, is partly traumatic in origin and partly chemical; the first is explained by the rough edges of the shavings, the second by the essential pine wood oil.

Burns also are a characteristic accident of this class of worker. According to E. Gunth, they represent about 10 per cent. of the accidents reported and frequently affect the feet. Thus, for example, in the course of eleven years, of 417 burns from molten metal 144 were on the feet. But they occur also on the arms, the face and the chest, if the men work without protection to the bare chest. Gunth gives these percentages: 35 per cent. on the arms and hands; 10 per cent. the face: 20 per cent. the feet; chest, abdomen, back, each 3.4 per cent. In steel works 20 per cent. of all burns affect the corner of the eye.

Small subcutaneous haemorrhages on the skin of the face have been observed due to the violent action of calorific radiations; callosities on the hands and feet, etc.

It would obviously take too long to set out here the facts concerning the frequency of the accidents to which the workers in this industry are exposed. It will be sufficient to recall to mind the figures already quoted.

But of all ill-effects poisoning by gas, and especially by carbon monoxide, is the most important. The symptoms which are most frequently reported are headache, anaemia, indigestion, vertigo, eburnity, vomiting, cough, palpitation, sleeplessness, inexplicable fatigue, etc. The old types of blast furnaces required the presence on the gantry staging of three or four men either to charge the furnace or to watch progress. These workmen were naturally exposed to the inhalation of toxic gases and such cases were consequently very frequent. To-day technical improvements allow charging to be done automatically and the presence of a workman is only wanted for about twenty minutes in a twelve-hour shift. At the same time the workman should take the necessary measures so that in the course of repairs or of work that he is called on to do, he is not exposed to the risk of poisoning.

Cases of poisoning have also been reported from manganese, vanadium, tellurium, etc. (see these articles).

In 1920 some Dutch labourers who in rainy weather were discharging vessels carrying a cargo of "Lux" (alkaline hydrate of iron), in the form of a reddish powder intended for gas works, complained of painful points localised at the tips of the fingers. These appeared only a few hours after work was commenced and developed into a gangrenous condition. The medical examination carried out fourteen days later elicited the fact that baskets filled with the material were carried to the place of discharge. The labourers carried the baskets on their left shoulder holding the rim with the right hand. The powder passing through the clothing reached the shoulders, where similarly gangrenous points were formed. The points showed themselves generally on the middle finger of the left hand.

Among the special sense organs the eyes are particularly affected by accident and disease. In addition to cataract, choroiditis, retinitis, and conjunctivitis, due especially to the action of dust, calorific and luminous rays, special mention should be made of ocular accidents, of which siderosis of the eyeball is one of the most frequent. In certain German factories, for example, 9 per cent. of the accidents affected the eyes; in the engineering
trade a seventh of all the accidents affected the same organ and one serious accident to every 1,000 workmen has been found. Generally the left eye is most frequently affected.

Peri in 1910 described a characteristic form of palpebral conjunctivitis among the ironstone miners of the island of Elba or among those engaged in transporting the ore. The lesion was due to mechanical injury.

In 1898 Risley described a special form of partial cataract in iron workers. This cataract occupies the lower and internal section of the lens; lesions of the same sector have been found in the choroid. Mauthner has stated that this is also the place for senile cataract to be located. Schneyder, of Soleure, has found cases of cataract recently in different stages of development in casters and rollermen. The lesion is due to the molten iron when at a white heat, and when manipulated by the workman at a distance of 1.5 to 2 metres. The lesion shows itself after twenty-three to fifty years' work, but, according to the author, examination by means of suitable apparatus allowed of distinction being made between this cataract and senile cataract or other types. Cases of cataract have been described by Thompson and Cridland among puddlers; by Roberts among chainmakers; by Healy among men rolling sheet iron; Schneyder considers that the ultra-red rays of short wave length, rather than the ultra-violet rays, are the cause of the cataract.

Mechanisation and automatic working, short hours, small glory holes, the wearing of suitable glasses (made of a lower oxide of iron) against the action of the rays are the best means of prevention.

The hearing is also frequently affected. The noise (see that article) is really enormous: rhythmic, monotonous blows provoked by the tools used mingle with the noise of cranes, falls of materials, blows from hammers, mallets, engine whistling, etc.

Kober has excluded iron as a cause of siderosis of the skin; this was, however, found by Blaschk in millers (particles of iron had penetrated into the skin of the back of the hands). A pigmentation has been noted in casters, more serious lesions in workmen handling iron rich in phosphorus (lesions due to Thomas slag). Callosities and bursitis, etc., have been reported. Stigmata are mentioned in the treatises of Ramazzini and Palissier. Bateman in 1815 described a severe case of eczema which he attributed to the action of steel dust and heat.

As to the frequent and sometimes serious accidents which occur, it will suffice to say that for the great iron and steel industry regulations for diminishing the risk have been drawn up. Thus, as examples, reference may be made to the detailed measures for the prevention of accident in iron foundries, blast furnaces, puddling, at the rolls, etc., set out by the "Südwest-deutsche Eisen-Berufsgenossenschaft" of Saarbrucken (1902), of the "Schlesi-sische Eisen- und Stahl-Berufsgenossen-schaft" (1896-1901), etc.

HYGIENE

Hygienic measures must above all relate to technical organisation of the industry. All operations should, as far as possible, be carried out by mechanical and automatic arrangements, doing away consequently with hand labour. In practice, modern industry seeks to rationalise its equipment for reasons of economy: apparatus and machinery are more and more perfected day by day, and gases and vapours are generally recovered and utilised for heating, lighting and other purposes.

Emphasis should be laid on cleanliness on the premises, because it cannot be admitted, as was formerly the case, that foundries must necessarily be black and dirty.

Special attention should be paid to natural and artificial lighting by seeing that the sources of light are not hidden by machinery or part of machines and do not create troublesome and dangerous shadows.

For natural lighting, workrooms in the form of sheds are obviously the best: for artificial lighting, the amount advised or required in different regulations vary between a minimum of 6 to 27 lux (see article "Industrial Lighting").

Ventilation should be arranged in such a way that the sources of heat do not increase excessively the temperature of the shed and do not expose the workers to radiant heat. Considerable improvements have been made contemporaneously with the technical advances in siderurgy. It must be remarked, however, that the actual relative security was preceded by a period in which carbon monoxide poisonings were particularly frequent. This fact is attributable, partly at least, to the utilisation of the gas as a motive power, demanding, as has been said above, more careful purification than for gases destined for heating boilers.
This fact has led to more complicated piping, longer flues, giving rise to accidental escapes, so that the importance of cleaning them out has been increased. Further, the cooling of the gas in the process of purification has increased not only its richness but also its toxicity.

Still, it cannot be denied that considerable improvements have been introduced; thus in modern blast furnaces, charging at the gantry staging is completely automatic, suppressing radically the principal danger of asphyxiation. This is the reason why aerial piping is preferred more and more to underground, which permits not merely of relief valves, explosion outlets at various equi-distant points, and manholes, as well as of the cleaning of flues.

In this last extremely dangerous operation, methods of isolating the path in question have been improved — hydraulic safety doors, double joints, sand baths, etc. In certain works the dust in the flues is taken away by a mechanical arrangement inside connected up to a current of water with numerous taps for cleaning, and with explosion outlets at various equi-distant points.

However, despite all ingenious means, it is still necessary from time to time to enter the flues either to carry out repairs or to rid them of the very hard and adherent deposits which form in them.

The principal precautions to be taken on entering flues are:

1. Proper isolation of the portion entered. — All the means used with this object cannot here be indicated in detail, as they vary from one factory to another; but it may be recalled that a single separator is not to be trusted. In this respect even hydraulic joints may fail: it is advisable then to double the means of closing.

2. Rational ventilation of the portion of flue visited with control of this ventilation. — It is dangerous, as is often done, to rely solely on simply opening the closing plates to ventilate the flues; it is absolutely indispensable to evacuate the heavy gases by a current of air sweeping through the flue. The method of effecting this ventilation will depend on local circumstances. It is a matter for the engineers of the section to do the best they can with the means at their disposal. After a sufficient time has elapsed to allow of the removal of the gases steps must be taken to test the air in the flues.

3. Organisation of the work and means of rescue. — The presence of a competent technical foreman is indispensable at the moment when men enter the flues and during all the time that the job lasts.

No man ought to be allowed to work alone; each member of the gang must be provided with a safety belt and rope, the free end of which is entrusted to mates outside. The manholes and openings to get rid of the gas should be numerous; an excellent plan is to arrange them so that the manholes in the upper part of the flue alternate with the openings for the removal of dust in the lower part. Lastly it is indispensable to be certain of the sound working condition of the rescue apparatus which must be kept quite close by.

In modern steel works and rolling mills the equipment has been so much improved as to reduce considerably the fatigue and dangers: charging and quasi-automatic control of the converters and retorts, puddling furnaces mechanically moved and heated by gas, stripping and mechanical transport of ingots, movement of the rolls of grooved iron controlled from a distance.

For a large number of workmen provision of clothing to protect them against burns from sparks is to be recommended: asbestos gloves, fire-proof aprons, sabots strengthened stockings, etc. Protection against radiant heat and protection of sight still leave much to be desired; emphasis must be laid on general arrangements (screens, solid or of close metal gauze) rather than on personal protection which to a great extent is still necessary from time to time to enter the flues.

The screen may be moved before the fire. These screens are sometimes watered with running water.

Among personal means of protection, goggles should be mentioned. It must be recognised that to have to wear them constantly is very disagreeable; before the furnace fire they ought not to have to be worn for more than a short time and in unusual conditions, when it is radically impossible to replace them by transparent screens (see article "Goggles").

Notable improvements have also been made in large foundries diminishing considerably the causes of insalubrity. In this connection mechanical casting of pieces in series should be referred to. This renders unnecessary the
awkward positions in which the body has had to be maintained which accounted for considerable fatigue among the casters. An objection, however, to this mechanical system of casting is the shaking and intense noise that it produces, which in themselves constitute a cause of fatigue.

Scouring of large objects is effected like ordinary cleaning by means of the sand blast in closed chambers, and this constitutes definite progress in the effort to combat pneumonoconioses.

For removing the sand from small castings use of a helmet with supply of fresh air under slight pressure is highly commendable. Where they are castings use of a helmet with supply of fresh air under slight pressure is highly commendable. Where they are

constitute, where they are mechanical grids for removal of sand constitute, where they are used, an improvement not without value.

Similarly, substitution of gravel for the sand generally used is a happy innovation reducing notably the amount of dust.

The prevention of accidents, organised on the lines of modern technical principles, allows of marked reduction in the frequency and gravity of the lesions. Thus, for example, in the United States over a period of twelve years the number of accidents has been reduced from 270 to 115, and by making the men wear protective clothing the number of burns has been reduced by 30 per cent.

The American Steel and Wire Corporation has been concerned for a number of years with the safety of its workmen (numbering about 5,000) and has organised a medical service with a hospital, where the victims receive competent treatment from a trained staff. The Corporation also from time to time organises lectures at which workmen from different departments of the works assist and are made aware of the best methods available for preventing accidents. A safety committee has been created which includes three workmen. The following figures show the excellence of this organisation:

<table>

</table>

While the number of accidents has fallen by 83 per cent. since 1917 and the number of lost days by 47 per cent. the fall relates to slight accidents. But the duration of incapacity for each case has changed from 22.4 days in 1917 to 70.3 in 1924, which shows greater severity of the accidents.

According to Peri, prevention of accidents rationally organised can effect striking results in practice. Actually he has been able to reduce the number of accidents by arranging for strict initial medical examination of applicants; adequate selection of workmen to be employed in the departments where the risk is high; substitution wherever possible of mechanical for hand work; in controlling the use individually of measures of prevention prescribed by the management; in awarding prizes to persons collaborating in the prevention of accidents while at work; in discharging persons who show themselves unsuited to the occupation; by diminishing as much as possible excessive turnover of workmen especially at certain times of the year.

Naturally, washing accommodation, baths and sanitary conveniences should be provided, corresponding with the requirements of modern hygiene (see article "Personal Hygiene").

LEGISLATION

Among the many restrictions on the employment of women, young persons and children in the iron industries, the following are cited:

Women are prohibited from processes and industries in which poisons or fumes and dusts are given off in France (roasting sulphur containing ores, when the gases are not condensed, and the ores contain arsenic, pickling and galvanising iron, evolution of fumes and manipulation of acid).

Young persons of less than sixteen years of age are prohibited in Belgium from working in galvanising works for iron and cast iron (pickling and galvanising); boys of less than sixteen years, in the province of Quebec from picking iron by means of acid, from galvanising iron, and from the manipulation and packing of iron oxide; in Spain, from the refining of iron (places where fumes are given off and where acids are handled), and from galvanising; boys of less than fifteen in Italy from the mechanical preparation of the minerals; in Japan from work giving off much dust in mineral and metal industries; boys of less than eighteen in France are in the same category as women. Girls of less than eighteen are excluded from work in the province of Quebec (as are boys of less than sixteen); young women under twenty-one years of age in Spain, in Italy and in Japan (as in the case of boys), etc.

Health Regulations dated 30 October 1919 which apply to foundries, were issued by Royal Decree in Norway; by the Union of
Socialist Soviet Republics (Regulations of 22 July 1920 on safety rules for rollermen, 15 November 1920 on cold working of metals, 25 April 1921 applying to copper and iron foundries, and 23 December 1921 on work at forges).

Detailed regulations for iron foundries and engineering works are in force in Denmark (31 August 1906). They deal with the height of the sheds from the ground, natural and artificial lighting, cleanliness, cleaning of machinery, use of special rags when handling white lead, red lead, etc., cubic space, ventilation, meal rooms, sanitary conveniences, etc.

A Welfare Order was enacted in Great Britain, dated 12 October 1917, for the prevention of first aid and ambulance arrangements in blast furnaces, iron foundries and engineering works.

Health Regulations for the iron and steel industries are dealt with in the Labour Act of the State of Jalisco (Mexico) dated 13 August 1923 (sections 205 et seq).

The British Welfare Order applying to the tin plate industry is dated 1917 (No. 1035), and that for galvanising works, etc., 1921 (No. 2032).

Legislation also has often been enacted as regards employment of male young persons in night or foundries, etc., for vocational training, weekly rest, hours of work (eight hours), annual holiday, etc.

It would be too difficult to give an account of all existing legislative measures in all branches.

Obligatory notification is required in the Netherlands of cases of lung diseases, subcutaneous cellulitis over the joints, cataract, in persons employed in steel works, iron and other metal foundries; ulceration of the cornea and conjunctivitis in men employed in forge work.

Compensation for cataract is provided for by British and Russian law; and for siderosis in Argentina. Periodic medical examination (monthly) is required by the German Regulations applying to basic slag works (see that article).

**Iron Carbonyl**

Iron pentacarbonyl Fe(CO)$_5$, discovered in 1801 by Mond, Lauger and Quincke is in the form of an amber or reddish brown coloured oily liquid which boils at 102-103°C, solidifying at 20°C in yellow crystals. It is insoluble in water and can be mixed with most solvents. Its ignition point is 34-35°C.

It is obtained by directing a current of carbon monoxide or mixture rich in carbon monoxide on to metallic iron in a fine subdivision, at a pressure of at least 50 atmospheres and at a suitable temperature (between 100° and 200° C.). The formation of iron carbonyl is accelerated by catalysts (oxides of aluminium, of bismuth and of nickel).

Stable when kept in a closed vessel protected from the light, iron carbonyl decomposes when exposed to direct sunlight, giving iron monocarbonyl Fe$_2$(CO)$_5$ and carbon monoxide. This decomposition can be prevented by adding an azo dye.

Recently (1926) it was proposed that iron carbonyl should be substituted for lead tetra-ethyl. In fact there is on the market already an anti-detonating product under the name of "Motaline," which is a mixture of equal volumes of iron carbonyl and of petrol and which wholesale manufacturers use for preparing "Motaline," that is, motor spirit containing 0.2-0.25 volumes per cent. of iron carbonyl (4 litres per 1,000 of spirit). "Motaline" is said to be without danger, for it only ignites when it falls on a hot substance. Escape gases from motors using Motaline is said to be non-toxic, for iron carbonyl in burning gives carbon dioxide and oxide of iron.

The danger from spontaneous ignition of iron carbonyl fumes can be prevented by adding to the liquid a small quantity of hydrocarbons.
Considerable amounts have been manipulated during a period of fifteen months without symptoms of poisoning. Certain authorities, however (Kisskalt, Oliver), consider the product to be toxic and hold that it produces the same symptoms as nickel carbonyl. Cases of occupational poisoning have not however been met with so far.

**BIBLIOGRAPHY**

***

**Ironing**

The material necessary for ironing consists in irons, furnaces or heating apparatus, tables and boards, as well as various accessories (grids, iron stands, rags, spatulae, marking stamps, various receptacles, etc.). The irons most usually employed are oval or round in form, with varying dimensions. As heating apparatus there may be used simple cooking stoves or special furnaces having a cover worked by weights in counterpoise, and drawers for the wood or coal. In certain cases types heated by electricity are used. In large establishments ironing is done mechanically by placing the articles to be ironed (linen, sheets, blouses, dresses, lace, curtains, etc.) either on a board covered with felt, up and down which there passes a compressing cylinder of heated metal, or in a special machine which is steam-heated.

Where the articles in question do not require very particular ironing they are simply subjected to calendering.

Ironing properly so called is preceded by damping of the articles to be ironed and in certain cases by dressing, which includes starching, or less frequently gumming (embroidered silks, fine laces, etc.).

**PATHOLOGY**

The pathology of ironers varies greatly from one establishment to another in accordance with the more or less up-to-date plant and material used. While in certain workshops conditions of work are still fairly primitive and constitute a real health risk, there exist side by side others in which use of mechanical processes and the introduction of electricity have rendered the work almost harmless, so to speak. It is with this fact well in mind that there is given below the various occupational risks which ironing may involve.

It should first of all be noted that the workrooms themselves may leave much to be desired from a hygienic point of view: workrooms encumbered with an undue amount of material (very often the linen is suspended from pulleys or ropes attached to the ceiling), dark workrooms situated in the basement (Lehmann) which are often badly lighted and badly ventilated. The vitiated air often contains carbon monoxide. According to an American enquiry referred to by Koher and Hayhurst and which comprised 244 workrooms, the analyses of the air revealed in the atmosphere near the ironers 55.4 per cent. of carbon monoxide per million parts of air, whilst near the windows the rate did not exceed 7.4. In 30 per cent. of the workrooms in question a smell of gas was perceptible. The heating of the irons was effected by gas in 50 per cent. of the workrooms. In 41.8 per cent. there was used a mixture of gas and air under pressure. Electric irons were used in 2.4 per cent. of the workrooms. Willesik and Martindale found in a workroom using gas irons from 0.3 to 0.8 and even 1.4 cub. cm. of carbon monoxide per 10 litres of air and 12-24 cub. cm. of carbon dioxide.

Thus, as has been found to be the case for various industries, the risk from carbon monoxide poisoning is greater in ironing establishments where producer gas is used. It is for this reason that its use has now been abandoned. Carbon monoxide poisoning amongst ironers is therefore not to be desired from a hygienic point of view: workrooms encumbered with an undue amount of material (very often the linen is suspended from pulleys or ropes attached to the ceiling), dark workrooms situated in the basement (Lehmann) which are often badly lighted and badly ventilated. The vitiated air often contains carbon monoxide. One day, however, on which the ventilation system was working badly, twelve women workers showed symptoms of acute poisoning by carbon monoxide. The troubles were attributed to the gas used, which was thereafter replaced by lighting gas. The latter is, moreover, not quite harmless, for on several occasions cases have been reported of carbon monoxide poisoning amongst women engaged in ironing. Since the war (1914-1918) there have been reported in the Netherlands six cases due to the use of badly constructed irons which caused liberation of lighting gas with incomplete combustion. The victims, aged eighteen to forty-three,
presented the following symptoms: headaches, somnolence, loss of consciousness (in three cases) and pain between the ribs (in one case). It is only necessary to read the medical press in order to find mention of numerous cases similar to these. The action of the vitiated atmosphere is also manifested by the occurrence of anaemia amongst those exposed to it, and Willesik and Martindale report that in the case of one-quartermaster of the workers in an ironing establishment there was found a diminution of about 10 per cent. of the normal rate of haemoglobin.

In other cases poisoning has been found to be due to various other toxic products. There should here be recalled cases due to volatile compounds of arsenic given off from coke furnaces (Lehmann, Kohler, and Hayhurst). The cases reported by an English Committee in 1901, and which affected persons working in an ironing establishment, presented symptoms consisting in vomiting, weakness in the legs and a case of complete paralysis of the legs with paraesthesia and suppression of the plantar and rotular reflexes. There were no skin troubles. In this case analysis led to the detection, not of carbon monoxide, but of considerable quantities of sulphur dioxide.

The presence of the latter caused the investigator to make tests for the presence of arsenic, which he found in a proportion of 0.001 per cent. Arsenic was also detected in the urine of two of the victims most gravely affected. Ironers who use irons heated by coal may show symptoms due to the action of coal dust (Leymann, Lewin).

Other diseases observed amongst ironers are more usually attributed to work executed in a standing position, to the special posture of ironers and to the posture required particularly by certain operations (the ironing of starched articles and of men's garments, etc.): varicose veins, flat foot, gynaecological troubles, digestive disarrangement, slight burns. Occupational stigmata (callosities) have been described on the palm of the right hand and on the fingers as a result of the pressure exercised on the iron. Codet-Boisse considers a special deformation of the wrist joint to be a result of this pressure — slight dislocation in bayonet form (known under the name of "Madelung's deformation").

The usage of an iron for hours at a time for polishing men's garments, shirts, collars, etc., causes dorsal flexion of the hands at the wrist joint which may lead to compression of the epiphysis of the radius.

There has been reported besides, especially amongst young women engaged in ironing, loosening of the wrist joint which causes slight simple dislocation in without alteration of the bones, inflammation of the tendons, accompanied by pain spreading from the thumb to the middle of the dorsal region of the forearm, a sensation of heaviness in the fingers associated at times with a feeling of stiffness of the arm and occurring especially during the night, and ceasing on the commencement of work. Finally, atrophy in the terminal region of the radial nerve may occur (Kron).

In Great Britain an enquiry carried out in 1926 relative to lesions and deformations of the hand amongst ironers engaged in marking stockings with electric irons provided the following data. The operation in question was slightly different from ordinary ironing by reason of the fact that the iron had to be lifted after each movement, and that a balancing movement had to be imparted to it. Each worker completed about 750 stockings per day. After the day's work blisters formed at the level of the top of the metacarpal joint, especially of the little finger. In six or seven weeks they hardened and at the end of two years there occurred a hardened state of the palm of the hand, especially at the level above referred to. At times the tendon flex of the small finger appeared to be implicated, for complete extension was inhibited. In the case of workers with a long record (six years or over) there occurred deformation recalling Dupuytren's contraction. After cessation of work the skin reassumes its normal aspect. Nevertheless, slight contraction of the flexion of the small finger has been noted in the case of a worker after resting for nine months.

Hygiene

The workroom should be spacious, well lit and well ventilated. The ironing tables must be broad and fairly high in order that the worker is not obliged to bend more than necessary. There is also recommended the use of holders made of soft cloth, which is a bad conductor, in order to diminish the effect of hard pressure and excessive perspiration of the hands. Cast-iron furnaces should be subject to control with a view to avoiding diffusion of toxic gases (carbon monoxide) in the workroom. As a general rule the damper should never be completely closed. Gas furnaces should be placed under a chimney with a good draught.
and any vitiation of the atmosphere should be combated by an adequate ventilation system. Artificial light should be electric with a view to complete elimination of the risk from the escape of toxic gases. The same should be the case with regard to the heating apparatus wherever it is possible.

Women ironers should take requisite precautions to avoid chills (from abundant perspiration and exposure to draughts) by wearing wool or flannel next the skin. Occupational deformations should be corrected by requisite gymnastic exercises. Blisters forming the initial stage of callosities should not be burst, as this leads to risk of subsequent infection.

Peripheral paralysis occurring amongst women ironers is subject to compulsory notification in the Netherlands. Chronic teno-synovitis is compensated in the U.S.S.R.

BIBLIOGRAPHY

***

Ivory

Ivory, which is got from the tusks of African and Indian elephants, is shown on section to be formed of concentric layers. Old tusks often contain cracks, which are filled in by mineral mastics. It is yellow in colour when taken from young or adult animals, becoming greenish in the case of aged animals.

Besides elephant tusks, there are sometimes utilised those of hippopotami, walruses and narwhals, etc.

Ivory is used in the manufacture of various objects (billiard balls, frames for fans, piano keys, small objects of furniture and sculpture, etc.). The powder and the debris are used in the manufacture of artificial ivory (by agglomeration) or in the manufacture of animal charcoal.

Ivory, cut into pieces of varying size according to the objects to be manufactured, may be encrusted with dirt and more or less covered with fat. Under such circumstances, it has first to be treated chemically, and thereafter placed in a hot alkaline bath, followed by plunging into cold water. Where necessary, it is bleached by means of peroxide of hydrogen or sulphuric acid with sodium peroxide. All requisite precautions require to be taken in the course of these operations.

For the manufacture of certain articles, the ivory requires to be tinted. Where it is necessary to achieve penetration of the product into the interior of the ivory, after passing through an alkaline bath and washing, it is plunged into a very slightly acidulated bath of nitric acid in order to remove the external scale and expose the cartilaginous part. It is then rinsed thoroughly in cold water, and thereafter submitted to the dyeing process. It must not be plunged into hot water, as this would cause cracks in the ivory, or at least, where this is done, it must be immediately thereafter placed in cold water. Manipulation of ivory is similar to that followed in regard to bone in the bones industry (see that article).

Artificial ivory is manufactured either with the debris from ivory agglomerated by the use of glues and appropriate mineral substances, or by substances having a similar aspect to ivory (cellulose, galalith, etc.). For the manufacture of animal charcoal, see article "Bones Industry".

Sources of risk are almost exclusively confined to liberation of dust, which may be avoided by executing cutting and sawing of the plates by the damp method and by providing adequate ventilation over the grindstones and cutting machines so as to prevent the dust being disseminated in the atmosphere (see article "Bones Industry").

***
J

Jewellery Industry

Gold and platinum cannot be said to possess interest from the standpoint of industrial poisons. Silver is not a toxic metal, but absorption of silver compounds may give rise to argyria (see article "Silver").

INDUSTRIAL OPERATIONS

Goldsmiths' and silversmiths' work comprises a large number of operations, including melting, casting, forging, rolling, presssing, filing, planing, polishing, soldering, welding, galvanising, engraving, engine turning, and chiselling. These operations are mostly effected in a sitting position and are partly machine and partly hand work.

In factories for refining precious metals silver mixed with copper, melted, cast and mixed with water in granulated form is dissolved in sulphuric acid. After decantation the silver is precipitated by the copper and the silver thus obtained is thereafter melted.

Gold is treated with hot concentrated sulphuric acid which dissolves silver. The gold powder obtained is washed and melted; the silver which the gold may contain remains in the mother liquor and is precipitated by the copper.

Platinum dissolved in aqua regia is precipitated by alkaline salts and thereafter melted.

Goldsmiths and jewellers use gold and silver ingots, or mostly metal in sheets, plates or leaf, etc. For the making of "flat stock", bars of gold are sweated by means of silver solder on to bars of brass of the same width in a gas furnace giving firm fusion.

Plated gold and silver are prepared by means of copper foil lined with silver or gold foil, adherence being effected without welding by rolling red hot.

Where only a few copies of the articles manufactured are required the processes followed by the goldsmith are very variable: round or oval articles are turned; others are cast in moulds — they are stamped in a press or planished with a hammer. The different parts of an article are assembled and finally welded together.

Decoration consists of carving, chasing or chiselling (in the case of cast ornaments), engraving, polishing, etching, incrustation, enamelling, etc.

On the other hand, for articles to be turned out in quantity cutting out and stamping is done by rolling in matrix cylinders with hollow engraving which effects automatic engraving, engine turning, etc.

Table cutlery is manufactured by rolling in matrix cylinders or by stamping in a press. The work is finished off with a file, then silvered over by a galvanoplastic process (silvering) or gilded with vermeil. Polishing is done on a lathe provided with a brush and by applying putty powder. As polishing substance there may also be used "polishing red" or colcothar, pumice stone ground in oil, tripoli, etc.

After polishing with putty powder a special brilliancy is imparted to the polished article (burnishing) by means of revolving discs provided with buffing leathers impregnated with colcothar, or Viennese calcium dissolved in olein. The dust from the polishing wheels is collected under water in tanks which serve for the ultimate recovery of gold and silver.

Enamelling of precious metals is effected by use of vitrifiable colours dissolved in water which are baked in an enamelling furnace (or muffle furnace). Enamelling of small objects is done by blowpipe, polishing being effected by the use of rottenstone or putty. The latter operation may expose
the workers to the risk of lead poisoning (Tula enamel; see article “Silver”).

The jeweller engages in goldsmiths' work and also in that of making jewellery, for he handles both precious metals and precious stones. His work, however, is finer and more delicate than that of the former, the objects handled being of smaller dimension. In connection with the making of fancy jewellery there now exists an extensive industry of imitation jewellery. Precious stones are replaced by false stones, pearls by false pearls, and gold by copper gilded by the mercury process or by plating processes. Another branch of the industry is devoted to plated jewellery, gold and silver plated leaf, etc.

The floors of the workrooms are usually made of polished brick covered with wooden lattice work to prevent the dust being carried away by the workers' feet.

DANGERS

During the operations of melting, the workers exposed to radiant heat from the crucibles become subject to forms of eczema, particularly when persons of undue susceptibility are involved. The operations of moulding and stamping demand very considerable muscular effort, and involve the risk of shocks which in the case of certain individuals have fairly serious results. Stamping and polishing are equally trying, especially when the manufacture of silver articles is in question. Where foot machines are used affections of the abdominal organs and haemorrhage have been noted among women workers. Hand work also has been known to give rise to urinary paralysis.

Soldering may also be regarded as trying work where the heat source is defective and the use of the blower has often to be resorted to. It happens fairly frequently, especially in technical schools, that the same blower is used by various persons; in this event the same well-known disadvantage met with in the work of glass blowers is involved; the mouthpiece therefore ought to be the personal property of each individual, or, better still, a compressed air blower should be used.

The use of soldering lamps exposes workers to the harmful action of combustion gases, especially carbon monoxide, particularly where work is effected in confined quarters. The action of toxic fumes given off by molten metals, acid solutions, and electrolyte baths must also be recalled. Amongst such metals account must be taken chiefly of lead and of mercury, amongst the acids, hydrochloric, nitric and sulphuric, and amongst other products liberated by the electrolytic baths particular mention should be made of prussic acid. Nitric acid mixed with hydrochloric acid is also largely used for scouring metals.

Polishing is generally done with a hot solution of caustic soda or with calcium or by means of a sand blast effected in a closed apparatus with exhaust. The chemical products used are notoriously responsible for irritation and burning or corroding of the skin and the mucous membrane.

For scouring, benzin, petrol spirit, trichlorethylene, carbon tetrachloride, etc., are used and the use of these products often causes vertigo and headaches. Zapon lacquer also gives rise to similar troubles. For this reason cleansing by electrolytic process, which is greatly superior from a hygienic point of view to the methods in actual use, has been recommended. For this purpose a solution of chloride or Glauber salts, which, under the action of the current, liberates chlorine or sulphuric acid, is used. Mention has already been made of the use of cyanides for electrolytic baths. Cases of discomfort or of poisoning may be prevented by installing good localised ventilation.

The danger from mercury poisoning common during the operation of hot gilding is now rare.

The use of ammonium sulphide for decorative purposes is often the cause of irritation and burning due to liberation of sulphuric acid.

Polishing of silver is hard work causing muscular and articular pains, especially when done by hand; it is now, however, mostly done by machinery. The cleaning of metal with beer and with Panama powder (with a basis of saponin) is also an operation in course of which the workers are exposed to irritation of the skin and mucous membrane. Finally, attention should be paid to the lighting, especially for workers engaged in engraving who require a very high-powered lighting system (200 lux), the luminous rays being concentrated on the working post by means of a globe filled with water.

Waste, dust, debris, cinders, sweepings and washing water are carefully assembled and subjected to treatment for the recovery of the precious metals. The cinders are sorted and washed and triturated in a mill with mercury; the amalgam obtained is thereafter heated in order to remove the mercury.
The mortality rate from lung diseases amongst goldsmiths in Berlin during the years 1886-1893 was 42.5 per cent., of which 40.2 per cent. represented tubercular cases. Mortality statistics collected in America for jewellers (inclusive of clock and watch repairers and gold and silver workers) for the years 1908 and 1909 showed that out of 866 deaths 122, or 17.8 per cent., were due to pulmonary tuberculosis; but this relatively low average figure, for all ages, is modified for proportionate mortality according to the divisional periods of life, which reveals the proportionate mortality from pulmonary tuberculosis at the younger ages to have been quite excessive — 50 per cent. between the ages of 15 and 24 and 29.7 per cent. between the ages of 25 and 34. The experience of an American industrial insurance company shows that of 812 deaths from all causes 39.5 per cent. were due to diseases of the lungs and respiratory passages and the conclusion of an investigation based on these figures is that jewellers are subject to a decidedly excessive mortality from pulmonary tuberculosis at ages under 45 and particularly between 15 and 24. As regards morbidity, the same results were formerly noted by Zadek amongst the jewelers of Vienna. As regards mortality he found that it was highest for the group of workers engaged on metal work — and that both as regards total mortality and mortality for the different age groups. In fact for the group 15-20 years of age the mortality was twice as high as the average mortality for all the members of the Sickness Fund for the ages in question.

PATHOLOGY

The occupations of gold and silversmiths are often chosen by workers of peculiar physique, and this partly explains the frequency of chronic afflictions of the eyes and respiratory organs and especially tubercular infection. Other lesions are derived from acid, mercurial and lead fumes, etc., given off during various operations.

Inspection in this industry has not infrequently revealed a tendency to overcrowding, and this, together with a continuous sedentary position in a stooping attitude due to the absence of adjustable seats, and an unduly high temperature constitutes injurious factors often aggravated by the presence of dust, and other adverse conditions, such as eyestrain incident to work on the various fine processes. The occurrence of visual defects is due to much of the work being done at close range and involving eyestrain in the absence of an illuminating device. Where the light source is too glaring and highly reflecting surfaces are handled irritation and ocular fatigue are caused. Emery wheels used in stone-cutting wear away quickly and give rise to the generation of a certain amount of toxic lead dust. The process of colouring gold causes the emanation of chlorine fumes, which irritate the respiratory passages. Soldering produces not only eyestrain but exposure to heat, inhalation of the products of combustion and possibly also of coal gas due to defective tubes and burners. Finger injuries are not uncommon amongst workers operating stamping and pressing machines. Attention has been called to the fact that miscarriages and premature births are of frequent occurrence amongst the women workers employed in the Pforzheim jewellery industry, and this has been attributed in some measure to the use of the foot power presses. One authority suggests, however, that the constant handling of brass goods may perhaps constitute a subtle form of lead poisoning to which the embryo is especially susceptible. A case of lead poisoning notified to the English factory inspectorate affected a woman worker employed in a workshop where medals were enamelled and who had got into the bad habit of pointing with her lips the brushes used for applying the enamel.

HYGIENE

Good exhaust systems are essential to combat the dust generated especially in the operations of filing, turning and polishing. The importance of the recovery of the metal dust from an economic standpoint usually results in this precaution being adopted; local exhausts are fixed close to the work and at the level of the work and having filler shaped orifices for catching the dust. These localised exhausts over each machine or tool are connected up by piping to a strong ventilator at low pressure. Flannel filters are inserted between the exhausts and the ventilator, causing the dust to fall into sacks or other suitable receptacles, while the air escapes outside. Both filters with automatic cleaning device are used. For operations concerned with imparting brilliance for which cotton-covered polishing buffers are used, liberating in the dust textile fibres, cleaning is not done automatically but by hand (Frois).

By reason of the great variety in the work it is advisable to ensure that a limited number of operations only be effected on each machine, which should be fitted with the hood appropriate to such operations.

Brightening (antivage) is only a
special kind of polishing calculated to impart great brilliance. It is obtained by rubbing the objects on wheels covered with cotton cloth impregnated with Viennese calcium and grease (oil) revolving at great speed. It is advantageous to provide the workers directly with prepared blocks of the chalk and oil, thoroughly mixed, which, applied to the polishing wheel, spread the chalk thereon without liberation of dust. Despite all precautions, however, a little dust is raised, and the application of hoods, as in the previous operation, is not possible, for it is essential that the workers should have free access to the lower part of the polishing wheel. Frois remarks on the possibility of enclosing the working post by a sheet metal box, leaving the lower part entirely free. Where it becomes a question of imparting brilliance to very large objects the sheet metal box would acquire such dimensions that the pressure would no longer be sufficient for withdrawing the dust blocking up the channel. It would then be possible to branch at the back of the box the pipe of a ventilator providing air at a pressure of 150 mm. of water. Emptying of the pipes is rapidly effected and the material recovered is calcined in furnaces.

The dust recovered is calcined to remove particles from the buffers and the extraneous matter and the cinders are then passed to a foundry for proper treatment by isolating compounds.

JUTE

BIBLIOGRAPHY

Prof. G. M. Kober (Washington).

Jute

French and German: Jute. — Italian: Juta.
Spanish: Yute.

GENERAL REMARKS

Jute is a textile fibre obtained from various species of the genus Corchorus growing in certain marshy regions of the tropics, but cultivated on a large scale almost exclusively in Bengal and Assam.

The fibre is found in the ligneous layer covered by the stalk. The principal ingredient of this fibre is cellulose mingled with a complex ligneous substance called lignose. For the purpose of comparison, one might say that cotton fibre consists almost entirely of pure cellulose, whilst that from flax contains about 40 per cent. of peptose, and raw jute contains 35 to 40 per cent. of lignose.

Its chemical composition allows of easy combination with basic substances, but at the same time this renders it very sensitive to the action of chemical agents such as those employed for bleaching purposes.

For this reason jute is rarely bleached right through, as carbons of soda and hypochlorite weaken the fibre too much.

When the dyeing process is reached the jute, in consequence of the processes to which it is subjected, loses about 10 to 15 per cent. of the fibre.

The qualities of jute as it is met with in commerce are very variable, especially as the place of origin.

Serajgunge is a soft jute of moderate strength easily bleached and with a tendency to produce a thread whose fibres form points or balls. Its colour varies from white to a bluish or reddish grey. Sometimes red fragments are found derived from the roots. Serajgunge Jute is grown in the basin of the Jumna.

Naratingunge is fairly stout. It is soft to the touch and readily separates into simple long fibres. It often retains earthy matter derived from the retting water. Its colour is creamy white, but the ends of the fibres are red. It is useful for making rope and weaving.

Ultraja Jute much resembles the two sorts just described, but is often of a
lower quality because of retting conducted in stagnant waters which affects its colour deleteriously. This variety comes from Haldibari, and is almost always of a pink colour.

The quality Daisee is of a soft and silken character; it is obtained from Cordia cajan fistula. It tends to be at times bright, and at times grey and brown. Its good qualities render it very suitable for spinning. It is used for the weft and the wool in weaving, where a definite colour is not indispensable.

Dowrah jute is of average strength, rough, hard, breakable and deep in colour; it is used for strong woven material such as sacking and for ordinary purposes and when used pure, or mixed, for cordage.

The fibre Bimlapatum or “Bimli” for short, is resistant, hard and short. In mixtures it is used for the weft in weaving strong material. It varies from a light to a deep grey and possesses no lustre. It is the kind most widespread and is found in different parts from India to Java. It belongs rather to a kind of hemp from Hibiscus cannabinus and is described as a bastard jute. Chittagong jute is closely allied to the varieties coming from Naraingunge and Chittagong, but is better prepared, cleaner and almost free from fibres drawn from the roots.

Lastly, Tossa resembles the better qualities of Daisee. It has a beautiful lustre, spins very well, and is suitable for fine thread where colour is not a matter of importance as it is brown.

As has been said above, almost all the jute comes from India and particularly from Bengal. The plant might be cultivated successfully in other countries where, however, the efforts have not been attended with much success as the retting processes in vogue in India are much superior.

From jute resistant materials are manufactured, especially sacking and packing materials, carpets, curtains and passementerie; or when mixed with other fibres velvet, rope soles, cord, string.

**INDUSTRIAL PROCESSES**

To obtain the jute fibres the plant is cut down immediately after it has flowered. Then it is retted, generally in running water, sometimes in stagnant water and the bark is removed by hand. The annual production is about ten or a dozen million bales, of which more than one-half is consumed locally by the factories in Bengal. Great Britain, particularly Scotland (Dundee), consumes about a million bales. The rest is worked up in Germany, in France (North), Italy (Piedmont), the United States, Japan, etc. One bale weighs 400 English pounds (about 180 kg.); but there are bales of 112-130 kg. (“cutcha”).

The jute arrives at the factories as a mass of unspun fibres, fairly long and strong, of a silky appearance and of very diverse qualities and tints as has been described. In the factories it undergoes the later changes by processes analogous to those employed in the manufacture of flax and hemp. In order, however, to give the fibres the suppleness they lack, they are oiled, i.e. impregnated at an early stage with oil.

This oiling is effected at the moment when the fibres pass through the batching machine. It is carried out in various ways according to the taste of the manufacturer and to the uses to which it is going to be put. Sometimes an oil is used which has no smell if it is a question of a jute of high quality; sometimes fish oil is used or soap solutions, etc. The quantity of oil used varies with the season of the year. For good spinning the fibres should contain from 10 to 12 per cent. of moisture.

After passage through the breaker, which divides it into strands, the jute goes to the cording machine, from which it emerges in the form of a ribbon which becomes converted into thread by passage through the roving and spinning frames. Spinning is done dry. The thread is delivered to the client not in bulk, but on reels or on cops. For some fine sorts the fibres are combed instead of being carded, but the tow which falls from the combing machines is collected and placed with the sorts which go directly to the cards.

**STATISTICS**

The statistical data available provide no morbidity or mortality returns for this class of worker exclusively, being included with returns for textile workers generally.

**PATHOLOGY**

The workmen are often incommoded by the dust arising from the manipulation of the fibres; these dusts frequently set up the syndrome (known under the name of “mill fever”) characterised by febrile attacks accompanied by violent coughing, bronchial catarrh and prostration. The particles of dust which irritate the respiratory passages are made up of bits of fibres the jagged edges of which set up marked irritation of the mucous membranes (by anaphylactic phenomena). Further, account should be taken of a chemical action due to the oil emulsion and the alkaline solutions used in oiling (Carozzi). The symptoms last two or three days and often disappear without treatment. Oliver
also states that statistics furnished by the Dundee Hospital showed a high number of cases of lobular pneumonia.

Skeletal deformities (of the legs) have also been described among jute workers, due mainly to constant standing on a continually vibrating floor. These deformities have been met with among workpeople who commence work very young, when their bones and joints are in process of development and more sensitive to the action of injurious causes (Carozzi). By others this pathological process is attributed to a sort of osteomyelitis (Klein).

As a consequence of the excessive noise in the weaving sheds and diffusion of dust in the air causing plugs of wax in the ears, deafness is common.

Hoarseness, noticeable in workers employed in the preparing and spinning room, is due to the dust and over-fatigue of the voice caused by the necessity of speaking loudly because of the noise.

Throat troubles are often associated with chronic pharyngitis especially in women and children.

The particular frequency of pharyngitis among jute workers is brought out in the following figures collected by Zambler: 65 per cent. of cases among jute spinners, 15 per cent. among jute weavers, 20 per cent. among silk spinners and 21 per cent. among domestic workers. The particular frequency of adenoid vegetations among women and children should also be mentioned (Zambler). Moreover troubles affecting the respiratory passages are also favoured by the high temperature common in the spinning rooms.

Fatal cases of tetanus among the jute workers of Dundee have been reported. The spores were found in the dust collected under the breaking machines and enquiry brought to light that they had come over in the earth attaching to the jute plant from India (Legge, 1898).

According to Hope and Hanna, jute workers are also said to be liable to diabetes. Skin affections have been described in workpeople engaged in boiling jute in alkaline baths (soap, caustic potash or soda: Prosser White). In a Dutch spinning mill where the thread was impregnated with a solution of yellow soap, impure fish oil and mineral oil, more than 50 per cent. of the 87 young women employed suffered from dermatitis (1916). This was characterised by irritation of the skin, redness and swelling, dry eczema, papillary hypertrophy and inflammation, advancing even to suppuration (Kranenburg).

The colouring matters and oils handled in manipulating jute are the cause of folliculitis observed, notably in India. The lesion is non-suppurative in character brought on by mechanical obliteration of the orifices of the subcaneous glands by debris from the corneal layer, the exfoliation of which was obstructed by the presence of the oil on the skin. The accumulation of this debris is frequent among the natives, who do not use detergent soap sufficiently, water alone being insufficient in these cases (Curjet and Acton).

Although it cannot properly be called an unhealthy industry, work in a jute factory is prejudicial to health, especially in countries where work is carried on from father to son. In such cases the children are exposed to all the unpleasant elements in the work, which ends by lowering their general resistance and affecting their growth unfavourably.

According to Oliver (1908), young girls of seventeen and eighteen years of age look as though they were thirteen; anaemia is rife, with a considerable incidence of tuberculosis among the jute workers. It is necessary, however, as for all statistics on the effects of inhaling dusts dating back for a relatively long period of time to consider the data as suspect. In the absence of bacteriological examinations such statistics include, under the designation of tuberculosis, all bronchitic, chronic and severe pulmonary affections (Agasse-Lafont).

HYGIENE

As has been said, the processes which jute undergoes in its manufacture are practically the same as those for flax (see article "Flax"). The workpeople are exposed to the same risk of dust, rather less, doubtless, in consequence of a certain moisture given to the material in the process of oiling. Naturally all kinds of jute are not equally dusty. Jute cannot be spun when wet. In the preparing and spinning rooms the relative humidity found to be most favourable is from 70) to 75 per cent. Generally a temperature of 18° C. is maintained with 70 per cent. relative humidity in the preparing rooms and 22° C. and 80 per cent. in the spinning. Artificial humidity is, therefore, necessary in the majority of rooms. (See article "Air: Hot and Humid Atmospheres").

As to the processes carried out at the place of culture — harvesting, retting, extraction of the fibres, etc. — the
workpeople are subjected to the same inconveniences as are those employed in the garnering of rice. It was thought for some time, doubtless owing to coincidence, that risks encountered in the spinning and weaving of jute would involve more serious consequences than in factories where textiles are worked, on account of tetanus, but nothing of the kind has proved to be the case.

In the process of breaking on a large scale, energetic ventilation of the workrooms should be adopted by means of fans so arranged as to direct the dust either under the furnaces or into collecting chambers. Some authorities recommend the introduction of ozone into the workrooms where jute is manipulated. Care should be taken to place the furnaces outside, to warm the rooms by means of steam pipes and to illuminate them from the outside by enclosed lamps, and to arrange the machines so as to avoid incommoding the neighbourhood by noise or vibration.

**Legislation**

In Germany young persons under eighteen years of age are prohibited from employment in rooms in which opening, batching, breaking, unravelling, oiling, mixing and removing the dust from jute are carried on (Order of 8 December 1909). Young persons under eighteen years of age and women are prohibited from work in the Netherlands, in processes preliminary to spinning if unprovided with a medical certificate (Act of 1920, section 33, subsection K, and section 35).

Boys under fifteen years of age and women under twenty-one are prohibited from work in breaking, carding and cleaning jute in Spain where there is exposure to dust. The same applies in France to young persons under eighteen years of age in large scale breaking, and in Estonia to young persons under fifteen years in jute spinning.

Special regulations for the manufacture of jute are not numerous, because generally the processes are regulated by the same restrictions as are laid down for the textile industries, and particularly for flax.

In Great Britain the Regulations of 28 August 1907 deal with spinning and weaving of hemp and jute and of hemp and jute thread and processes connected therewith (see article "Hemp Manufacture").

In India (Punjab) the Factory Regulations of 17 October 1922 state in section 23 that in every room of a jute mill in which opening bales, machine hackling, carding, preparing or other processes giving rise to dust to such an extent as to constitute a source of danger to the workers, are engaged in, efficient locally applied exhaust ventilation shall be installed as near as possible to the point of generation of the dust.

**Bibliography**

P. Boulin (Lille).
Kapok

This name, which is a Malayan word, is given to material used for stuffing upholstery, provided by the fruit of several colonial plants belonging to the family of Bombacaceae, and found chiefly in the West Indies, Indo-China, Japan, Central and South-ern America, tropical Africa, etc. The best qualities of kapok come from Java and Calcutta.

The fruit resembles a cucumber of 8 to 14 cm. in length, and when opened shows a woolly mass, the real “kapok down”, in which the seeds are quite free.

Kapok with long and silky fibres is used for filling mattresses, pillows, cushions, seats of motors, etc. For some years, thanks to carding machines which do not break the fibre like ordinary weaving machines, it has been possible to weave the kapok into cloth and to make knitted goods and various garments of it.

The great flexibility of kapok explains its utility for rescue articles (life belts, life buoys) for a weight of kapok can succeed in keeping afloat a weight 30 to 35 times heavier.

Treated with sulphuric acid and nitric acid it gives a product which, like gun-cotton, dissolves at least partially in alcohol and ether and leaves, on evaporation, a film similar to that of collodion.

The seeds of kapok are used for the oils which they contain (20 to 25 per cent.) in soap making or as substitutes for edible oils in the manufacture of margarine. The cakes are used for cattle fodder.

The fruit is gathered before it is quite dry. It is opened by hand and the kapok removed. This operation must be effected as rapidly as possible, since when left in the shell the fibres rapidly take on a colour which diminishes their value. The workers entrusted with this operation must carefully examine the quality of the fibre, eliminate that which is spoilt (mildewed) or belonging to a secondary quality (with greyish or reddish fibres). The raw kapok is generally placed in bales weighing 40 to 50 kg.

The best qualities of kapok come from Java and Calcutta.

The operations of cleaning and ginning kapok, as well as those of winnowing, are so dusty that entering a factory is like penetrating into a thick fog (Heijermans) in which a peculiar and special sensation affecting the nose and throat is experienced. There is pricking and pain in the eyes. After a certain time there occurs acclimatisation to the inhalation and to contact with the large quantities of this dust. The process of winnowing is all the more harmful since the workers who recover the kapok are immersed in it up to the shoulder while shovelling it up.

The injuries to the lungs caused by kapok are much better known since the use of X-rays has revealed amongst workers in this industry a sclerosis of the lung, whilst ordinary clinical symptoms did not show up anything of importance (Heijermans).

The hygienic measures to be taken are similar to those provided in regard to other textile fibres and in particular to cotton.

As regards legislative measures, the only one in existence is that issued in the Netherlands, which requires compulsory notification of pulmonary troubles occurring amongst workers in kapok factories. ***
Lace

General Observations

Lace can be made by hand or by machine. Hand-made lace includes:

1. Needle-point lace done with a plain needle and sheet of paper or parchment on which the pattern to be executed is reproduced by pricking. According to the way in which it is made, needle-point lace is called Venetian, Alençon, Brussels, English, etc.

2. Pillow-made lace (made with thread wound on bobbins) is done on a lace pillow or cushion (a kind of stuffed box), carrying a piece of paper on which is chalked or pricked the pattern to be executed. Pins inserted on the cushion serve as indicating points for attachment of the threads unrolled from the bobbins. Such lace is called Valencienne, Malines, Flanders, Spanish, etc.

3. Appliqué lace, filet lace, artistic guipure.

In machine-made or woven lace (Dentelle mécanique ou d'imitation, Maschinen spitze) the interlacing threads imitate the pillow-made lace on tulle (a net-like tissue with open mesh, generally of hexagonal shape). Guipure can also be made mechanically on open-work tissue for furniture, curtains, bedspreads, etc.

After their manufacture, these different kinds of lace must be washed, dried under pressure, finished, goffered, bleached, or dyed.

Pathology

In some branches of the lace industry excessive heat and moisture are found. According to Arlidge, goffering is the process most injurious to health, because it has to be done with machines heated by gas, from which there is a risk of poisoning from carbon monoxide.

Making lace from thread involves a certain risk as the hemp dust is liable to contain silica.

Mention should be made of the risk of lead poisoning among workmen charging the thread with lead acetate or who dust the lace with white lead to bleach it.

The mortality rate from tuberculosis in this industry is very high, except in Great Britain, where the death-rate from tuberculosis is below the average of the other branches of the textile industry. On the contrary, mortality from alcoholism, diseases of the liver and of the nervous and circulatory system is in excess.

Knowles (quoted by Prosser White) describes dermatitis among lace-makers probably due to acids.

According to the statistics of the Leipzig Local Sickness Society, the mortality rate in the lace industry is very low: 0.35 per cent. for men and 0.5 per cent. for women. There were 620 sickness days per 100 workmen and 910 per 100 workwomen.

An enquiry carried out in September 1923 in the "Liverce" Lace Factory of Moscow gives interesting details as to the sanitary conditions in this industry.

The personnel consisted of 600 persons, the majority of whom looked after the machines. These machines were notable for their large size (manufacture of curtains) and complicated working, which demanded sustained attention and constant eye-strain on the part of the workmen. The threads, of very fine counts, were wound upon 80 to 120 bobbins, and were lit up from behind by small electric lamps, making it necessary for the weaver to work constantly by artificial light. This very complicated work requires an apprenticeship of several years. For this reason among the personnel, composed entirely of men, there were none who were young.

The enquiry covered 43 workmen distributed in age groups as follows:

<table>
<thead>
<tr>
<th>Cases</th>
<th>Percentage</th>
</tr>
</thead>
<tbody>
<tr>
<td>Below 30 years</td>
<td>0</td>
</tr>
<tr>
<td>30 to 39 years</td>
<td>14</td>
</tr>
<tr>
<td>40 to 49 years</td>
<td>23</td>
</tr>
<tr>
<td>50 years and over</td>
<td>6</td>
</tr>
</tbody>
</table>
LACTIC ACID  

Two workmen only had been employed for less than two years, 24 from five to nineteen years, 11 from twenty to twenty-nine, and 6 for thirty years or more.

The medical examination of these workmen gave the following results:

<table>
<thead>
<tr>
<th>Disease</th>
<th>Cases</th>
<th>Percentage</th>
</tr>
</thead>
<tbody>
<tr>
<td>Tuberculosis, diagnosed or suspected</td>
<td>15</td>
<td>35</td>
</tr>
<tr>
<td>Chronic rhinitis</td>
<td>9</td>
<td>21</td>
</tr>
<tr>
<td>Chronic bronchitis</td>
<td>14</td>
<td>33.5</td>
</tr>
</tbody>
</table>

The two last affections might have been attributed to inhalation of graphite dust with which certain parts of the machinery had to be powdered.

The eye diseases were distributed as follows:

<table>
<thead>
<tr>
<th>Disease</th>
<th>Cases</th>
<th>Percentage</th>
</tr>
</thead>
<tbody>
<tr>
<td>Chronic conjunctivitis</td>
<td>39</td>
<td>91.9</td>
</tr>
<tr>
<td>Blepharitis</td>
<td>3</td>
<td>6.8</td>
</tr>
<tr>
<td>Disease of the lacrimal duct</td>
<td>4</td>
<td>9.2</td>
</tr>
<tr>
<td>Myopia</td>
<td>16</td>
<td>37.2</td>
</tr>
<tr>
<td>Hypermetropia</td>
<td>16</td>
<td>37.2</td>
</tr>
<tr>
<td>Astigmatism</td>
<td>2</td>
<td>4.4</td>
</tr>
<tr>
<td>Changes at the back of the eye</td>
<td>4</td>
<td>9.2</td>
</tr>
<tr>
<td>Weakness of sight</td>
<td>3</td>
<td>6.8</td>
</tr>
</tbody>
</table>

While the hypermetropia might be considered as due to the age of the workers, the other eye conditions should be attributed to occupational causes: eye strain and the effects of artificial light.

The pathology of these workers is analogous to that of workwomen engaged in the clothing industry, for though the work may be done in a workshop it is generally carried on at home in villages. The work is sedentary and carried out in a bad position (bent head) which favours congestion and strain in bringing about visual accommodation.

In passing through the villages where the women occupy themselves with lace-making, they are not infrequently to be seen working at the door of their houses; but in bad or cold weather they work in their rooms, often badly ventilated and lighted, which explains the high incidence of eye maladies among these women. When the work is done by artificial light this is often insufficient and inadequate. When they work “white”, they are exposed to the dazzling effect from the brightness of the work.

The defects of accommodation show themselves rather early and prepare the ground for more serious damage. Lace-making may be said to bring out latent morbid phenomena and to favour the development of anæmia, hysteria, and other neurotic symptoms in the production of which other factors such as heredity, environment, food, etc., play a part.

These workwomen easily and quickly acquire a lessened resistance to the effect of the work. When examining them the oculist does not find errors of refraction or of accommodation, or of muscular insufficiency, but he finds fairly frequently contraction of the visual field or the characteristic type of alteration of the visual field (hysterical copiopia). In old myopic lace-makers complications arising from the myopia are frequently observed such as central retino-choroiditis and exudation into the vitreous body.

For fuller details, see articles “Clothing or Garment Trade” and “Occupational Diseases: Eyes”.

Heller mentions that the nail of the left index finger must be well developed in lace-makers to enable them to draw the needle from the pillow during work. The nail of the right index finger, on the contrary, is kept short in order not to break the thread.

For hygiene, see article “Clothing or Garment Trade”.

BIBLIOGRAPHY

Lactic Acid

Lactic acid (formula, C₃H₅O₃) is now industrially prepared by starting with amylaceous substances and, in particular, potato starch. A glutinous substance is prepared which is transformed into a wort and treated with a diastatic solution. When the saccharification of the starch is completed carbonate of lime is added and the lactic ferment is scattered through it.

The lactate of lime produced is decomposed by means of sulphuric acid in order to liberate the lactic acid. It is prepared in a similar manner by starting with the mother liquors from crystallisation of lactose. It can finally be obtained also by inverting sugar by means of sulphuric acid and treating it thereafter with caustic acid.

Lactic acid is used as a reducing agent in the dyeing of wool (after mordanting with chrome), in the printing of cotton, in tanning, as a solvent for certain colours (indoline, nigrosine),...
in chemical laboratories, etc. Eczema
and ulcerations of the skin have been
reported among flax weavers (see arti-
cle "Flax and Linen Industry"), as
well as amongst dye workers, arising
from the acid in question which forms
a constituent of the baths used for
these products.

HYGIENE

The wooden vats used for sacchar-
ification of the starch should be placed
in airy and well-ventilated workshops.
They should be steam-heated. The
fermentation vats should be provided
with airtight covers and so placed that
the gases liberated are withdrawn
under the hearth of the generator or
into the chimney. The vapour and
evil-smelling gases produced by the
decomposition of the lactate of lime by
sulphuric acid should likewise be
directed to the chimney.

Crude lactic acid should be con-
centrated in closed apparatus at a
reduced pressure and purified, and
similarly also lactates destined for
pharmaceutical use should be put into
earthenware receptacles and not into
containers lined with lead. Residues
of sulphate of lime coming from the
manufacture of lactic acid should never
be allowed to accumulate in the
factory. All waste water should be
neutralised before it is allowed to leave
the factory.

***

Laundries

French: Blancheries. — German:
Wäschereien. — Italian: Lavanderia. — Spanish: Lavadura.

In washhouses for the washing of linen
cloths of steam are liberated. Laundries
almost always have a washhouse attached,
since washing constitutes one of the most
important operations in laundry work.

Very often washhouses are found even
in public washing establishments.

Though to a great extent laundry work
is homework executed in private houses,
available statistics for large-scale under-
takings prove, however, the importance
of this industry. By reason of the greater
concentration in towns and the diminish-
ing aptitude and opportunity for home
laundry work, the industry is steadily in-
creasing. Usually ironing is also included
as part of the occupation, so that at the
present time laundry work affords occupa-
tion to as many women as any other
industry outside the textile trade.

There is an exceedingly wide range of
method followed in this industry, from
the primitive system of washing in open
tubs followed in domestic industry to the
highly organised systems with division of
labour followed in modern large-scale
laundries having the latest technical equip-
ment.

The unduly rapid changeover from one
extreme to the other has given rise to
undesirable anomaly between the two
systems. Smaller laundries are thus often
located in small unsuitable premises, often
really dwelling houses and never designed
for housing machinery, which shake with
the strain and which have small windows,
icapable of affording adequate ventila-
tion and light for the operations effected
with production of quantities of steam and
abnormal temperature.

Processes

Owing to the variety of methods
employed, an accurate description of
the work, typical of the industry in
general, is not possible, but in the
majority of large-scale undertakings
the following operations take place:

(1) Opening bundles or sacks of soiled
linen;

(2) Marking each piece;

(3) Separation of starched and flat
articles;

(4) Steeping;

(5) Washing with hot water, soap
and washing powder: this opera-
tion is followed or replaced by
soaping by hand;

(6) Rinsing;

(7) Wringing: done by hand by twisting
the linen or, more often, in
hydro-extractors which remove the
excess of water;

(8) Drying: the linen is placed in
tubs which are subsequently sent
to the drying chambers; in the
domestic industry it is often hung
in the open air on ropes or on
wooden frames.

The linen is then rolled in calender
machines in which folding is also
affected. It is thereafter starched and
finally ironed by hand or by machinery.

In some laundries the articles may
pass through seven or eight machines
for ironing alone. The drying chambers
are heated by steam or supplied with
hot air by propulsion fans. The
calender machines consist of huge
steam or gas-heated cylinders with
single or multiple rollers, and are
usually tended by young girls, who
stand in front of the rollers and feed
the edge of the material into the "bite"
of the roller or over the "lip" of the
single roller. A cloud of steam is given off as each fresh piece is inserted into the machine. The heat given off during this operation is sometimes very great. Over 90°F. may be registered on the feeding step of the machine, even in winter.

There is an endless variety of washing, wringing, starching, mangleing, and ironing machines—collar and cuff ironers, curling and gophering machines as well as electric or gas-heated irons. Factory work has caused a great increase in the employment of young unskilled labour (machine tenders), but at the same time conditions in factories, being subject to regulation, are, for the most part, greatly superior to those met with in domestic industry.

**Dangers — Pathology**

It is difficult to gauge accurately the effect of this industry on the health, since most of the diseases to which their occupation renders laundry workers liable are such as might equally well proceed from other causes. Certain investigations and statistical enquiries have shown health conditions in this industry to be in general satisfactory as compared with other industrial work. Yet, the heavy nature of the work and the attendant conditions, often of necessity highly unfavourable, undoubtedly provoke and aggravate certain forms of disease. The chief factors in introducing the various maladies from which workers in this industry suffer are: long and irregular hours (sometimes 72 to 76 hours, exclusive of mealtimes), constant standing and bad posture, atmosphere rendered hot and steamy by radiation from heat sources, lye fumes (often containing drops of lye in suspension), mechanical and strenuous effort, etc. These factors are usually present to a more pronounced extent in the case of the domestic industry, where the work is often executed in a room heavy with steam, which condenses on the walls and ceiling.

Where it is not possible to dry the linen outside (in smoky towns), the wet material flaps day and night across small inadequately ventilated rooms and passages, excluding light and air. The drying stoves and stoves or fires for ironing cause oppressive heat, rendered more obnoxious by the close odour of stores of soilied linen and fumes from the stoves, especially when the room is badly ventilated and without any provision for the removal of steam and bad air.

Miss May Smith (1922) conducted an enquiry into conditions in several London laundries where she found, for instance, in one case a temperature of 80°F. in November and in another, in summer, a temperature exceeding 90°F. The difference between laundries is enormous; for with a similar outside temperature of 61°F. the average temperature inside two laundries were 73°F. and 84°F. Very great differences were also met with as regards ventilation. Miss Smith is of opinion that were the problem seriously considered it would be possible to introduce universally such conditions of work as those at present obtaining in the best establishments.

As regards personal hygiene, one of the most important aspects of the question is the transfer of most of this work to immature young girls, who are specially liable to the bad effects of the occupation as exercised under the conditions above referred to.

Varicose veins are easily developed and ulceration and flat-foot are common evils resulting from constant standing. In addition to this the working of a foot-pedal, shaking and wringing linen, etc., are apt to exercise a bad effect on the genital organs. The rest obtained on "short days" by no means compensates for the overstrain and fatigue experienced on "long days". An English medical officer has drawn attention to the danger presented by the use of a product containing aniline oil for marking the linen. The report of the English Medical Inspector of Factories for 1924 contains a reference to two cases of skin absorption of aniline with vertigo, headache and cyanosis, affecting girls in a laundry using an ink solvent (containing aniline) to remove stains of indelible ink from a table-cloth, for a period of one hour.

Eczemas and skin eruptions are common, being due to the constant use of hot water and soap, both cutaneous irritants which remove protective fats and soften and diminish the skin and cause damage to the nails, which become loosened without, however, causing pain. They only rarely, as a matter of fact, fall off, so that certain authorities hold that it is not accurate to describe the effect as an "affection". Amongst workers occupied in the hot moist atmosphere of the laundries, there has been noted mycosis of the external canal of the ear due to *Aspergillus nigericus* or *flavescens*. 
which causes marked irritation, not only to the wall of the canal, but also of the membrana tympani, and consequent impairment of hearing. Affections of the upper respiratory passages are to be described to steam and to the alkaline fumes present, which dry the throat, give rise to thirst, and often lead to habits of intemperance. For this reason it was actually the custom in certain establishments to supply the workers with beer during a rest interval.

Investigation undertaken in France has proved the prevalence of pulmonary tuberculosis amongst workers in laundries, but great variance in statistics for different regions in regard to tuberculosis would appear to indicate that specially unfavourable conditions and not so much the work in itself, when carried out under the best hygienic methods, are responsible. One authority, while asserting that tuberculosis is very widespread in this industry, states that incipient forms of it are rarely diagnosed and treated as anaemia. The same author draws attention to the part played by heredity and infection, adding in this latter connection that many of the victims —are widows of consumptive husbands forced to take up the work in question in support of themselves and their families.

For these reasons it may be concluded that the work in itself is not conducive to the disease, but merely constitutes an unfavourable factor in its spread and development. Conditions peculiarly unfavourable to persons with a tendency to tuberculosis have been noted in departments where they are engaged all day in carrying heavy loads of wet clothes in a steamy atmosphere, often up to the ankles in water and soapsuds.

Bezançon (1923), of Boulogne-Billancourt, wished to investigate the accuracy of the current view of prevalent tuberculosis infection amongst laundry workers. The population centre in question (Boulogne-Billancourt), comprising 65,000 inhabitants, affords occupation to 5,000 laundry workers engaged in 400 establishments. While the tuberculosis mortality is high (26 to 30 per cent. of the general mortality) it affects chiefly amongst the laundry workers the men engaged in heavy work (steeping, machine-work, delivery, ironing) rather than the male and female workers engaged on the so-called dangerous operations (sorting, marking soiled linen, etc.).

Bezançon is of opinion that the cause of the tuberculosis incidence amongst adults in this industry is to be sought not in the occupation itself so much as in certain conditions liable to develop the disease amongst workers suffering from latent tuberculosis due to family infection at an early age. Direct infection in the industry when such exists would appear to be rare in the case of an adult. It is, however, very frequent amongst the children of these workers, especially children of small employers living in overcrowded workshops where they play with heaps of soiled linen which lie around in the common room.

Laundresses and ironers most usually present an anaemic appearance, characteristic of people who work in a restricted space and in hot moist air, inhaling coal gas which escapes from the tubes and jets (particularly carbon-monoxide). They complain of headache, fatigue, and exhaustion (Lehmann). The use of iron furnaces to heat the irons often gives rise to collective cases of poisoning by carbon-monoxide and even by arsenical compounds. In this connection may be recalled the poisoning of six women who suffered from the following symptoms: vomiting and loss of power in the legs — in one case almost complete paralysis with complete paraplegia below the knees and loss of patellar and plantar reflexes due to the presence of arsenic in the coal used for heating the stove. While no carbonmonoxide could be detected in the air samples taken, a noticeable portion of sulphur dioxide was found, which led the analyst the suspect also the presence of arsenic in the coke. He found 1/14 grm. per lb. (or 0.001 per cent.). Arsenic was also detected in the urine of two of the worst cases.

In an ironing room with gas irons, there was found 0.3 to 0.8 and even up to 1.4 c.c. of carbon-monoxide per 10 litres of air, and the carbonic acid content of the atmosphere reached 12.24 c.c. in 10 litres. The reduction of the haemoglobin by 10 per cent. was established as having occurred in the case of 25 per cent. of the workers.

Wilson, the English factory inspector, has demonstrated statistically the higher carbonmonoxide content in ironing shops using generator gas than in those using ordinary lighting gas. For this reason the use of generator gas has had to be abandoned in many establishments because of the occurrence of headaches, faintness, etc.

An enquiry was conducted by Miss May R. Mayers, medical inspector, New York State, in 1924 into hygienic conditions in New York laundries and the influence of such conditions on the health of workers. She also studied heart strain and strain of the vascular
system, and collected data regarding systolic and diastolic blood pressure, the pulse pressure, examination of the heart and urine, etc. This authority found as evidences of cardiac strain that the systolic pressure was abnormally high and the diastolic pressure abnormally low, that there was an accentuated aortic second sound, and a high pulse pressure, etc. The work was concluded by her to be unhealthy, especially from the point of view of heart strain and the circulatory system, in all but the very best laundries. The study in conclusion gives an account of the most adequate measures for improving conditions of work in the industry in question.

In certain establishments the ventilation system has been technically improved to the extent that once the blazing of the stove is over, the fumes are removed from the stove by means of ventilating fans, or drawn away by suction into a chimney.

Where one-foot lever machines are used for ironing, workers complain of fatigue and pains in the lower limbs, while a certain number of beginners have been known to develop acute appendicitis and hernia.

Margoniner cites, as the occupational disease of ironers, synovitis of the long extensor tendons of the right arm, beginning about the medial end of the metacarpal of the thumb and extending midway up the forearm, sometimes also affecting the shoulder joint. In the cases studied, he found paresthesia of the fingers affecting the region of the ulnary nerve attended by dullness of the finger tips, tingling and irritation and involving pronounced atrophy of the space between the bones of the thumb and first finger. These symptoms are to begin with worse during the night, but pass off on resumption of work. They are due to pressure of the finger tips on the iron and to the habit of rubbing on starch with the fingers.

Gastric affections common amongst ironers are gastric catarrh and gastric ulcer, caused, according to certain authorities, by pressure of the abdomen against the top of the flat iron. Other prevalent affections are enteroptosis (displacement through stooping position, constipation, etc.). Chronic muscular rheumatism and articular rheumatism are also fairly frequent, and occasionally cases of arthritis due most probably to a complex of causes, including bad nourishment, bad posture, etc. Other common affections are cardiacgia, kidney trouble plosis (due to the constant stooping position), retro or anteflexion of the uterus, dysmenorhea, hysteria, anaemia, etc. Two cases of death from tetanus were reported in a laundry affecting a man injured while starting up machinery, and a girl who got a splinter into her hand while washing up the mess-room floor, the flooring having probably been infected by the workers' boots. The question of the contraction of infection from soiled linen also presents itself in considering risks present in this industry. A Massachusetts investigation in this connection, however, proved negative, even as regards "markers", and general health conditions were found satisfactory.

Nevertheless, instances are known where infection has been transmitted, and Uffelmann cites cases of typhoid and cholera transmitted to washer-women by infected linen. The danger is probably greater in home and hospital laundries, where statistical data are lacking.

There is some risk of explosion in laundries where gasoline is used, and the bursting of hydro-extractors constitutes a certain risk. Burns are frequent among ironers, and a great variety of machine accidents which cannot, however, be described as typical owing to the great variety of kinds of machinery employed in the industry. Finger accidents are often sustained by workers attending to calender machines through the fingers becoming entangled in a hole or a string in the material and drawn between the rollers of the machines.

It has been stated that the hard nature of the work in general causes the women especially to be worn out while still quite young. They are also alleged to be rougher and more intemperate than women engaged in other classes of industrial work.

**Statistics**

The experience of the Leipzig Sickness Fund in regard to this class of workers shows the total number of days lost for all sickness to be under the normal figure for all workers, but the time lost on account of skin affections proved to be double the amount for all workers in general, while for rheumatism of the joints it was 40 per cent. higher than the average. The same experience shows a morbidity rate of 0.73 days per 100 workers and washers and a mortality hazard of 0.71 per cent.

In course of an enquiry effected in Belgium and covering 42 laundries employing 3,024 workers (2,309 of which were women), the tuberculosis rate was found to be only 9 per cent., amounting, however, to 16.2 per cent. amongst those directly engaged in the handling of soiled linen.
Of 45 male workers engaged in carrying heavy loads of wet clothes and often up to the ankles in water, 11 (24.4 per cent.) were tubercular or had suffered from pneumonia or bronchitis. In regard to throat and nose affections, the morbidity rate for laundry workers in general was found to be 44.5 per cent, and for those handling soiled linen 84 per cent. A quarter of the workers suffered from rheumatism. An examination for heart disease revealed five cases of dilatation and there were two cases of inguinal hernia. Of the workers 17.5 suffered from flat foot, 30.7 from varicos veins, and 20 per cent. from anaemia. Nineteen cases of miscarriage were found to have occurred in a total of 46 married women.

In the United States the mortality rate for tuberculosis was only 16.3 per 100 deaths from all causes (1909) for both sexes; in France, amongst 283 laundry workers (Landouzy) the percentage of death from tuberculosis was 25 for male workers and 56 for female workers. Of 12,000 workers in this industry one-third of the laundresses and female ironers and one-half of the male workers examined were found to be suffering from tuberculosis of the respiratory organs. The women appeared to be affected earlier (about 30 years of age) than the men, who were chiefly attacked at ages varying between 40 and 45.

According to the 1920 census, there were, in the United States, 396,756 laundresses. The mortality according to age groups and diseases was as follows in 1909:

Among 165 female workers under observation (Brooklyn, N.Y.) during three years, there were 1,876 cases of sickness distributed as follows: 436 cases of gastric disease, 323 cases of dysmenorrhoea, 124 of colds, 55 of sore throats, 36 of neuralgia, and 31 of rheumatism. The number of accidents in laundries was relatively slight, for amongst 95 persons only two accidents were reported in five years, and in another instance among 54 persons there were about two accidents attributable to carelessness in fifteen years.

Hygiene

Laundries should have concrete floors with uniform impermeable surface sloping towards a drain. They should be well aired and thoroughly ventilated. Slatted wooden platforms inclining towards a drain should be provided for the workers to stand on. All flooring should be kept clean and in good repair. Rubber aprons and water-tight boots should be provided for wet work. Laundries should be well lit, by good artificial lighting with absence of glare, where daylight is not available. Natural ventilation, being as a rule inadequate should be supplemented by mechanical ventilation, with exhaust installation to assure effective air exchange, and, at the same time, removal of clouds of steam. Such a system is absolutely essential for places where drying and wringing by hydro-extractors is effected. Tubs should be provided with covers and surmounted by hoods to draw off the steam into a chimney or outside. This method is, however, in itself inadequate, since evacuation of the hot air by hoods in this manner allows of the entry of outer air at a lower temperature, and this gives rise to the continuous formation of fresh steam. It is, therefore, necessary to heat the air which is sent into the workroom or at least dry it previously by passing it through hygroscopic material and allowing it to enter at a low temperature.

According to Bargeron, the problem was very satisfactorily solved in one workroom in which the tubs were surmounted by metallic hoods connected with a ventilating shaft having access to the outside air. Piping for the supply of dry air was installed near each tub. Supplementary piping was connected with a curved nozzle, which took the form of a detached rim enclosing the hood and having at regular intervals apertures directed at the same time towards the inside of the hood and downwards over the tubs. By way of these apertures there was supplied continuously from an aero-condenser a current of hot air which swept the surface of the liquid, and in this way ensured dissolution of the steam as it formed. There was no fear of undue air pressure in the surrounding atmos-
provided communication with the outside atmosphere.

Dirty water should be withdrawn by a sewer into subterranean channels. Where no sewer is available, the water, before being allowed to flow into a stream or river, should be subjected to disinfection. Measures of protection against fire, escape of gas and liberation of toxic or disagreeable fumes and of smoke should be adopted.

A separate room should be set apart for sorting the linen, which should be previously disinfected, more especially when belonging to houses or institutions where there are patients suffering from contagious disease, in the event of such disinfection not having been effected on the spot. Clean linen should never be deposited in the sorting room, which should be particularly well ventilated in order to exclude bad odours. The linen should be brought in in closed receptacles which should only be opened on arrival in the laundry. All washed and unwashed linen should be kept strictly separate and handled apart. No food should be partaken of or cooked in rooms where clothes are handled, but a separate room should be provided for this purpose. Good sanitary washing and cloak room accommodation should be provided, and a good supply of drinking water should be available for the workers.

As regards technical installation, attempt should be made to replace as far as possible hand work by machine work, not only for actual washing, but also for ironing. The use of electric irons is now becoming more and more general in substitution for the former heavy types of iron heated on coal fires. This system not only prevents general disorders arising from inhalation of noxious fumes, but also the occurrence of cases of synovitis, paresthesia, etc. This system not only prevents general disorders arising from inhalation of noxious fumes, but also the occurrence of cases of synovitis, paresthesia, etc. This system not only prevents general disorders arising from inhalation of noxious fumes, but also the occurrence of cases of synovitis, paresthesia, etc. This system not only prevents general disorders arising from inhalation of noxious fumes, but also the occurrence of cases of synovitis, paresthesia, etc.

LEGISLATION

In France, the employment of young persons under 18 years of age in workshops where soiled linen without previous disinfection is handled is forbidden. In Holland, young persons under 18 years of age are excluded from unpacking, sorting, and marking soiled linen, and adolescents from machine work in ironing rooms.

In general, legislative provisions provide for the application of hygienic measures in laundries in the interests of public health. Special measures of hygiene have, however, been issued for the workers in this industry in Denmark (Order of 23 January 1908), France (Decree of 13 October 1913), Great Britain (Order of 23 April 1920), Netherlands (Act of 1920, section 5, subs. 56 et seq.), Yugoslavia (Regulations of 25 October 1921, sections 208-215).

The Dutch law provides minima for height and cubic space of the workrooms, more especially where heating is by means of stoves, etc. The French, British and Yugoslav regulations comprise detailed provisions for steam laundries.

Soiled linen may not be introduced into the workrooms loose, but only enclosed in bags, rolls or special covers or other approved receptacles.

Before handling, soiled linen should be disinfected (immersion in a boiling alkaline solution or sprinkling with disinfectant). Bags or cases having been used for transport should also be disinfected by the same method.

The introduction of soiled linen into rooms where clean linen is kept should be forbidden. All water used for steeping and washing should be directly withdrawn from the workrooms by enclosed piping.

The workers should be provided by the establishment with working clothes kept clean and in good repair. The bringing of food and drink into the workrooms should be forbidden. General regulations in regard to liquids and fumes, as well as to the protection of machinery, should also be enforced in this industry.

Many legislative systems (Italian. Dutch, etc.) have also passed regulations limiting the length of the working day in laundries.

Dutch law also requires compulsory notification of cases of peripheral paralysis occurring amongst laundresses.

BIBLIOGRAPHY

Lead

Lead (symbol, Pb) has an atomic weight of 207.2 and a melting point of 327° C.; it is very rarely found in a metallic state in nature, but, on the other hand, is very abundant in combined forms, especially with sulphur. Sulphide of lead or galena (PbS), which is generally argentiferous and contains in its pure state about 86 per cent, of lead, is the most important of the ores used for the extraction of lead. Ores of less practical importance are the following: cerusite (PbCO₃) or natural carbonate of lead; anglesite (PbSO₄) or sulphate of lead; pyromorphite (Pb₃(PO₄)₂ PbCl₂), orphosphate and chloride of lead; mimetesite (As₂O₅), Pb(PbCl) or arseniate and chloride of lead; phosphogenite (PbCO₃ PbCl₃); mendipite (PbO PbCl₂), etc.

The following, which are mixed with chalk and clay and oxide of iron, should be mentioned: matlockite (galena with a streak of cerusite and fluorine) zinckenite (PbSb₂S₄); the red ore of lead or crocoisite (PbCrO₄); wulfenite or yellow lead ore (molybdate of lead), etc. Nardoite or bulangerite are used particularly for the preparation of antimoniated lead.

These different minerals are not pure, but are generally mixed with one another or with other metallic compounds. Thus, for example, galena is often associated with carbonate of lead, compounds of antimony, either arsenical or sulphurous, or with silver or zinc.

In the various countries the production of lead ore (monthly average for 1930) in metric tons was as follows: United States, 45,884; Mexico, 20,936; Australia, 13,884; Spain and Tunis, 8,089; Canada, 12,084; Burma, 6,744; Germany, 9,674; Italy, 2,016; Poland, 1,383, etc.

Lead is not only extracted from the ores which have been mentioned above, but also from certain by-products from metal works and other industries, such, for example, as lead ashes from zinc smelting works; deposits (rich in lead sulphate) from lead chambers; dress from refining lead; residues from white lead factories, containing traces, sometimes considerable, of carbonate of lead; skimmings from lead refineries; fumes collected in flues from smelting furnaces.

Chemical Properties and Industrial Operations

Lead is a bluish-grey metal, with a bright metallic lustre when freshly cut, which becomes dull on exposure to damp air, due to the formation of lead oxide; it is so extremely soft that it can be easily dented with the finger nail, or cut with a knife. It can be reduced to very thin sheets and drawn out into very fine wire.

It melts at about 335° C. and boils at about 1,525° C. (between 1,500° and 1,600° C.), emitting noxious fumes. In a very finely divided state it is liable to spontaneous combustion, even at ordinary temperature.

Lead in a mass is not attacked by sulphuric or hydrochloric acids, which, on the other hand, attack finely divided lead. Nitric acid dissolves it in the form of nitrate; acetic and other organic acids attack it in the presence of air. Distilled water, from which the air has been removed, does not attack it; but aerated water dissolves it to a certain extent in the form of hydrate. Generally, the quantity dissolved by water depends on the degree of softness of the water; rain water comes first, containing hardly any salts and much oxygen, carbonic acid, and ammoniacal compounds.

Lead Mines

The ores are got by excavation in drifts which may reach a depth of 3,000 metres and more. The bearing almost always necessitates the use of explosives. The work is carried on in the same manner as in coal mines, and all regulations for hygiene and the prevention of accidents laid down for those mines should be applied to lead mines.

Very often a first sorting of the ore is made in the workings, even at the face; in other mines the ore is ready to go straight to the smelting works.

In the workings the attention of the hygienist must be given not only to ventilation, lighting, and humidity, but also to the various kinds of dust which exercise not only a mechanical action on the respiratory passages, but also a general toxic effect on the system — an action which has not always been sufficiently taken into consideration.

It is evident that the inhaled dust of galena is absorbed less rapidly and easily than that of cerusite, but the danger is not less great, although it causes symptoms less marked than those due, for example, to white lead. The danger is naturally less when the ore is moist, and it is greater if the miner takes his food at his place of work without adopting those measures of personal hygiene which are indispensable for all unhealthy occupations.

In order to improve the value of the ore as it comes from the mine by the removal of vein-stone, such as carbonate of lime, sulphide of baryta, or fluor-spar, as well as to diminish the expense of transport and facilitate
further treatment, lead ores are first of all subjected to mechanical preparation. This includes several operations: breaking, often by hand, into pieces of a uniform size; picking, also often done by hand, to get rid of pieces composed chiefly of vein-stone. Thus are obtained a rich ore and a poor one. The first can be calcined at once; the second is subjected as a preliminary to "stamping" and several washings to remove the earthy matter.

The ore so obtained which is called "schlich" (mud) is sometimes crushed in pestle or ball machines, then it is sorted according to the size of the pieces by the use of sieves, revolving cylinders, and perforated sheets of iron, or cylindrical sieves; after which it is classified according to its density, which is determined by levigation or capillarity. If the distance from the washhouse to the smelting works is short, the pieces arrive sufficiently moist not to give off any dust. If otherwise, and especially if ores from overseas are concerned, the product is dry and very dusty. This condition is more pronounced if the ores are delivered in very small pieces, or oxidised compounds of lead are involved, such as cerusite and anglesite.

Lead-Smelting Works

The ore so obtained is sent for treatment to the smelting works.

First and foremost the ores are analysed chemically to determine their content in lead and other products with a view to obtaining adequate results for metallurgical purposes. A sample of ore in pieces is crushed by the so-called wet process, ground, dried, and sent to the chemical laboratories. All operations, as well as the cleaning of apparatus, must be carried out with care so as to prevent the liberation of injurious dust.

Although the working conditions differ at the various smelting works, certain fundamental principles are nevertheless commonly observed.

The ores are mixed according to their different compositions in order that the melted material may have an average proportion of lead and a good composition from the point of view of metallurgical requirements.

Charging the furnaces is done with alternate layers of fuel and ore, which are put in at the furnace mouth. The mass is stirred with a shovel, but in some smelting works mechanical mixers are used.

Dry ore should be moistened by means of an independent dust-laying hose connected to a supply of water. This measure cannot, however, be used in the Huntington-Heberlein process before mixing. In this case it is not possible to avoid raising dust, especially if the moistened ore arrives too late. The ore is turned over with the spade and put in heaps. It is best to do this mixing in a closed conical drum, at the discharge opening of which is a watering rose for moistening the furnace charge. Sometimes adequate ventilating shafts are used, which are connected by means of aspiration and filtration to dust collectors.

Müller has pointed out the high proportion of lead in the air of smelting works at Pribram, even if moistened ores are used, when the crushing machines are not closed hermetically. As a matter of fact, in 28 litres of air taken in the workplaces, he found 0.4 to 0.5 mg. of lead calculated as oxide.

When the mixing and crushing of the ore is finished, the product is stored and kept in the wet state. But in the case of lead clinders, or other lead residues, they should be immediately fed into the smelting furnaces.

The different kinds of ore require special treatment. Thus, for example, for cerusite or rich ores, the reduction is simply effected by calcining with charcoal on an open hearth; the lead collects in the smelting sump. If, on the contrary, the ore is poor in metal and contains little sulphur or other metals, then the method by precipitation is employed. The ore is melted at a high temperature, by preference after calcination, with coke and scrap iron. Sulphide of iron and metallic lead are formed. This method has, however, been almost abandoned, for it requires much fuel and gives dross still too rich in lead.

As regards galena the nature of the vein-stone has also to be taken into consideration. Flux materials, such as lime, scrap-iron, or litharge, are also added to the ores with the object of obtaining a fairly liquid dross.

The extraction of lead from galena is carried out according to two principal methods: by roasting and reduction, or by roasting and reaction.

The reduction method, which is used chiefly for very impure ore with silica vein-stone, transforms the sulphide into oxide, which is reduced. The second method, which is used for pure rich ore, with little silica, is based on the decomposition of a portion of
the sulphide into oxide of lead and sulphate of lead.

When the reduction method is employed, it is carried out on Scotch hearths, which are rectangular, under a cowl with an exhaust shaft.

Air, heated by being passed through the double lining of the furnace, reaches the melted ore, and oxidises the sulphide of lead which it transforms into litharge, whilst the sulphur in burning passes into the state of sulphur anhydride. The charcoal then reduces into lead the bioxide of lead which has been formed.

The method by roasting and reduction is very important, for it is used particularly for ores rich in silica vein-stone.

Picked ore is mixed with "schlich", with granulated metal from castings, dross from previous smeltings, debris from the floor of cupelling furnaces, as well as with the first products of the oxidation of lead from cupelling furnaces. All these materials play an active part in the smelting. In the course of roasting, the silica displaces the sulphuric acid which is formed and gives a silicate of lead: the iron in its turn reacts and forms a sulphide of iron. The fire, being forced by a blast, decomposes the sulphates which are formed, and by the addition of lime, which facilitates the melting, the mixture of sulphates and oxide and silicate of lead is reduced.

The process of reduction is carried out in shaft furnaces, which have the shape of a double cone, of which the upper part is called the furnace and the lower the hearth. The floor holds a mixture of clay and charcoal tightly packed, which forms a hollow leading outside the furnace. The opening for tapping passes through the lower part of the hearth and gives exit to accumulated liquid products, which are collected on a second hearth quite outside the furnace.

Condensation of lead fumes and lead oxide, which are driven off by the blast, takes place above the upper cone or breast of the furnace, where are also placed the closed doors for charging the furnace and removing the condensed products.

When the material is tapped from the lower reservoir to the second on the outside, the metallic product obtained is composed of two layers, one of which, the lower, consists only of metallic lead, and the other, the upper, of sulphide of lead with other metallic sulphides present in the ore and of sulphides of iron. This layer, called the
lead matt, quickly solidifies and is removed by the workman, who can thus draw the metallic lead and run it into moulds. The matts are treated to extract the metallic lead. Copper, which may be found in the ore, combines during these reactions with sulphur and is a considerable component of the fourth matt, which can thus be considered as a cuprous ore. It is, as a matter of fact, called "copper matt".

The method of roasting and reaction is used in most large lead works which use ores with a vein-stone which contains but little silica.

The operations are carried out in a reverberatory furnace, known variously as the sloping hearth, the English, Carinthian, or Belgian furnace, where the crushed ore is heated to redness.

Under the action of air, the roasting changes a part of the sulphur into oxide and sulphate with a liberation of sulphurous anhydride.

Oxidation of the "schlich" is obtained by mixing the mass; the oxide and sulphate react on the sulphide with sulphurous anhydride and metallic lead as resultants; this reaction is obtained by closing at the right moment the openings and urging the fire with the blast.

The converter method is to-day largely adapted to the metallurgy of lead. The Huntington-Herberlein process with its various modifications allows the reduction of the sulphide by melting iron with 5 to 15 per cent. of caustic lime, according to the quantity of sulphur contained in the ore. A jet of air under pressure oxidises the lead, whilst the sulphur is removed either as sulphurous anhydride or as sulphate of lime. The anhydride is recovered for making sulphuric acid.

Several works carry out the extraction of lead from the ores or other products by washing with brine.

This process is based on the fact that the chloride and sulphate of lead are soluble in a saturated solution of sodium chloride. In a dilute solution of salt the solubility of lead salts is less than in pure water, but in concentrated solutions the solubility is greater. As silver is easily precipitated by a saline solution, in the case of argentiferous lead a little acid or ferric chloride is added to prevent this precipitation.

This washing is used for residues from treatment by electrolytic zinc; for dust from sulphate of lead, a product from lead and zinc smelting works; for sediment of sulphate of lead from lead chambers; for oxidised ores.
containing carbonate or sulphate of lead; for concentration tailings, containing sulphide of lead or silver; and for complex sulphur ores of zinc, lead, and iron.

In order to change the lead from its soluble form in one of these various solutions obtained by washing, it can be precipitated either electrolytically, using anodes of iron or graphite, or by chemical means by hydroxide of zinc or spongy iron.

In some American smelting works the electrolytic method is used; this consists of casting working lead into plates as anodes suspended in electrolytes which are formed by solutions of fluosilicates of lead and hydrofluosilicic acid. Lead deposits on the cathodes formed by the thin plates of lead in a very pure state. The residue contains silver, antimony, arsenic, and copper. The danger from this method is very small indeed; but the process has not as yet been brought into general use.

Desilvering of Lead

Lead obtained by one of the processes described above is known under the name of “working lead”; if it does not contain silver, it is handed over at once for trade purposes.

Working lead obtained from galena is refined in order to extract in particular the silver that it contains, and also the antimony and other substances. The operation takes place in a cauldron placed in a covered furnace at a temperature of 800-950° C. Heat, conveyed by projection and ventilation tangential to the surface, oxidises the foreign elements as well as a small quantity of lead. The lightest elements, i.e. dross of sulphur, antimony, and antimoniated lead, become oxidised in the form of a spongy crust and come to the surface. They are removed by...

Fig. 29. — Work at a zinc slag distillation furnace.
oxidised and then removed by skimming.

The lead crystals, which contain less silver than the working lead, are taken up by means of a perforated ladle by hand or mechanically and conveyed to a cauldron or kettle alongside, where the operation is repeated. Thus there is a kettle containing poor lead and another containing lead rich in silver.

Recycling of the silver then follows either by the Pattinson or the Parkes process, which is also known as zincing.

In the first, the Pattinson process, the mixture of argentiferous lead is deposited in hemispherical kettles arranged in rows of 12-16, placed under an arch of masonry with a hearth and ash tray. It is then subjected to slow cooling which separates it into two parts: poor lead, which crystallises, and an alloy rich in liquid silver. The silver is separated by a series of meltings and successive separations. The process which was formerly done by hand is now done mechanically.

The Parkes process, or zincing, which has replaced the preceding process, is based on the capacity of zinc for absorbing silver from working lead and for the alloy so formed to be distilled, just as water or mercury are distilled.

Covered cauldrons are placed in special furnaces so that they are heated from below and at the sides, and in these zinc is melted at a temperature of about 1150° C. A certain quantity of this metal is added to the lead bath, which is vigorously stirred by hand or, better still, mechanically. On cooling, a triple alloy of silver-lead-zinc is formed, which collects as a scum on the surface of the bath. It is then drawn off by skimming and, after melting again with the object of removing as much lead as possible, the alloy rich in silver is submitted to fractional distillation. The precious metal is now obtained mixed with a little lead; while the zinc is returned to the process. Finally, the argentiferous lead is submitted to cupellation.

The last operation takes place in a reverberatory furnace; it depends on the property of lead to become oxidised in the air, forming a fusible oxide (litharge) which is driven off as rapidly as it forms. The metal pot is enclosed in a furnace heated by projection, while a blast of air plays on the surface. This operation is carried out at 1,000-1,150° C. A fresh refining takes place in a small crucible.

The run litharge may, however, give off noxious fumes; hence the need of using an exhaust hood connected with a ventilator. Between the furnace and the flue is placed a condensation chamber where the lead in the state of vapour is condensed and dust is deposited. It is also as well to provide ventilation here and to place of deposit before emptying the flues. Dry condensation is generally used instead of moist for practical reasons, and the workman has to enter into the chamber to clean it once or twice a year. In these conditions it is necessary to employ a ventilating fan with suitable regulation of the delivery of air, while care must be taken that the man works in the direction of the draught.

Whilst the Pattinson mechanical process eliminates danger from poisonous vapours set free by lead heated to redness and from handling lead crystals, the new system is nevertheless preferred because it is less dangerous and because the mechanical mixing does not require the continued attendance of a workman. The temperature is easily regulated, overheating is avoided, and good general ventilation, combined with the use of exhaust hoods, prevents the liberation of poisonous vapours into the workshop.

Sources of Poisoning

The industries in which lead is run, rolled, and cast in making pipes, gratings, plates, pig-lead, and small moulded objects, the occupations of plumber, galvaniser, filemaker, and solderer, and cutting lead plates or burning of old lead paint are sources of frequent lead poisoning.

Another source of poisoning which should not be forgotten is represented by metallisation, a process very much used to-day in large works (see article "Metallisation").

The use of the oxyhydrogen flame upon paint exposes workers employed on the breaking up of old ships to the inhalation of zinc fumes. A definite attack may result which can easily be confused with influenza; it is characterised by a sweetish taste in the mouth and shivering, lasting usually for a day.

The inhalation of lead fumes by the same workmen is much more serious, for it causes a sensation of heaviness, constipation, colic, and sometimes symptoms of encephalopathy. It is calculated that workmen may inhale under these conditions 0.215 grm. of lead in the course of eight hours' work. The use of respirators diminishes, but does not remove, this danger.
In addition to risks common to all mining (see article "Mines (Hygiene in)") and to troubles due to physical environment regarding temperature and ventilation, work in the galleries exposes men to risk from the spontaneous combustion of pyrites, which liberates sulphurous anhydride and sulphuretted hydrogen.

The chief danger of work in lead mines and smelting works is that from lead poisoning, caused particularly by the inhalation and ingestion of dust loaded with lead. Clearly this danger will be greater or less according to the nature of the crude material, whether it be sulphides, sulphates, carbonates, or oxides of lead, its solubility, and its condition whether wet or dry. The operations of crushing, washing, and stamping are naturally more dangerous when done by hand than by machine, if the dust which is raised is not adequately controlled and carried away and if it is finely divided. During refining, exhaust hoods are not always applied above the melting pots; and then poisonous fumes may easily become diffused in the workplaces. Account must also be taken of spurtling particles of melted lead, which cause burns on the hands, arms and face. The running of lead is not very dangerous, as it is not too hot; and there are no fumes, or only very few. Work at reverberatory furnaces is dusty and arduous on account of the manual work and the heat; but fumes are only slightly given off. Furnaces of the Godfrey or Holthoff types are little used; with a certain amount of attention they only give off a small quantity of lead fumes; the Huntington-Herberlein type of furnace often gives off dust, fumes and vapours rich in lead vapours, fumes, and dust of lead, which threaten the workmen employed in the various processes, if these are not carried out in separate places. However, even the best organised works have not a department where risk of lead poisoning is not present to a greater or less extent. As a matter of fact, the workmen exposed to lead poisoning are very numerous; they include, for example, men employed in the removal of lead cinders, in roasting, crushing and smelting, in charging and discharging ores and their products, in removing dross, in dismantling and repairing furnaces, in cupellation, in distilling zinc ashes, in removing waste, in grinding and sifting litharge and packing it into barrels, and in attending to the suppression of dust.

As regards danger from lead dust, it
is sufficient to mention the great danger arising from beating sacks, and flue cleaning. Vapours as well as fumes, are liberated during smelting and pouring.

Hygienic conditions naturally vary from one works to another. This fact easily explains the fairly considerable variations in the frequency of lead poisoning. Thus, for example, in Germany in 1921, 30 cases of lead poisoning were reported from one smelting works, compared with 15 in all the other lead works. According to Muller, in a smelting works at Scheriau (in 1903) 330 kg. of lead were lost each day into the air through the flues and 30 workmen out of 153 suffered from lead colic. In the Friedrich smelting works, from 1887 to 1892, the sickness from lead poisoning decreased from 82.9 per cent. of workmen to 19.4. Other facts could be easily brought to show that improvements in the plant may be of very considerable advantage from viewpoints of both economy and health. As a matter of fact, Muller found repeatedly quite high proportions of lead in the air of workplaces: for example, in 5 cubic metres of smoke from a furnace he found from 8.5 to 22.7 per cent.; in another case strengths from 12.3 to 18.8 per cent. In 1 cubic metre of air he found 1.184 grm. of lead. On the basis of several analyses of the air of an English smelting works, Cowan estimated in 1910 that 0.5 grm. of lead would be inhaled by a workman on the charging platform of smelting furnaces.

Among other metallic lead industries, those which cause the greatest number of cases of lead poisoning are soldering work and preparing lead plates, as well as the work of breaking up ships. These cases are also generally very serious, for they are due to the inhalation of lead vapour in heavy doses.

Hands, tools, food, drink, and tobacco are liable to be soiled by lead dust; thus the entrance into the body of poison by the digestive organs is facilitated. Inhalation of lead dust and of particles of lead may occur, especially when other factors come into play, such as: carelessness on the part of the workman; youth, or poor physique; alcoholism; unhealthy conditions of work; and also a certain predisposition (see article "Lead Poisoning").

Among other dangers to which workmen at smelting works are exposed, the following should be mentioned: carbon monoxide, cyanogen and its compounds, arsenic, oxide, mercury (Biondi), tellurium, sulphurous anhydride, especially during roasting; fumes and dust from fuel and limestone; radiation from ore and metal during smelting.

Finally, exhaustion caused by lifting and handling heavy tools must not be overlooked; great sweating in consequence of high temperature; diseases arising from cold due to draughts and sudden changes of temperature, accompanied very often by digestive troubles caused by abuse of drink and especially of cold water.

Among the gases and fumes which are given off from smelting works and which damage vegetation and sometimes the health of cattle in the vicinity, sulphurous anhydride and lead dust should be mentioned as the most harmful, causing poisoning of domestic animals in the neighbourhood.

As has been said elsewhere, lead poisoning is quite frequently registered under the name of its symptoms, without taking into account their etiology. Thus the diagnosis may refer to diseases of the intestines, kidneys, heart, and articulations, or to gout and paralysis, without any information as to whether these morbid conditions are essentially or in part due to the toxic action of lead. The German Sickness Insurance Offices, for instance, do not as a general rule receive any record from the clinic where the patient is treated, nor is any modification eventually placed on the case sheets, with the result that numerous cases, especially the less serious ones, escape the knowledge of the inspectorate. As a matter of fact, according to section 343 of the Factory Act (R. G. O.), the Sickness Insurance Office should inform the inspectorate of every case of lead poisoning — just as of cases of poisoning by phosphorus, arsenic and mercury; further, the Offices, by virtue of the Order of 21 June 1922 (Prussian Ministry of Commerce) are obliged to send the same notification to the medical factory inspectors. Then chronic invalid workmen are deleted from the statistics.

However that may be, it is quite clearly established that lead poisoning, and especially its serious forms, such as encephalopathy, have no doubt diminished in German smelting works compared with the period before hygienic measures were taken; and this is due to the elimination of the most serious hazards. This improvement in the hygienic situation of men employed at lead smelting followed almost immediately upon the application of preventive measures; it has been observed for a long time in the smelting works at Brunswick, and in those of the Government at Freiberg.
The frequency of sickness, apart from good conditions of general management, depends in a definite way on labour turnover. As a matter of fact, it is often necessary to discharge workmen who are not familiar with the occupational risks, or who are not sufficiently clean in their habits. Besides, the frequency of sickness is also affected by increased risk due to sudden disturbances in the processes and to repairs. On the other hand, resistance to poisoning can be increased by good conditions of pay, food, living, and housing, and to sum up, by raising the standard of well-being, and by a healthy life lived under healthy conditions.

**STATISTICS**

Before examining the hygienic and sanitary conditions of workmen employed in lead and smelting works, it is advisable to know the results of certain enquiries made in these industries.

### LEAD MINES

Among the most important mention must be made of the enquiry made in Australia at the Broken Hill mines, which employ 6,538 persons exposed continually to the action of lead: 3,305, or 50.5 per cent., had worked for a period of ten years or less; 1,851, or 28.3 per cent., for more than ten and less than twenty years; 1,104, or 16.9 per cent., for more than twenty and less than thirty years; 1,104, or 16.9 per cent., for more than thirty years. (The report on the enquiry at Broken Hill has been criticized by Dr. C. Badham, Medical Officer of Industrial Hygiene, New South Wales.)

Out of 3,502 persons of the first group, 29, or 0.6 per cent., showed symptoms of lead poisoning. Of 1,851 of the second group, 23, or 1.2 per cent., had lead poisoning, as well as 30, or 2.7 per cent., of the 1,104 of the third group; whilst out of 660 workmen of the last group, 6, or 2.3 per cent., showed symptoms of plumbism.

Out of 61 workmen known to have lead poisoning, 27 had been employed solely underground. Of 660 miners who had been employed entirely underground for ten years and over, 1, or 0.15 per cent., suffered from lead poisoning. Of 412 miners who had worked entirely underground for more than ten and less than twenty years, 11, or 2.6 per cent., were affected. Of 271 miners who had worked entirely underground for more than twenty and less than thirty years, 10, or 3.7 per cent., had had poisoning. Of 67 miners who had worked entirely underground for more than thirty years, 3, or 4.5 per cent., suffered from lead poisoning. Of 196 truck-pushers and 63 vein-stone workers who had been employed entirely underground, 1 truck pusher and 1 vein-stone worker who had been alone were found to have lead poisoning.

In Australia the workmen employed in sulphide of lead and zinc mines quite frequently have lobar pneumonia, which is particularly serious and ends fatally. As regards silicosis, the above-mentioned Commission of Enquiry at Broken Hill (1920-1921) also turned its attention to the incidence of this disease and examined 6,538 persons. The results are given in the following table:

<table>
<thead>
<tr>

</tr>
</tbody>
</table>

Of 726 persons who had worked both on the surface and underground for a period of ten years or less, not one was found to be affected by lead poisoning. On the other hand, as soon as the period of work exceeded this figure of ten years, an increasing percentage was noticed in relation to the number of years spent at work either in the mine or about it.

If the figures for arteriosclerosis and nephritis reported among the miners of Broken Hill are compared, for example, with those for stonecutters at Sydney, the following comparison is obtained:

Rambousek in 1906 originally asserted that there was not a case of lead poisoning among 10,000 lead miners (galena) of Bavaria; but later he admitted that he had been able to detect some slight cases of lead poisoning among these workmen.

In a galena mine in Bulgaria Zweitkoff (1931) examined 75 out of 156 workers, 15 of whom were women, and found 27 cases of lead poisoning characterised by subjective and objective symptoms. He attributes this high incidence of lead poisoning to the dust raised during the hewing of galena, to the drinking water which was exposed to dust, to lack of personal cleanliness, to the operation of sorting the ore and perhaps also to transformation of the galenite into other more soluble compounds under certain conditions.

Some cases of lead poisoning have been reported among the miners of the department of Aveyron (France) and several cases among the miners of Sardinia (galena mines).

In English galena mines, cases of lead poisoning are rare, although cases have been reported among those who handle cerussite imported from Australia. Pneumonoconiosis and phthisis are more common. The mortality from tuberculosis among lead miners is calculated at 3.9 per 1,000 living compared with 1 for coal miners. Sometimes it would appear to be due to bad housing conditions (Oliver).

In England and Wales the comparative mortality 1 for the two periods 1900-1902 and 1910-1912 relating to “lead miners” is as follows 2:

1 “Comparative mortality” is the number of deaths, between the ages of twenty-five and sixty-five, which would have occurred when the rate of the occupational mortality for different causes and at different age periods is calculated on the number of the general male population, which at the time of the census of 1901 showed 1,000 deaths. This “standard” number of population was 71,005 men.

2 The statistics for 1912 do not provide figures for the category of workers termed “lead miners.”

Comparison of the number of observed deaths from phthisis with those expected, particularly from the age of forty-five onwards, among lead miners in Wales, brings out the excess of mortality experienced due to dust inhalation.

In Italy, miners in Sardinia, according to an investigation of Loriga, become unfit for work at an earlier age than that of other Italian districts. This fact is strictly in accordance either with damage caused by mining or with greater precautions taken by employers to get rid of the less capable workmen.

The Sardinian miners marry less frequently and remain widowers more frequently than the miners of other districts. The miners' wives, like their husbands, have a higher percentage of early deaths. They also have a smaller number of children than other miners. Without entering into details of an economical kind, which would clear up several of the points under consideration, it is sufficient here to mention that if the hygienic conditions are in general bad, the conditions of safety are, on the contrary, better. So serious are conditions of living of these miners, that their average age at death is about forty-four years (Fronzia) compared with fifty-five for the peasant and agricultural group.

The sickness rate is also higher than for other regions; it increases — and this is important — with age. The commonest diseases are: lead poisoning, mercurialism, malaria, and respiratory diseases, of which pneumonia and bronchitis are the chief. According to Fronzia, the children of the
miners are difficult to rear; their height and weight are less than the average, and the same applies to chest measurement. These facts account for the great number of rejections at examinations for military service.

Lead-Smelting Works

The health conditions of German lead smelters are not exactly known, particularly in reference to lead poisoning. However, the reports of the factory inspection department supply facts regarding certain German smelting works.

In 1906 Rambousek found 150 cases of lead poisoning among 4,000 smelters. In four smelting works the average was from 10 to 11 cases of lead poisoning per 100 workmen.

An enquiry made by H. Engel in 1920-1922, and published in 1925, dealt with twenty workplaces employing 853 men. These workplaces were personally visited by the author with the object of detecting symptoms of lead poisoning, with the following results:

<table>

</table>

At a further examination, 111 solderers and 20 tinners had their blood and urine examined. Engel found that 68 workmen among the 111 solderers had symptoms of lead poisoning; 19 had a haemoglobin value above 71 per cent.; 63 had polychromatic red cells; 85 had basophilic red cells, of whom 20 had the condition very marked; 120 had haematoporphyrin in the urine, of whom 28 exhibited it in a pronounced degree. Out of 20 tinners 21 had symptoms of lead poisoning, 2 had polychromatic red cells, and 2 had basophilic red cells.

An enquiry conducted by Schwarz in 1925 among workmen definitely exposed to lead poisoning, based on the results of blood examinations, enabled him to conclude that positive cases are in proportion to the extent that workmen are exposed to the inhalation of lead in the form of vapour or dust.

Smelters of lead with 44 positive cases out of 58 examined, men using high temperature flames in breaking up ships with 13 cases out of 14, ore-crushers in lead-smelting works with 8 cases out of 13, and smelters of the dross are all much affected. The search for haematoporphyrin in the urine has very often a positive result, which nevertheless does not run parallel with basophilic granulation, but is a useful diagnostic feature. On the other hand, examination of the blood pressure is of no advantage. The blue line and lead colic which are noticed among these workmen in the first months or even weeks of employment, are too well known to dwell upon here.

In Bavaria during the period 1927-1929, 85 out of 617 cases of lead poisoning notified affected founders and welders.

The smelting works of the Prussian Government at Hildesheim give the following figures:

<table>

In Prussia (1929) out of: 1,124 cases of lead poisoning reported, 304 affected lead founders.

If any proof is necessary of the advantages of good hygiene, it is sufficient to mention that the age of retirement for workmen exposed to lead now often exceeds fifty years. Thus, out of 887 smelters at the works of Friedrich and Walther Kroneck, there were, in 1906, 45 workmen
aged from fifty to fifty-five years, whilst in 1912 there were 88. In these smelting works 13 per cent. of the personnel were affected with lead poisoning in 1901; in 1912 the percentage was only 4. A commission appointed in 1925 to enquire into the health of the lead-smelting works of Port Pirie in South Australia issued a report full of interesting facts on the industry in question.

An enquiry made in 1910 had emphasised that complete figures did not exist to enable any approximation to be arrived at relative to the incidence of lead poisoning among the lead smelters. During the period 1907-1909 there were reported about 150 to 200 cases among smelters, pointers, and other workers in contact with lead. Lead poisoning being caused chiefly by poisonous fumes coming from the furnaces, the plant was promptly improved, which led to a rapid diminution in cases of lead poisoning. The investigators agreed that the general state of health of the manual workers was good. The return for the incidence of lead poisoning was more difficult, for there was no compulsory notification, and legal compensation only came into force in 1912.

The cases of which there is information were distributed as follows: for 1910, 1 case; 1916, 5; 1919, 5; 1920, 4; 1921, 3; 1922, 56; 1923, 89; 1924, 334; in the first five months of 1925, 126 cases. Cases of lead poisoning treated in hospital at Port Pirie were as follows: 1910, 10 cases; 1911, 9; 1912, 21; 1913, 58; 1914, 30; 1915, 22; 1916, 48; 1917, 31; 1918, 13; no case in 1919 or 1921, as the factory was not at work; 1922, 16 cases; 1923, 19; 1924, 46; the first five months of 1925, 12 cases.

It is probable that these cases only represent a portion of the lead poisoning occurring among manual labourers, most of the patients preferring to be treated at home. Attention should, however, be drawn to the fact that a medical referee board would have accepted as true lead poisoning only a small percentage of these cases; the others being probably due to chronic intoxication.

Analysis of the blood of 300 workmen did not show any objective modification of the leucocytes, polychromatophiles, poikilocytes, etc.; 89 basophilic granulations, which were slight in 53, moderate in 24, and strong in 12.

The 397 cases which were known to have occurred from 28 June 1917 to 31 December 1924 are classified as follows according to the special process on which the patient was employed:

(The figures in brackets refer to fatal cases.)
In 1919 the reports of inspectors showed that a hall, used as a canteen, opened directly into the foundry of the factory, with the result that the dust contained 15 per cent. of lead.

In 1920 the increase in cases of lead poisoning is explained by the fact that one smelting works had a particularly high incidence with 23 cases.

The cases of lead poisoning notified in France among lead smelters and workmen brought in contact with metallic lead are as follows:

In the State of Ohio from 1920 to 1925, out of 443 cases of lead poisoning granted compensation, metal-work accounted for 12 cases, enamelling for 14, and smelting works for 4. Most of the cases arose at accumulator factories, 145 cases; in painting automobiles, 114 cases; at white lead works, 54 cases; tetraethyl lead, 24 cases; and at painting work, 20 cases.

In Russia, Salosnow in 1926 examined 234 workmen of five sections of the lead works, and found 15 per cent. of these men were aged from twenty to forty years; 13.2 were over fifty years; 33.5 per cent. had worked in the smelting works for less than three years; 44.4 per cent. from three to five years; 12.4 per cent. for more than fifteen years. Whereas 66 men (29 per cent.) did not show any important sign of ill-effects, the others, on the contrary, showed symptoms of disease; stated more precisely, 57 (24.3 per cent.) exhibited symptoms of infectious diseases; 51 (21.7 per cent.) of respiratory diseases; 7 (2.9 per cent.) of nutritional troubles. Only two had definite signs of pulmonary tuberculosis, whilst 43 (18.4 per cent.) could be considered as tuberculosis suspects. Lead poisoning was found in 26 workmen, 15 of whom (or 11.2 per cent.) were employed in the metallurgical section.

**DETECTION**

For the detection of traces of lead in the air of workshops, the well-known methods can be used which are described in the article "Lead Poisoning" for the detection of lead in the body.

A known volume (from 5 to 10 litres) of air is aspirated from the atmosphere to be analysed by means of ordinary apparatus under precautions observed by experts in the subject.

The aspiration effectively mixes the lead vapour with, and fixes it in, a solvent, and arrests lead dust by filtration on wool.

The usual methods employed for detecting traces of lead are: transformation of lead or a lead compound into nitrate; treatment with sulphuric acid or soluble sulphates; a white precipitate forms, soluble in potash, and in boiling hydrochloric acid. This acid, as well as soluble chlorides, gives a white precipitate of lead chloride, which is insoluble in ammonia. Potassium chromate gives a yellow precipitate, soluble in potash; iodide of potassium gives a yellow precipitate, soluble on warming, which reprecipitates on cooling into yellow golden flakes. Sulphurified hydrogen with lead salts causes a black precipitate of sulphide of lead.

In 1903 Trillat suggested a new method for testing for lead based on the blue coloration, stable to heat, which the base of tetramethyl of diphenylmethane gives in a solution of acetic acid in the presence of some dioxides, such as that of lead.

The air sample is drawn through a filter of cotton wool which retains all the dust; it is then passed into an absorption tube containing dilute sulphuric acid to fix the lead vapours. The cotton wads are reduced to ashes by calcination after the addition of some drops of dilute sulphuric acid; the solution from the absorbing apparatus is evaporated to dryness and slightly calcined.

It is on these residues from calcination that the tests with the Trillat reagent are carried out. This reagent is prepared as follows: A mixture composed of 30 grm. of pure dimethylaniline, 10 grm. of formaldehyde, and 200 cc. of water acidulated with 10 grm. of sulphuric acid is heated for an hour in a water-bath. After cooling, it is rendered alkaline with a large excess of soda, and the excess of dimethylaniline is removed by passing into the solution a strong current of steam for ten minutes, until the last traces of amine...
are entirely removed. The cooled solution deposits a crystalline mass, which may be recrystallised once in alcohol to purity it completely. This process gives easily 15 to 20 grm. of the base. The reagent is prepared by dissolving 5 grm. of the base in 100 cc. of pure acetic acid. It is preserved in a closed bottle and shaded from light.

The solution should not be of a blue colour, nor give this colour on boiling. The reaction should occur in a medium acidulated by acetic acid, to the exclusion of mineral acids, even in traces. It is also necessary to present the lead in the form of a salt capable of regenerating the dioxide; this is done by oxidising it by an alkaline hypochlorite.

The substance to be analysed is treated by sulphuric acid or by sulphate, so as to present the lead in the form of a salt capable of regenerating the dioxide; this is done by oxidising it by an alkaline hypochlorite.

The reaction should occur in a medium acidulated by acetic acid, to the exclusion of mineral acids, even in traces. It is also necessary to present the lead in the form of a salt capable of regenerating the dioxide; this is done by oxidising it by an alkaline hypochlorite.

This process gives a crystalline mass, which, in spite of good exhaust, have not been removed. But strong draughts must be avoided, for they cool the furnaces, interfere with the effective action of exhaust hoods for fumes, and stir up any dust which is lying about.

The floor, constructed of plates of sheet iron or Dutch tiles set in cement, should be smooth and kept in good condition, clean and moist. It should be carefully washed, especially in the vicinity of the furnaces, and collections of refuse should be removed at once. Dust should be removed from the furnaces, the walls, and the ceiling either by washing, or, still better, by using a vacuum cleaner. A copious spray of water only serves to stir up the dust. The walls should be smooth, so as to offer the least possible surface to which dust can adhere, and whitewashed, which makes the workplaces more comfortable, lighter, and allows the immediate removal of deposits of dust. Walls can be easily and rapidly whitewashed by a sprayer.

Unloading trucks with the shovel or emptying sacks containing ore causes large quantities of dust, which can be avoided by sprinkling with water. The cleaning and drying of sacks should be done so as to prevent all danger, by beating them in closed apparatus supplied with an efficient exhaust for dust.

The handling of dry lead ashes, lead dross, and debris of white lead, as well as of other waste used in the preparation of lead, gives off particularly injurious dust, because it is finely divided. The transport of these materials to the smelting houses takes place everywhere by means of conveyers, not always closed, and more rarely by means of sacks. Generation of dust should be avoided while emptying and cleaning articles used for conveyance.

Ore should be moistened as it is travelling to the furnace, after crushing, when it is in the small trucks going up the incline. It is advisable that these small trucks should be supplied with covers.

If the ore is kept for the night-shift in receptacles placed at the top of the furnace, the heat dries the ore and favours the liberation of dust when it is put into the furnace. It is preferable to keep the ore in front of the furnace, for in that case it keeps moist a longer time.
Efficient exhaust ventilation for vapours given off during roasting must be maintained. If the installation is not adequate, abundant white vapours of sulphate and oxide of lead penetrate into the workplace; this trouble presents a very serious risk to the health of the workmen. A good draught in the interior of the furnace will prevent any escape of fumes from the working apertures.

The mechanical system, with automatic charging and discharging, has wonderfully improved the hygienic conditions of smelting works. Workmen are no longer exposed, as they used to be, to radiations from furnaces and to risks from fumes and toxic gases.

The same applies to the conveyance of roasted ore to the converters. When the exhaust device acts well and all the apparatus is kept in good working order, no fumes escape from the doors for raking the furnace.

The conditions of the workmen employed in emptying the melting pots are certainly not so good. When the product is split on the ground, it gives off clouds of smoke and dust which completely envelope the workmen and make a bath and thorough cleansing of their clothes a necessity. The smoke contains as much as 10 per cent. lead and it is impossible to moisten the roasted mass, the addition of water having the effect of slaking the lime present in the mass and causing decomposition of the ore. The Sinter process prevents fumes entering the foundry better than other methods do, except, of course, when the exhaust ventilation is defective.

In other cases the roasted mass should be moistened before it is loaded into the trucks. Stokers should be only allowed to go under the fire-bars to clear out the ashes under cover of a strong current of air. The fire-rake should have a long handle. Mechanical cleaning is naturally to be preferred.

The Savelberg process, which is another modification of the Huntington-Heberlein process, is still less dangerous, for this process does not involve preliminary roasting.

The good technical organisation of some works shows once more the beneficent influence which results from the hygienic precautions. The work, for example, in the smelting works of Freiburg in Saxony is essentially mechanical and automatic; and the removal of fumes and dust is assured as far as it is possible.

It must be admitted that in certain cases, for example, at roasting and smelting processes, the introduction of exhaust hoods is difficult to arrange, for they diminish still more the available space, which is too limited as it is. The conditions are particularly unhealthy where several of these furnaces are arranged together in one place.

Reveratory furnaces are not entirely above criticism; the different types of furnaces for roasting and smelting, although less dangerous because they require lower temperatures, all have the same defect: the chimney-stacks are too short and there is not a strong enough draught to carry off effectively the gases and vapours.

Free escape into the air of the workplace of fumes from leadcasting must not be allowed. Incandescent and fuming dross, if plunged into tanks of water, may cause explosions.

The hours of work for the shifts employed on these operations should be limited.

In spite of numerous attempts to improve the process, the crushing of the roasted ore before it passes to the melting furnaces is still laboriously carried out by the use of hammer, chisel, and pick. The ore must be constantly moistened so as to prevent the generation of lead-laden dust. In spite of all precautions, soldering the hands cannot be avoided and an expert has found on them, in spite of thorough moistening, as much as 0.64 grm. of lead. The utmost cleanliness should be insisted upon from these workmen.

Crushing the masses roasted by the Huntington-Heberlein process is a very difficult operation, and reasons have already been given why it is not possible to moisten them before crushing; but whatever the circumstances, moistening ought to be done at the time the ore passes to the furnace.

Workmen employed on crushing should wear respirators; the hours of work should be lessened; work should be alternated with change to employment on less dangerous processes; utmost cleanliness must be insisted upon; old methods must be replaced by the most modern with mechanical crushing; roasting should be done in rotary furnaces which allow the roasted material to be automatically discharged and do not require hand labour for working or transport.

Whereas work at melting furnaces was formerly an important source of lead poisoning, to-day, by reason of improvements in technique, it only represents a cause of secondary importance. But these happy results will only be attained, even with a perfect plant, if every possible preventive measure is adopted.
The roasted and crushed ore is carried in large trucks into the smelting house and emptied on the floor by the furnace; it has to be loaded again, this time into small trolleys which carry it to the furnace mouth, where it is thrown into the furnace. This work, which gives rise to a great quantity of dust, can be made less injurious to health by installing a mechanical feed for the furnace by means of an aerial metal cable. The ore is contained in hoppers which empty themselves automatically, whilst a closing system prevents the escape of gases and vapours. Workmen should be forbidden to take pieces of ore in their hands to put them in the furnace. The question of automatic charging should be carefully studied by the technical management of smelting works, when the work involves roasted material at the upper layer.

Moistening this roasted material when it is rapidly introduced into the furnace is technically possible and has been used for years in Canadian smelting works in British Columbia.

The technical managing staff should prevent the possibility of damage caused by work in front of the lower part of the smelting furnace. All escape of fumes containing lead should be prevented during the discharge of molten metal and liquid dress, all the more so as the tap holes are used several times in the course of a day's work.

Exhaust ventilating hoods should be provided with a strong draught above the channels for the escape of dress, reaching as far as the pots receiving the dress and so arranged that the dust particles do not interfere with work at the tap holes, but should prevent the entrance of cold air which interferes with proper action of the draught.

An exhaust hood should be constructed, luted to the side of the furnace with clay, above the tapping hole for the dross and the channel for its removal. Within the actual hood, opposite the tap hole, an opening for raking should be placed. The hood may be attached to the masonry of the furnace by chains, so that it can be easily raised when occasion requires. The exhaust pipe should open into the flue for the removal of the fumes. A common hood for tap holes is not recommended. Workmen should be forbidden to inspect the exhaust shaft, through the hood, for that exposes them to the effect of gases and fumes, the furnace mouth should be most carefully closed; the charging cylinder should always descend sufficiently deeply into the mouth of the furnace; fumes should be carried off by lateral pipes, connected to an exhaust, which can be easily inclined downwards and open into a dust chamber.

In some important works where a series of pots are placed on a revolving disc, a fan is placed in the exhaust flue. A common hood can then be placed above the tap hole for the dross and independent hoods above each pot receiving the dross.

In order to prevent the escape of fumes during the opening of the tap holes for the lead, while the metal is running, the use of an automatic tap hole, or syphon of the Arent type has been proposed and it certainly limits the escape of fumes.

The withdrawal of fumes ought also to be provided for over the point of exit of the lead, when the workman ladles out the metal material that has been melted or in a special pot arranged at the side, in order to run it then into the mould.

The arrangement of the Caron mechanical flow can only be used in large smelting works. In this system the lead from all the furnaces is collected in a large reservoir and from there directed automatically into the moulds. A single workman is sufficient to supervise the whole operation, which does not expose him to the injurious action of fumes and vapours.

Furnace cleaning for the removal of debris must only be done when the furnace is quite cold and aired. During the removal all crusts should be thoroughly moistened to prevent the raising of great quantities of dust. The work of repairing masonry should only be done after the furnace has completely cooled.

The removal of fumes and dust is certainly a most important thing. Lead fumes escaping from the furnaces become changed immediately on cooling into dust which is deposited on the walls, the ceiling, and the floor. These fumes escape with gases from the furnace mouth, become deposited in the flues and dust chamber, stick to the clothes, hands, and hair of the workmen, and, as the dust is very finely divided, the slightest draught sets it in motion. In old lead-smelting works this dust is found in such great quantities that even clearing it away may be dangerous to health. It is not always possible to collect it at the actual source, and this is why care is necessary to collect it where it is deposited, so as to render it ineffective.

When the temperature of the operations passes beyond the point of vaporisation of lead, which happens fairly often, great quantities of lead vapour are formed, which are not only
an important cause of poisoning, but represent also a loss of considerable quantities of metal, if these vapours are not subjected to condensation.

The surrounding temperature being below the point of their vaporisation, these vapours condense immediately and float for some time in the air; then they descend slowly in the form of a very fine dust, which is of a greyish-blue colour, sometimes the colour being a little lighter. This dust easily becomes diffused in the air and does not take moisture when watered. Only a slow and penetrating watering is of any use; but it is difficult to carry out, for, on the one hand, the dust chambers are of large size, and, on the other hand, there would be a formation of sulphuric acid which ruins the clothes of the workmen whose duty it is to do the cleaning. So it is preferable for the gases from the furnace fire and the fumes to be made to pass into flues and chambers and collected in a large flue leading to the dust chamber.

This installation requires cleaning at regular intervals, an operation which is not without danger for the men; hence it ought to be carried out, so far as is possible, with every protective measure.

The pipes used for the removal of the gas fumes are cleaned by raking with curved hooks. In a smelting works at Ems the cleaning of these pipes, arranged in the shape of a saw, takes place through the lading holes which are on the short side of the bottom plate. A pipe fitted with a funnel, which has a valve, is inserted below them, through which a hook passes and is introduced into the lading holes. The partial cleaning of the flue is thus done without raising dust.

But to clean the larger flues the workmen must enter them, and as it is not possible to moisten the dust, poisonous clouds arise during the operation. This is why recourse is had to burning the dust some time before removing it by suspending in the flue a cage filled with burning coke. The transformed product is, however, still capable of giving off dust, and if the workman passes into the flues before they are cool, he is troubled by the gaseous given off by the still smoking dust.

Many attempts have been made to replace hand work by an automatic process, for it is an urgent matter to render such an unhealthy operation less so. The dust collector, constructed on the model of the Arent dust collector, has given good results. A series of oblique baffle plates, arranged from left to right, are immersed in water in a long rectangular chamber. The fumes enter from below by the small side of the chamber, keeping close to the partitions in making a zigzag course in the water to reach the opposite side, where they are sucked out. The dust thus remains in the water from which it is recovered from time to time. The precipitation of dust and smoke by the electric process of Cottrell (see article "Dust, Fumes and Smoke") is also very useful and gives good results, especially in dealing with strongly acid gases which do not lend themselves to methods of filtration.

Some English and American smelting works make use of filtration chambers placed above the dust flues. These are tall erections in which long cotton bags are suspended; air, drawn from the flue, and still rich in quite fine particles of dust, is aspirated through the sides of the bags; the dust is deposited on the inside and is brought down by shaking by hand, but more frequently by mechanical shaking. It falls through holes in the floor of the building into dust chambers (Beth filters, etc.). (See article "Dust, Fumes and Smoke").

In spite of all, these arrangements only eliminate part of the dangers which threaten the workman. As a matter of fact, these methods have no great practical value if the operations of dust removal and of carrying off fumes are not done mechanically. At large works the search continues for a satisfactory solution to the mechanical problem of dust removal; but whilst it continues, the workmen must be provided with every means of prophylaxis and every facility for combating the dangers arising from this operation, which has to be frequently carried out, especially when the plant is not large.

The chamber must be cooled before emptying; it must be so large and high as to allow the collection and removal of dust easily and be affected merely and without difficulties; the flues must be so spacious as to allow the workmen to stand upright and permit them to manage easily their shovels and trolleys. These flues must be closed during the removal of dust; a canvas shoot at the bottom of the trolley allows the dust to fall gently into the transport trucks, which must be provided with covers.

The working shift must, of course, be very short and not exceed four hours a day as a maximum; but the plant should be so arranged that the cleaning only takes place once a year.

In desilvering works it is necessary to protect the workmen who watch the litharge for the mirror to appear by interposing a protective screen and by insuring good evacuation of the fumes,
as well as by insisting on cleanliness of the workers' hands, which become soiled by handling lumps of lead.

If crushing is done at the works it should be done in hermetically sealed crushing machines, from which the sifted powder falls straight into the receptacle in which it will be removed without the dust being able to escape into the workplace.

During the desilvering process it is often difficult to protect the pots by a hood coming very low, for such an arrangement would obviously interfere with the work. But it is essential to maintain thorough ventilation of the place, as the workmen who have to remove the scum and slag are in all the greater danger, because this work is very hard and they are obliged to lean over the pots.

The Rozan process and certain other systems adopted by large smelting works, ensure conditions of work, excellent both from the viewpoint of hygiene and of economy, for they avoid manual contact with lead from the beginning to the end of the operations.

It may be said that modern technique can apply systems which prevent all escape of lead vapours and fumes and reduce to a minimum danger of lead poisoning from inhalation of lead. It is evident that fumes containing at the same time arsenic and antimony should also be evacuated, and that these measures must be completed by the utmost cleanliness on the part of the men.

Manipulation of working lead also calls for practical measures of cleanliness and dust removal, as mentioned above. It must not be forgotten that the clearing away of lead waste includes also dealing with arsenic and antimony; a risk much more serious and complicated, which it is necessary to limit or eliminate as far as possible. Without repeating here what has already been said above regarding exhaust hoods, it will be sufficient to insist once more upon covering up the channel which conveys the molten metal to the cupellation pot, upon the use of receptacles for collecting the slag and upon measures of cleanliness, etc.

Danger of lead poisoning is particularly serious when open hearths are used.

Working overalls with caps, gloves, and shoes should be provided, and, if occasion requires, respirators, which should be cleaned and have all dust removed every time before use. Particular care should be taken that the workmen who work with shovels wear respirators.

Ordinary clothing should never come in contact with working clothing. It is best to provide for each workman an iron locker, divided into two compartments. Cloakrooms should be located in the part of the smelting works least exposed to dust. Bath rooms provided with sand-soap, brushes, and towels should also be installed there. Workmen should be able to have a bath during working hours. Those who are employed in the removal of dust should take a bath daily, and those who work in other departments should take a bath at least once a week. Attention should also be given to care of the teeth.

Fatigue, which is localised, especially in the muscles of the neck, back, and upper limbs, should be reduced by carrying on the work as much as possible mechanically and automatically. Workmen who are continually on the move, however, cannot show serious localised fatigue, especially when raw materials are moved by means of locomotives, in trucks on inclines, by mechanical elevators, or by endless chains.

Technicians have for a long time past shown remarkable powers of invention in this branch and have still a fertile field for investigation. But it will never be possible to replace manual labour entirely. That is why it is necessary to create and apply the special means of protection described above.

Strict selection of the men on engagement by a thoroughly experienced doctor is of fundamental importance. Every person must be excluded who is affected by tuberculosis in any form, epilepsy, hysteria, neurasthenia, and all kinds of neuroses, as well as any person having a predisposition to mental diseases or alcoholism, or those subject to rheumatism and those with diseased kidneys; for lead poisoning has particularly serious consequences for such persons. These measures may be difficult to apply when manual labour is scarce, but an employer should, in his own interest, not hesitate to dismiss from the industry those whom he will have to discharge sooner or later in any case.

Periodical health inspection should be arranged, which should not be limited to a simple medical examination, but should include a complete examination for all known symptoms which may indicate the early appearance of lead poisoning. Any sick workman should be temporarily suspended from contact with lead and employed in another occupation, or, if
necessary, removed permanently to non-injurious work.

Great sweating caused by the high temperature with consequent dehydration of the tissues, thirst, extra consumption of liquid, which easily causes catarrhs of the digestive system, can only be limited by providing sufficiently large areas in front of the furnaces so that the workmen need not be exposed to the immediate environment of sources of heat. A water supply, protected from dust and easy of access, should of course be provided.

A supply of suitable drinks is also to be recommended (see article "Personal Hygiene").

Instruction of the men should be taken into serious consideration so that they may know how to make rational use of preventive appliances, adopt the layout of their work, and other medical instructions. This education of workmen should be given at the works, not only by the foremen, but especially by the works doctors, according to a fixed scheme strictly carried out.

LEGISLATION

Women are excluded: from the manufacture, melting and manipulation of lead in Argentina; from melting lead and from any process in which lead figures in Great Britain; from casting lead and making sheet lead in France; from work involving the use of lead, from accumulator factories, etc., in the Netherlands and Switzerland; from manipulating any substance or any compound in the dry state containing more than 2 per cent. of lead in Pennsylvania and New Jersey; and in Japan from every place where dust, fumes, or gas containing lead are produced.

Young persons of less than fourteen years are excluded in Belgium from lead-smelting works, from the shops where the smelting takes place, from shot making, and also from works where copper, bronze and lead are smelted; of less than fifteen years in Japan from workplaces where dust, fumes and gas from lead are given off, and from work on ores, and metals where dust is given off very abundantly; in Poland from lead industries; in Italy from the treatment by smelting of argenticiferous ores of lead and from works for the treatment of metallic lead; of less than sixteen years, as well as women, in Argentina; in Greece from factories where lead or its alloys are prepared; in Spain from the manufacture of heavy metals, from dry pulverisation and sifting of ores, from the metallic lead industry, from casting and fitting of articles of lead or of its alloys; in Great Britain from casting melted lead, from lead-smelting works, as well as from any work dealing with the manipulation of lead; in Canada (Quebec) and in New Jersey from any operation in which lead is used; of less than eighteen years in France from casting lead and making sheet lead, even in accumulator factories; in Poland from all operations which require contact with lead; in the Netherlands and Switzerland from work in the preparation of lead; and from accumulator factories; of less than twenty-one years in Pennsylvania from work in the preparation of lead.

Young girls of less than eighteen years in Great Britain, Canada (Quebec), and Greece; of less than twenty-one years in Spain, Italy, Japan, and generally in all the other countries are excluded from the processes mentioned above for young persons.

The First International Labour Conference, held at Washington, 1919, passed a Recommendation concerning the protection of women and children against lead poisoning in consequence of the dangers to women from the point of view of maternity, which certain industrial operations present and with the object of allowing children to develop physically. The Recommendation requires that the employment of women and young persons below eighteen years shall also be prohibited from work at furnaces where reduction of ores of zinc and lead is carried on; from lead smelting, and also the smelting of old zinc; from the manipulation, treatment or reduction of ashes containing lead and from the desilvering of lead; from making solder and alloys containing more than 10 per cent. of lead; and that the employment of these persons on work where salts of lead are used shall only be authorised on condition that the following measures are adopted: ventilation so placed as to remove dust and vapours as soon as formed; cleanliness of tools and workplaces; notice to be given to the public authority of every case of lead poisoning, and persons affected by poisoning to be compensated; periodical medical examination of persons employed on the work under consideration; installation under satisfactory conditions of cloakrooms, lavatories and dining-rooms; provision of special protective clothing; prohibition of the introduction of food or drink into the workplaces.

The Conference, on the other hand, recommends, in industries where it is possible to replace soluble salts of lead by non-poisonous materials, that use of the said soluble salts of lead should be the subject of the strictest regulation. Any salt of lead is considered as soluble which, as regards more than 5 per cent. of its weight calculated as metallic lead, is soluble in an aqueous solution of hydrochloric acid with a strength of 0.25 per cent. of acid.

A long series of provisions have been laid down by the legislatures of various countries regarding the hygiene and protection of workmen employed in smelting lead.

Thus, for example, in Germany according to section 16 of the Factory Act (R.G.O.) the working of all smelting works is subject to the previous permission of competent authorities. According to section 139 (b) of the same Act, the inspector
requires the application of measures necessary for the protection of the lives and health of the workers.

The Prussian Decree of 1904 even provides for a preliminary examination of plans for new works, or of those undergoing reconstruction (opinion of civil engineers, the factory inspector, and the medical officer of health).

The German Order of 16 June 1905 lays down measures on the setting up and working of smelting works (according to paragraph 120 (e) of the Factory Act (R.G.O.) and particularly those with smelting processes. This very detailed Order lays down the dimensions of the workplaces, the ventilation, the removal of dust, instructions regarding the floor and walls; the provision of drinking water near the furnaces and cauldrons; the covering in of crushing machines and the removal of dust from sacks; the moisturizing of material, except the roasted mass from the converters; the collection of dust, fumes, gas, and vapours, and their removal mechanically, or by other efficient means, by casing, screening, sifting, or melting. Adequate sealing, and constant supervision of joints to prevent any escape of vapours, gas or dust; opening of apparatus only to take place after dust has been deposited and cooled. Special authority is to be required when it is desired to set up furnaces for the distillation of zinc from the lead oxide, provision drawing the attention of workmen against the damage which gases, vapours and dust may cause. Workmen employed in removing dry dust from the interior of dust chambers or flues must not work longer than four hours a day. They must also wear suitable clothing, caps, and respirators.

If soluble salts of lead are to be handled, some greasy substance should be issued for rubbing over the skin of the hands and face, or impermeable gloves should be employed. Douché baths, lavatories, cloakrooms, and dining-rooms must be provided and care taken to see that the men use them.

A monthly medical examination is laid down by German legislation; and the results of the examinations are entered in a health register. The Ordinance of 27 January 1909 does not apply to lead-smelting works, even if they make lead compounds or lead colours. Nevertheless, an admonition is given to bear in mind the instructions which are enumerated therein. According to the Prussian Decree of 9 April 1921, the district medical officer is the most suitable person to supervise the hygienic and health conditions of smelting works; he submits his reports to the consulting medical inspector of factories.

In Austria lead-smelting works come under the Ordinance of the Federated Social Ministry of 8 March 1923, which lays down rules for the protection of the lives and health of persons engaged in lead and zinc-smelting works and zinc-white factories. This very detailed Ordinance lays down measures for the starting of new works and workshops in general, as well as measures for their actual working.

It provides for the number of hours of work daily in different sections of the works, for measures of personal hygiene, as well as for supervision of the health of the workmen by medical certificate on engagement, periodic medical examination, exclusion from processes with a danger of lead poisoning of persons specially sensitive to the action of lead; for examination for lead in the air of the workplaces by qualified experts, in special cases, and for the posting up of a warning notice for the workmen.

Regulations adopted 19 November 1925 by South Australia for the prevention of poisoning by lead and by carbon monoxide, provide for posting up, as well as distributing to each person employed, a notice drawing the attention of workmen to the risk of lead poisoning and poisoning by carbon monoxide. Each case of poisoning, if only suspected, should be notified to the factory and workshop certifying surgeon. The Regulations provide that lead material shall be so moved and stored that no vapours, dust, or gas is generated. The Regulations also lay down preventive measures for persons who enter furnaces, or dust chambers; and measures concerning ventilation, personal hygiene, wearing of respirators, dining-rooms, lavatories, and douche baths. In New South Wales the work of mines and smelting works is regulated by the Mines Inspection Act of 1911, section 48. Western Australia also adopted preventive measures against lead poisoning in 1925 (Ordinance of 30 January). In Tasmania the regulations for mines and industries date from 1915.

In Canada (British Columbia) regulations have been drawn up by the Consolidated Mining and Smelting Company of Canada.

In France the special regulations concerning the particular measures of hygiene applicable to industries where the personnel is exposed to lead poisoning (1 October 1913) deal, among other matters, with lead metallurgy, the cupellation of argentiferous lead, and the making of alloys of lead. In addition to measures of a general kind, it must be mentioned that cauldrons should be placed in an airy place separated from the other workshops. Exhaust hoods or other efficient arrangement for the removal of fumes must be installed: (a) above the tap-hole for lead and slag in the industry of the metallurgy
of lead; (b) in front of the furnaces in the industry of making oxides of lead; (c) above the melting pots for lead or its alloys in the other industries enumerated in the first section of the Order.

In Great Britain regulations are provided by the Act of 1911, No. 752, and by that of 8 November 1921. The Order of 23 December 1920 dealt with the better protection of women and children against lead poisoning, whilst that of 31 March 1922 deals with certain processes with a risk of lead poisoning in the India-rubber industry.

In India the Indian Factory Act of 1911 regulates work in mines and smelting works.

In the United States, the State of New York enacted in 1915 measures for the removal of vapours, gas, and poisonous dust; the State of New Jersey also made provision in its "Standard 1911." An Order on the lead and copper industries dates from 1914.

Norway enacted an Act dated 30 October 1919 containing hygienic regulations for lead-smelting works.

In Rhodesia regulations have been drawn up by the Mining Society.

In Russia the law takes into consideration work in the industries of copper, silver, and lead, and in general all work which causes contact with lead.

Sweden has published some Memoranda for lead smelters.

Some detailed measures are laid down by the legislature in Yugoslavia in the Regulations on the hygiene of work of 25 October 1921 (sections 135 et seq.).

A monthly medical examination is laid down for lead smelters in Germany, Austria and Great Britain; quarterly in Austria and in Yugoslavia for workmen at lead-smelting works not employed in smelting; annually in Austria for lead workers and those who make lead articles; without laying down any period in Czechoslovakia for workmen in lead industries. Cataract among smelters is compulsorily notifiable in the Netherlands. Cases of sickness caused by lead poisoning among lead smelters are compensated as accidents in the countries which are given in the article "Lead Poisoning".

Russia also compensates for cataract among lead smelters.

BIBLIOGRAPHY

See publications quoted in the Bibliography of Industrial Hygiene, published quarterly by the International Labour Office.

The illustrations are from drawings and photographs published by the author in his article on lead-smelting works in Bd. 1 of the Handwörterbuch der soz. Hyg. von GROTHAUN and KAUF, Leipzig, Verlag F. C. W. Vogel, 1912.

(Berlin).

Lead Colours

CHEMISTRY

Lead colours can be classified as White (white lead, sulphate of lead, etc.); Yellow (Cassel yellow, iodide of lead); Red (red lead, chrome red, litharge, Brunswick yellow, English yellow, or patent yellow) is an oxychloride of lead, and like the iodide is very little used. Naples yellow or antimony yellow is a compound of antimoniate and oxide of lead, used especially in the ceramic industry.

The neutral chromate of lead is found in the natural state as crocoite; it is prepared artificially by precipitating a solution of acetate or nitrate of lead with potassium. It is a heavy powder, golden yellow in colour and insoluble in water. The basic chromate of lead (or chrome red) is made by treating the neutral
chromate with an alkali. Orange chrome is a mixture of these two chromates.

These chromates are usually mixed with foreign substances and especially with sulphate of lead, which is produced, at any rate in part, in the process of manufacture.

USES

They are used as oil colours, lacquers, and varnishes in the painting industry and all industries using colours (ceramic pottery, manufacture of coloured papers); in the textile industry (mordanting, finishing, dyeing), and principally in the cotton industry. The colour is fixed in the fibre which has been previously steeped in a solution of a lead salt, and then treated with a solution of chromate, and finally with an alkaline solution to give it a reddish tone.

DANGERS

The manufacture of lead colours exposes the workers to the same dangers as other lead industries (red and white lead, etc.). The operations of mixing, grinding, and packing should be done in such a way as to reduce to a minimum the raising of dust, by adopting either hermetically closed apparatus with efficient exhaust ventilation, or exhaust hoods locally applied to the bins and boiling vessels. Wherever possible the material should be damp. With chromates of lead danger presents itself also at the time of boiling, because the steam carries up with it minute particles of chromate of lead. This process must therefore be carried out under an exhaust hood. Pressing the cakes of chromate should also be done in a moist state; it can easily be shown that the hands, arms and clothes of the workmen are nevertheless covered with a thickish layer of pigment.

The danger from chrome green is limited to the dust given off during dry grinding—a process generally carried out in closed apparatus under negative pressure. Grinding the colours in oil should be carried out under the best conditions possible (see article "White Lead"). Similarly, in packing the aim should be to protect the worker by ensuring the least possible contact with the poisonous substance.

The danger in dyeing with lead compounds has been emphasised by Koelsch and Ilzhoefen (1925); cases of lead poisoning have been noted amongst furriers who made imitation chinchilla by treating skins by acetic of lead and ammonium sulphide.

STATISTICS

The frequency of cases of lead poisoning from colours and varnishes is closely bound up with the hygienic conditions of the workrooms and the personnel. In Great Britain the reports of the Medical Inspector of Factories show the following figures in triennial periods:

<table>
<thead>
<tr>
<th>Year</th>
<th>Cases</th>
</tr>
</thead>
<tbody>
<tr>
<td>1909</td>
<td>561</td>
</tr>
<tr>
<td>1910</td>
<td>171</td>
</tr>
<tr>
<td>1913</td>
<td>9</td>
</tr>
<tr>
<td>1921</td>
<td>8</td>
</tr>
<tr>
<td>1925</td>
<td>10</td>
</tr>
</tbody>
</table>

(The raised figures indicate deaths.)

SYMPTOMS

(See article "Lead Poisoning"). Lesions of the skin occur not infrequently, mainly as a result of the action of the chromates (see article "Chromium and Chromates").

HYGIENE

The same measures on which stress has been laid for white and red lead and lead compounds come into play here (see those articles).

LEGISLATION

Austria. Regulations of 15 April 1908.
Canada (Province of Quebec). Regulations on the packing of lead colours, 1909.
France. Ministerial Decree of 1 October 1913.
Germany. Regulations of 27 January 1920 (see article "Lead Compounds").
Great Britain. Regulations of 21 January 1907: requiring locally applied exhaust ventilation, periodical medical inspection, etc.
U.S.S.R. Regulations of 11 October 1924.
Switzerland (city and surroundings of Basle). Regulations of 27 June 1914.
Western Australia. Regulations of 22 December 1923.

These regulations comprise the removal or absence of poisonous dusts, the exclusion of women and children, medical examination on the commencement of work and periodically afterwards, and welfare provisions common to all unhealthy industries.

The exclusion of adult women is required in Argentina, Germany, Great Britain, South Africa, certain States of America (e.g. New Jersey and Pennsylvania). Young persons under 15 are excluded in the State of Delaware and in Japan; under 16 years of age in the majority of the States of America and in Argentina, Germany, Greece; under 18 years of age in Great Britain, Norway, Netherlands, Poland, South Africa, Switzerland, etc. Boys under 15 are excluded in Italy; under 16 in the Province of Quebec (Canada) and Spain; female young persons under
18 years in the Province of Quebec and in Greece; under 21 years in Italy and Spain. (See also articles "Lead" and "Red Lead ".)

The periodic medical examination takes place monthly in Belgium, Great Britain, Illinois, Missouri, New Jersey, Ohio, Pennsylvania; fortnightly in Germany; quarterly in Austria, France, and Yugoslavia.

For the notification and compensation for industrial diseases, see the articles "White Lead" and "Lead Poisoning".

---

**Lead Compounds**

Among the compounds of lead which deserve special mention are the following:

(a) Arsenate of lead, very toxic and very often used in agriculture as an anti-parasiticide and even scattered from aeroplanes for the purpose of disinfection of forests (see article "Arsenic"); recent particulars of several cases of poisoning are known;

(b) Chromate, used especially in dyeing cotton, wool, wood, etc., although there are numerous non-toxic colours available which can replace it (see article "Lead Colours");

(c) Sulphate (Pb SO₄ with 73.61 per cent. of lead). This occurs in nature in the form of rhombic crystals (anglesite) or it can be obtained by precipitating solutions of lead by sulphuric acid. Lead sulphate had long been thought to be non-toxic as it is almost insoluble in water; but researches dating from 1904 have shown that it is soluble in diluted hydrochloric acid as well as in solutions analogous to gastric juice; and even in gastric juice itself. Goadby has shown experimentally that it is even more soluble than the carbonate (white lead) and the oxide (litharge). The presence of peptone in the gastric juice is said by Blum to increase, although in minimal degree, the solubility of lead salts. Carlson and Woelfel (Chicago) have also investigated this subject and concluded, after a long series of experiments, that the sulphate is toxic, and that none of the regulations directed against prevention of lead poisoning may be omitted in the case of sulphate of lead.

(d) Sulphide. This is interesting both on the practical and theoretical side. In its natural state the sulphide occurs as galena which never exists pure, but contains cerussite, lead, silver, antimony, mercury, and other substances. Statistics relating to several thousands of workers in the mines of Pribram, and recorded over a period of ten years, tend to show complete absence of evidence of cases of colic and only a few of gastritis and constipation. Investigations by Biondi and Frongia (1907), however, in the Sardinian galena mines, employing hundreds of workmen, brought to light the frequent occurrence of affections with a clinical picture resembling slight plumbism. Thus, in addition to symptoms of lead absorption (blue line, punctate basophilia, constipation), they detected traces of lead in the urine. Symptoms of genuine lead poisoning were exceptional (colic, neuritis, encephalopathy), although formerly they had been reported by a practitioner in the district. Possibly improvements in the industry or in the conditions of the workers had resulted in lessening the power of the toxic substance to affect the system.

Frongia examined 456 workers engaged in sorting and washing the mineral and found that it had a noticeable effect on the functions of the sexual organs: arrest of the development of the signs of puberty, disorders of menstruation, sterility, etc., all of which signs he attributed to the action of lead as they affected the subjects of chronic plumbism.

Galena, which sometimes contains mercury (e.g. in Sardinia from 0.5 to 3 per cent.), may cause mercurial poisoning among furnace workers from evolution of mercurial vapour.

Hamilton also cites cases of lead poisoning among some workmen employed in a galena mine in the United States (25 cases in 1912).

Lead sulphide in a pure state is considered as harmless by Rambousek in view of its almost complete insolubility in water.

Teleky and Biondi do not agree with this view, although they admit that very little of the pure compound can be absorbed and that it must be, therefore, relatively very slightly toxic. Investigations by Murgia, however, in 1911 have shown that it is absorbed and quickly eliminated in the urine. Toxic signs are to be observed, but they are slight. Carlson and Woelfel of Chicago have also investigated this subject. Their conclusions are that sulphide of lead is soluble in human gastric juice; that its solubility is less than that of the basic sulphate.
and basic carbonate of lead, but that it is sufficient to endanger the health of men employed in galena mines and in manipulating the material if dust is raised in the process, and, finally, that these workmen should be protected against the risk of lead poisoning as much as any others.

Among the *organic metallic derivatives* of lead, tetra-ethyl is the most important (see that article).

A chemist was engaged in preparing *lead bromide* by making potassium bromide react on acetate of lead in an acetic solution when there occurred a violent explosion during grinding in a mortar. The chemist, ignoring the fact that this reaction caused formation of a compound very sensitive to friction, i.e. a double bromate of acetone and lead, fell a victim to its effects.

The chemist, ignoring the fact that this reaction caused formation of a compound very sensitive to friction, i.e. a double bromate of acetone and lead, fell a victim to its effects.

Mention only need be made of the following compounds: acetate (Pb(C₂O₄)₂ + 3H₂O) is commercially obtained by dissolving litharge in acetic acid, or by the reaction of acetic acid and air on lead. It is used specially as a mordant and for the preparation of different salts and lead colours. The basic acetate is used to impregnate the textile fibres (especially silk), in the manufacture of white lead, of acetate of aluminium, in tanneries, etc.; chloride (PbCl₂) which is given off under certain conditions as a vapour in some industrial processes, as e.g. "tinning" of kettles and saucepans; sesquioxide of lead (Pb₂O₃); peroxide (PbO₂), used in the accumulator industry and the manufacture of matches; nitrate; iodide; silicate (see article "Pottery Industry"); nitrate (see article "Explosives"), lead tungstate used in rapid-drying paints, and more recently lead selenide used in rubber compounds to increase resistance to abrasion.

**TOXICITY**

(See article "Lead Poisoning.") Noteworthy is the apparent extreme toxicity of lead tetra-ethyl, as judged by the number of persons poisoned in the Standard Oil Petrol plant, New Jersey (1924), which may be explained by the extremely fine state of division of the lead.

**SYMPTOMS**

(See the same article.) In the cases of poisoning by lead tetra-ethyl the symptoms mainly affected the central nervous system (excitement, delirium, convulsions, insanity).

**HYGIENE**

The measures set forth for the protection of workers in white lead, red lead and litharge factories are also appropriate for other compounds of lead. The materials should be deposited in covered receptacles, or under conditions preventing the escape of dust into the workroom. They should not be manipulated or packed except under conditions preventing the escape of dust or facilitating its removal by exhaust ventilation as near as possible to the point of origin. Processes should be carried out as far as possible by mechanical means in closed apparatus provided with adequate exhaust ventilation for the removal of dust and fumes. These compounds, if possible, should be handled in a moist condition.

All possible measures should be adopted to ensure hygienic conditions in the premises (impermeable floors, etc.) and the welfare of the worker (washing accommodation, baths, cloakroom, working clothes, etc.).

Workers should be medically examined before employment and periodically afterwards. (In Great Britain in white lead works this visit is made weekly; in other lead industries either monthly or quarterly; in Germany bi-monthly; in Belgium monthly, as is also the case in Illinois, Missouri, New Jersey, Ohio, Pennsylvania; in Austria, France and in Yugoslavia it takes place quarterly.) On the subject of notification and compensation, see the articles "White Lead" and "Lead Poisoning".

**LEGISLATION**

The regulations in Germany, for compounds of lead (27 January 1920) relate to acetate, chromate, peroxide, sulphate and other lead compounds; those of Western Australia (22 December 1923), Victoria (12 November 1923), and New South Wales (31 May 1929), to factories manufacturing or handling lead compounds; those of Belgium (5 November 1910) to chromate, oxides and other lead compounds generally. The English regulations (23 August 1921) cover acetate, nitrate, sulphate and lead compounds in general. Regulations dealing with the same class have been made in France (1 October 1913), in Russia (31 March-13 April 1913), and in certain States of the U.S.A. (Illinois, New Jersey, Ohio, Pennsylvania, etc.).

As regards exclusion of women and young persons, see the articles "White Lead", "Red Lead", and "Litharge". See also articles "Silver", "Pottery Industry", "Enamels", "Canning and Food Preserving Industries", "Lead", and "Zine".
Lead Poisoning
(Plumbism or Saturnism)

French: Intoxication par le plomb or Saturnisme. — German: Bleivergiftung. — Italian and Spanish: Saturnismo.

The morbid changes caused by lead and its compounds in the body are generally called "plumbism" or "saturnism".

Sources of Poisoning

Although certain writers have drawn up lists of industries and processes in the course of which lead poisoning may occur (Layet gives a list of 111; Gilman Thompson one of 150), it is wisest not to draw up a detailed list because every day in industry toxic substances are being replaced by others less clear non-injurious; and, on the other hand, toxic substances are being introduced into processes hitherto considered harmless. Thus recently (1924) the manufacture and even the use of lead tetra-ethyl (added to petrol for motor engines with the object of avoiding misfire and as an "anti-knock") has already set up lead poisoning among those who manufacture it and also among garage workers and chauffeurs.

Lead poisoning is an occupational risk to workpeople employed in the extraction, melting and manipulation of metallic lead, and in manufacturing or using its compounds.

Besides metallic lead, lead alloys (with antimony, tin, brass, bronze, etc.) must be taken into account, and, in addition to lead compounds, lead colours largely used in the varnish and lacquer industry, etc.

Lead and its alloys expose to risk of lead poisoning workers engaged in the following processes: the extraction of lead from the minerals which contain it; the preparation and working of metallic lead and its alloys; the demolition of metal constructions (battleships; during cutting up; by means of an oxyhydrogen blowpipe, of lead plates; burning of paint, etc.); accumulator factories; in the making of cutlery, emery wheels, electric lamps; type casting; in diamond and jewellery polishing; in making lead wire capsules for bottle, copper instruments, in dental work, etc.; as well as plumbers, file cutters, welders, tinsmiths, framemakers, etc.

The handling of lead compounds (acetate, chromate, chlorides, oxides, etc.) exposes a great many workers in a number of industries to the risk of lead poisoning; among these might be mentioned the manufacture of lead compounds (see that article and "Tetra-Ethyl Lead"), of colours, varnishes, lacquers, dyes, paper, enamels, ceramics, coach painting, house painting, etc.; engraving; hide, skin and leather industry; making of rubber, glass and mirrors, artificial stones, matches; work in many chemical factories; in the textile industries; making of artificial flowers, lace, etc.

It is also of interest to recall certain rare sources of lead poisoning such as: packing leaden figures covered with a lacquer (Bleyer, 1906); the handling of lead seals by a customs house officer (Mannkopf, 1891); polishing garnets (von Jaksh); handling amber (Schuler, 1902); cigar-making work effected on a leaden table (Pel, 1897); polishing precious stones (Grossmann, 1907); marble polishing using a mixture of wax, alum, sulphur and metallic lead (Schrakamp, 1903); besides the case of a telegraph operative working with accumulators and especially Leclanché elements; and that of an asbestos weaver using lead threads (Netolitzky, 1897), etc.

The degree of risk varies very much according to the technical organisation of the factories, the methods of work, not only for the different lead industries, but for the same industry and in the same country. Despite this fact, an attempt has been made to classify, according to the degree of risk, lead industries and processes; and this classification, based on British experience between 1900 and 1918, would comprise in decreasing order of gravity the following industries: white lead works, manufacture of pottery, coach-painting, smelting of metals, painting and application of colours in industries other than coach- and ship-painting, accumulator factories, colour and varnish factories, soldering, printing, file cutting, and manufacture of red lead. The reports of the medical inspectors, however, in 1919 and 1920 alter this classification, placing accumulator factories first, followed by smelting of metals, white lead and pottery works.

German experience (Wachter, 1908) adopts the following order: manufacture of white lead, red lead, lead piping and lead shot, painting operations, lead and zinc smelting, and letterpress printing.

In the United States, Hamilton and Gilman Thompson place lead smelting first, followed by manufacture of white lead, electric accumulators, pottery, etc. Hayhurst, on the other hand, places the manufacture of electric accumulators and other electric apparatus first, followed by coach-painting, pottery,
white lead, paint and varnish factories, etc.

TOXIC ACTION

Lead and all its compounds are toxic, and it seems of little use to discuss which of the compounds is the most poisonous. Certainly, the more soluble the compounds the more poisonous they are, and the finer the state of subdivision in which they find themselves, the more readily dissolved they are in the organic juices whence they undergo more rapid absorption. Lead and all its compounds, even the insoluble compounds, are absorbed through the alimentary canal. The mechanism by which this is effected is not yet well understood, but the fact is proved by experience. Absorption takes place also by other channels — certainly through the respiratory tract, although in the case of inhalation of lead dust, an important rôle is played by the intestinal tract, following ingestion of the dust inhaled. Probably also, although there is no absolute proof of it, lead is absorbed through the skin, but this channel is practically of little importance.

Certain authorities (mainly British) consider that lead enters the system principally through the respiratory tract, the digestive tract playing a comparatively unimportant rôle. Others, on the contrary, regard the digestive tract as the principal channel of entry and support their view on the experimental fact (Lehmann, Saito, etc.) that only 12 per cent. of the lead dust reaches the lungs, while 70 per cent. enters the digestive tract. Evidently a large quantity of the dust inhaled by the nose and mouth deposits itself on the moist mucous membrane and is removed in blowing the nose or is to a large extent swallowed with the saliva. Whatever be the truth, this discussion, from a practical point of view, is only of secondary importance;

1 There is present in the system of the average individual small traces of lead, derived from drinking water, foodstuffs, and even the dust in the air. During its deliberations the British Committee on Tetra-Ethyl Lead (1926-1930) effected systematic research for lead in the urine of a large number of persons. This research revealed that normal urine always contains a small proportion of lead: 0.040 mg. per litre (average of fifty-five samples). Persons living in the country showed the presence of lead 0.023 mg.l than town dwellers (London: 0.049 mg.). Those exposed to the lead risk showed a higher content: 0.38 mg. These various figures correspond to the returns previously furnished by American and Australian authors. The data concerning workers in accumulator factories are particularly suggestive: founders, 0.059 mg.; fitters, 0.02 mg.; welders, 0.34 mg.; dressers, 0.35 mg. per litre.

the campaign should be waged against the real enemy — dust.

The medical sub-committee which studied the problem of lead poisoning (from white lead) at the International Labour Conference at Geneva (1921) expressed the opinion that “in so far as concerns painters, by far the most important danger is from dust which enters through the nose and mouth. Penetration of lead directly through the skin is without any practical importance, but in many ways lead can be deposited on the skin and be carried thence to the mouth.”

A characteristic of lead and its compounds is to act in very small doses. Though it may be true that the largest part of the substance introduced into the organism passes out without being absorbed and that its assimilation is relatively difficult, its elimination, on the other hand, is very slow. The rather paradoxical opinion has even been expressed (Brouardel) that the toxicity of lead and its compounds is so much the greater the smaller the dose absorbed. Cases of fatal poisoning by a single dose of a salt of lead are very rare.

There is difficulty in determining the dose capable of setting up chronic poisoning, but very small doses renewed daily suffice, even if their total sum does not reach the amount necessary to occasion acute intoxication, assimilation being much more complete.

The dose calculated by Legge and Godby as capable of setting up chronic plumbism is 2 mg. inhaled daily in the form of dust; by Teleky as 1 mg. daily over a period of several months. A dose of 10 mg. sets up very severe toxic symptoms in a short time. According to experiments by Lehmann (1924) on small animals extending over several years, the toxic effect was apparent as soon as 10 mg. of lead was given daily per kilo. weight for two or three months.

Lehmann (1925) considers that under the most favourable conditions the amount of lead absorbed in colour factories per day per workman is up to 2 mg. and under less favourable conditions from 5 to 10 mg. In his enquiry he found from 0.3 mg. to 3.8 mg. per cub. metre of air (results of 12 analyses) and an hourly deposit of 0 to 5 mg. of lead per cub. metre when the conditions were very good (in a white and red lead factory); from 6 to 10 mg. when the conditions were good; over 20 mg. when they were fair. He considers 40 to 60 mg. as the greatest permissible limit (in special cases he found as much as 300 mg.).
Absorption is favoured by several circumstances such as heat, sweat favouring solution of lead oxides, and also by certain food (acids, salads, etc.). Nowakowski (1931) is of the opinion that the biological reaction of the human organism varies in accordance with the seasons; this would explain the variations in the number of cases of lead poisoning which he has noted amongst certain categories of workers exposed to lead risk.

Lead exerts an effect on metabolism now definitely proved. It enters into combination with the albuminoids of the living cells and gives rise to albuminates and protein compounds of lead which are eliminated with difficulty, and which, as they leave, carry away the cell where they were formed. Knowledge at present fails as to the form in which lead circulates in the organism, but there is proof that it can always be recovered in the blood serum.

The experimental researches of Tscharny into metabolism during lead poisoning provides the following conclusions: diminution of the alcaline reserve of the blood with acidosis; diminution of acid-soluble phosphoretted compounds and premature increase of lipoidal phosphorus; substitution of lead for calcium: retention primarily of lead in the bones, which is accompanied by hypercalcaemia and increased elimination of calcium in the urine; diminished elimination of uric nitrogen, followed shortly by retention of nitrogen in the blood, accompanied by abnormal starch reduction in the nitrogenous compounds. Lead poisoning thus produces, prior to anaemia, forms of colic and paralysis, quantitative troubles and desaggregation of nitrogenous substances and elimination of nitrogenous compounds.

According to Schmidt, lead is not only a powerful poison of the cell nucleus, a specific irritant of the haemopoietic organs (of the bone marrow in particular), but exerts a destructive influence on the elements of the circulating blood and is the principal cause of the different lesions found in the various organs and tissues as an effect of its accumulation and of its specific action on the walls of the capillaries: retina, kidneys, intestines, nervous tissue, etc.

Schmidt has also shown that lead is found in the blood principally in the leucocytes, in less quantity in the red blood cells, and still less in the serum.

According to recent research (Scremin, 1924) it would seem as though lead introduced into the system was converted into phosphates which as such are deposited by the blood in the tissues; phosphates being only slightly soluble, the quantity of the soluble lead substances is certainly very small. This fact should be borne in mind in understanding the very slow development of toxic signs in lead poisoning.

The localisation of lead in the different tissues and organs has given rise to difference of opinion among various authorities and it seems to vary according as the poisoning is acute or chronic, and whether of long standing or recent. In addition to the "normal lead" introduced into the system every day, which A. Gautier estimates at 0.5 mg., different investigators have found in the organs and tissues of victims lead located especially in the hair, the nervous system (marrow, spinal cord, brain), the lungs, the liver, the heart, the kidneys, the spleen, the bones, the cartilages, etc.

The largest amount is said to be found in the reticulo-endothelial system.

As has been said above, a large proportion of the lead dust absorbed through the digestive tracts is expelled with the faeces without having undergone notable change. The soluble substances or those which can be made soluble on contact with organic liquids are eliminated more slowly.

The emunctories in decreasing order of importance are the bile, the urine, the saliva, and the skin. It should be remembered that a portion of the lead excreted by the bile in the duodenum is again absorbed by the intestine.

The kidney is one of the emunctories which is most rapidly and seriously damaged by the passage through it of lead, and its damage favours saturnine impregnation of the organism as well as accumulation of toxins. Elimination by the urine goes on even for years (15 to 20) after all contact with the toxin has ceased. Administration of iodine can increase and sometimes speed up the elimination.

Amongst chronic victims of lead poisoning the administration of very small doses of lead causes increased elimination of lead by way of the mouth and re-appearance or accentuation of the Burton line or marking of the gums, etc. Baader considers that this fact should be interpreted as an active mobilisation of the lead and that it is necessary to recognise therein proof of the outbreak of important visceral reactions amongst lead patients. This fact also proves the danger of bringing into contact with lead a worker who has already suffered from serious attacks and that a serious relapse may be feared on resumption of work, even for a short duration.
and with due precautions as regards hygiene.

For some time past distinction has been drawn between "absorption of lead", "impregnation" and "poisoning". By absorption is meant the first stage of poisoning, the toxic substance not having so far produced important changes; by impregnation, the second phase with organic changes sufficiently developed as to be detectable on medical examination and not to be regarded as insignificant; by poisoning, the last phase with signs of the reaction of the organism to the poison manifested in typical lesions, but still a phase at times without very clear symptoms and notoriously without realisation by the individual that he is ill.

Although it can be logically held that once absorption of lead in the organism has taken place, lesions, however slight they may be, may be present in certain tissues or organs, this does not justify application of the term "lead poisoning to the condition simply because signs of absorption are present. Once this is considered, a definite limit exists between "impregnation" and "poisoning" — a thing difficult to allow, especially because it may lead support to the view that the condition of absorption is a condition without importance.

The problem of resistance to lead has not yet been properly determined. It seems, however, to be now commonly recognised that, though there are apparently individuals who, when exposed to absorption of lead, are capable of not presenting the usual clinical picture of lead poisoning, it is not so far known if such persons possess natural or acquired immunity. In the first case, what is the form of immunity? In the second, what is its mechanism? What is certain, however, is that acclimatisation to lead has been definitely proved in animals and that this result has in no sense been due to insufficient absorption of the metal because the presence of lead has always been controlled in the urine. The mechanism by which an acquired immunity has been the subject of several hypotheses — all of them rather vague — and it has not been thought necessary from the practical point of view of industrial hygiene to insist too much on this phenomenon. Whatever the truth may be, lead workers, especially after a short period of work, become specially susceptible to the action of lead (Teleky).

Neither age nor race is a protection against lead poisoning. So far as concerns the slight incidence of poisoning among young people, it has to be remembered that not many of them are to be found in factories and workshops where there is exposure to the risk of lead poisoning. The relative immunity of children, advanced by some writers, must be absolutely denied. As regards sex, while English opinion inclines to the view that women are more susceptible to the action of lead than men, this is not accepted by German writers, who consider that their poor state of nutrition, personal and industrial fatigue, added to housework, long hair and type of clothing favouring the accumulation of a greater quantity of the poison upon them, are sufficiently potent factors to account for the apparent disparity. Data from the United States are not sufficient to allow the experts to support either of these views. All, however, agree that in women lead poisoning assumes a more severe form (manifesting itself in convulsions and amaurosis, etc.) than in men. Further, menstrual troubles are also very frequent.

Similarly, the baleful influence of lead on the foetus is well known. It is not necessary for the mother to be affected by lead for the children to develop symptoms of lead poisoning. English, German and French data show the frequence of miscarriages, although in certain cases it may be difficult to ascribe them all to lead. The wives of workmen in lead industries also present a large number of miscarriages, but though English, Italian and German data are definite on this point, American data, on the contrary, are scarce and rather contradictory. It is useful however to remember that Bedson has found lead in the liver and kidneys of infants whose mothers suffered from plumism.

Other factors are of moment: the precise occupation itself for poisoning is accelerated in proportion as the occupation involves greater exposure to the risk and the dose absorbed is augmented; the habits of the subject, bad habits having an indisputable effect on initial and subsequent attacks; those affected by lead show a characteristic weakness for alcohol and alcoholic beverages; constitutional diseases and all causes of weakness (alcoholism, tobacco, etc.). Though
alcoholism and plumbism may co-exist and induce a kind of hybrid symptomatology, and though alcoholism predisposes the workman to fall a victim more readily to lead, the conclusion should not be drawn that every lead worker is an alcoholic.

Syphilis, it should be remembered, brings about lesions in the same organs as lead poisoning does, so that lead encephalopathy is hard to distinguish from cerebral syphilis. Tuberculosis is also a sufficiently common condition for old subjects of plumbism, and to-day the former view of an antagonism between the two maladies cannot be admitted.

Hereditary lead poisoning does not unfortunately require to be proved. It is admitted that lead disturbs profoundly, not only the function of maternity, but medical sub-committee of the International Labour Conference, Geneva, 1921) expressed the opinion that the statistics are vitiated as to mortality by the exclusion of cases of death due to saturnism which are grouped under other headings, and (b) secondarily by the inclusion under saturnism of cases of death due to other causes. Generally authorities agree that statistics of industrial poisoning have been and always are very far from giving an exact review of the health conditions of an unhealthy industry. The medical sub-committee referred to added that "obligatory notification by a medical practitioner of suspected cases of saturnism, and the certification of these cases by an independent medical man appointed by the State, would provide (as is now the case in certain countries) satisfactory statistics".

The introduction into industry of mechanical or automatic methods reducing more and more contact of the workman with the poisonous compound, replacing the old dry processes by wet, wider substitution of harmless or less dangerous substances for lead compounds in certain industries or industrial processes—these all undoubtedly diminish the number of cases of lead poisoning. Although, however, the severity of the morbid appearances has been much lessened, it does not follow that the lead poisoning has decreased or that there is any reason to make light of the extent and importance of the clinical condition known as slight plumbism.

Sufficiently detailed statistics relative to different industries exposing the workers to the risk of lead poisoning have been given in the articles "Painting Industry", "Printing Trades", "Lead", "White Lead", "Red Lead", "Accumulators", "Pottery Industry", etc. Thanks to the compulsory notification of all cases of lead poisoning arising under Dutch law, 1911, the English Factory and Workshop Act, 1895, and the French Act of 1919, very valuable information is available as to the frequency, the symptoms and causation of this industrial disease. If other countries imposed similar statutory obligations, they would obtain similar precious information; but at present only the English statistics, and, up to a limited extent, the French, are of remarkable value because (especially for the English cases) reports by independent inspectors and certifying surgeons are available.

In Prussia (1929), 1,124 cases of lead poisoning notified by certifying surgeons were distributed as follows: foundries and lead factories, 304; zinc foundries, 22; type-founding establishments, 6; printing works, 51; welding and tinning, 41; other processes connected with metallic lead, 25; storage batteries, 12; lead colour factories, 53; painting (building and other industries), 164; pottery and manufacture of lithograph transfers, 99; breaking up of ships, 6. In Bavaria (1927-1929), 617 cases of lead poisoning notified were distributed as follows: foundries and lead factories, 64; printing works, 77; welding and tinning, 37; storage batteries, 14; lead colour factories, 31; painting in the building trade, 84; enamelling, 147; pottery, 14; manufacture of lithographs and decoration, 12; various, 41.

United States.—In the State of Illinois, from 1 July 1914 to 30 June 1915, of 211 cases of lead poisoning, 50 were lead poisoning (156 among lead smelt and refiners); from 1 July 1920 to
1 July 1923, 318 cases of lead poisoning, 18 of which occurred in the painting industry; 52 in foundries, 199 in white lead, lead colour, and lead paint factories, 61 in lead foundries, etc. According to Wade Wright (1917), while, during the five years' working of the Massachusetts General Hospital, only 147 cases of lead poisoning were diagnosed, no less than 148 were diagnosed in the first year after an industrial clinic was opened in the same hospital. Of these 148, 68 were painters, 9 ship painters, 11 rubber workers, etc. In 1921 96 cases of lead poisoning, 45 affecting painters, 9 ship painters, 9 rubber workers, and 34 workers in the rubber industry, were reported to the Factory Inspection Department. In the State of New Jersey in 1917 54 cases of lead poisoning (out of a total of 83 cases of industrial diseases) were reported. In the State of New York during the period 1912-1922, of 744 cases of lead poisoning, with 104 deaths, 284 (53 deaths) were house or ship painters, 50 (8 deaths) coach painters, 152 (3 deaths) workers in accumulator factories, 64 (5 deaths) while lead and paint and colour workers (6 deaths), lead foundry workers, and 34 (25 deaths) workers in other lead industries. In the State of Ohio, the Workmen's Compensation Act of 1919 on occupational diseases notified in virtue of the Act of 1919 on occupational diseases numbered 8,628, of which 1,362 (18.9 per cent.) occurred in smelting metallic lead; 3,099 (35.9 per cent.) in enamel and repair of accumulators; 648 (7.5 per cent.) in white lead and minium factories, etc.; 391 (4.5 per cent.) in various branches of the painting trade; 177 in glassworks and potteries; 171 in the chemical industry, 247 in the printing trades; and 130 in various industries and occupations. Continuing attention to the last three years (1926-1928), which show 4,070 cases of lead poisoning, it is found that the figure for simple colic is 2,766; for incapacity for work lasting eight to thirty days, 3,069; whilst cases of permanent partial or total incapacity notified by the certifying physicians only reached the number of 13. Cases of death give a total of 9. Cases notified in 1929 amounted to 1,846, and in 1930, 1,682.

Great Britain.— Without going into details, which are given for the different industries in which there is risk of lead poisoning, the average number of cases in groups of years may be given as follows:

* The small figures are the number of fatal cases.
† From 1924 onwards the statistics include cases occurring amongst workers engaged on painting of buildings. Notification of these cases has been compulsory since 1 January 1927.
‡ Of which 131 occurred during demolition of battleships. These cases reached 30 in 1923, 17 in 1922, 7 in 1921 and 3 in 1920. They were made the subject of a special Memorandum published in April 1925 by the Factory Department of the Home Office.

A comparative indication of the incidence rate of lead poisoning among workers handling lead is given in the table below, and especially for the period 1910-1914, reveals interesting facts. Thus there has been a diminution in the number and severity of chronic cases, in the frequency of relapses, etc. Gastric symptoms are by far the most numerous, followed by anaemia, paralysis, rheumatic pains, headache, and encephalopathy. English experience has shown that paralysis and encephalopathy have been much less frequent in the period 1910-1914; paralysis is much more frequent among men than women, whereas it is the reverse in the case of cerebral symptoms.

1 The rates for house painting in this table are calculated in two ways, viz.:
(a) from the number of notifications and of death certificates received in the year. This, however, does not represent the total incidence, since notification is not obligatory in the case of house painters.
(b) on the assumption that in house painters the "deaths from lead poisoning" bear the same relation to the "cases of lead poisoning" as the corresponding totals do in the lead workers in the combined factory industries. This relation is known for the lead workers in the combined factory industries, and the "deaths from lead poisoning" among house painters are known from the copies of the death certificates received from the district registrars.

The cases of paralysis occurring in the period 1910-1914 numbered 606, of which 352 were definite paralysis and 253 of weakness or loss of power, affecting mainly the two forearms (352 paralysis and 181 weakness), 72 the right forearm (55 paralysis and 20 weakness), 50 the arms and legs (20 paralysis and 30 weakness), 35 the left arm (19 paralysis and 16 weakness), 29 the legs (9 paralysis and 20 weakness), 23 the fingers, etc.

The diminution in central nervous symptoms is notable. Thus in the period 1910-1914, 97 cases of epilepsy, psychical disturbance and optic neuritis occurred as compared with 60 during 1910-1914, and only 17 in the third period.

Examination of 247 death certificates in which lead poisoning was entered as directly or indirectly the cause showed that cerebral haemorrhage, paralysis and chronic lead poisoning accounted either alone or in combination for at least 195, that is, 78.9 per cent., while encephalopathy was responsible for only 8, or 3.2 per cent.

The English report, however, lays stress on the fact that "reported cases of lead poisoning in common with other forms of industrial disease do not represent quite all the incidence: latent, unrecognised and neglected cases undoubtedly exist as with other notifiable diseases."}

SYMPTOMS

Like every other disease, the symptoms at the onset of lead poisoning are variable, and at this early stage there exists no symptom enabling a certain diagnosis to be made. Yet clinical appearances, combined with laboratory practice, make possible the diagnosis of the majority of doubtful cases.

The symptoms of acute and sub-acute poisoning are much the same: salivation, metallic taste in the mouth, and a feeling of retrosternal and epigastric burning when the salts have been introduced by way of the digestive tract. Further, there is severe colic, a subicteric facies, constipation, and sometimes vomiting.

The pulse is slow, though not always, and hard, the affected person is subject to convulsive attacks with a condition of stupor, shivering, etc. Occasionally these end fatally. Relapses occur after recovery and without fresh absorption of the poison.

The symptoms of chronic lead poisoning may be classed in two main groups: those of slight and those of severe plumism.

The symptoms of slight plumism may also be regarded as the premonitory signs of lead absorption; they mainly consist of presence of lead in the urine — sometimes intermittent — and existence of the blue line on the gums, Burton line.

Usually there are both general and special symptoms affecting particularly certain organs or systems which react to the poison according to the individuality of the sufferer (changes in the blood, especially in women, or a blue
line, or weakness of the extensors, etc.): whence comes the variety of the initial symptoms and the disagreement which at first sight would appear to exist between different writers on this point.

The general state of health is affected at a sufficiently early stage; the pallor to be observed is the sign of a generally bad condition. The saturnine facies is difficult to diagnose at first, and is much discussed. The patient complains of a peculiar metallic sweet taste, of loss of appetite; sometimes there is nausea and vomiting. Often there is fetid breath following on the bad state of the mouth and gums. According to Koelsch, with ordinary dental care the gums are normal though anaemic. When dental care is defective, and especially if there is individual predisposition, a more or less marked stomatitis exists, which is but an aggravation of the gingivitis coupled with dental caries and local nutritional defects due to the albuminates of lead circulating in the blood, so much so that it is possible to speak, as Koelsch does, of saturnine gingivitis or stomatitis capable of assuming a very severe ulcerative form.

A blue line is also frequently found at this stage. Distinction, however, must always be made between a blue line due to the deposition of lead dust on the buccal mucous membrane and especially on the gums, and the blue line attributable to elimination of the poison, which latter alone is evidence of lead in the system.

In Biondi’s opinion the first has no resemblance to the second, which is localised exclusively at the edge of the incisor and canine teeth, and falls where the teeth are absent. If the junction of the teeth and gums is touched with a solution of sodium monosulphide a line that is absent or faint is often brought out.

In cases of lead absorption the blue line occurs in some 20 to 40 per cent. (according to the amount of dental care bestowed) and in persons suffering from lead poisoning in 70 per cent. of the cases. Oliver has found it without other symptoms in 50 per cent. of lead workers; Koelsch in 12 per cent. of 5,000 working painters whom he examined. The blue line may however be lacking in 20 per cent. of cases of lead poisoning (Teleky) or even 25 per cent. (Oliver). According to Teleky, it should be regarded as the least frequent symptom of lead poisoning.

Bluish black specks are also found on the lips and inside the cheeks.

A late symptom sometimes noted is inflammation of the salivary glands—especially the parotid, more rarely the sublingual—on one or both sides, commencing insidiously with pain or swelling of the temporal or mandibular articulation, and involving disturbance in salivary secretion (increase or diminution). Parotitis due to lead was observed by Thielemann in 12 of 50 cases of poisoning (that is, 24 per cent.).

English writers describe further a special form of anaemia with prominence and a glintient condition in the cornea and sclerotic, suggesting organic disease of the heart which, however, may not be present.

The patient suffers from constipation, diminished flow of urine, in which, at an early stage, the presence of lead and haematoporphyrin is found.

Digestive disturbance is considered by some authorities as an early sign and admitted by all as of very frequent occurrence. The liver plays a considerable part in the morbid picture (cirrhosis, chronic angiocholitis, etc.), and finally changes in metabolism showing themselves in increase of uric acid in the blood and favouring attacks of gout in persons predisposed to it. Gout is said to be frequent in France and Great Britain, but is on the contrary rare in Germany. Severe anaemia, arteriosclerosis, nephritis, etc., find a sufficient explanation in the view taken that lead favours a uricemic state by retention.

Colic, which may sometimes be an early sign, is an epiphenomenon in chronic poisoning. Compared with other lead symptoms, it is without doubt the most frequent and, in view of the length of time it lasts and the frequency with which it occurs, represents a serious economical loss to industry. It is the expression either of the direct action of lead on the smooth muscle fibres of the intestine, or of indirect action on the mesenteric nerve supply.

The peripheral nervous system is affected by varied disturbances:

(a) Motor: in the classical type of paralysis of the forearm, partial or complete, uni- or bi-lateral, occurring either suddenly or slowly and insidiously. The paralysis is due to a lesion of the nerves and muscles in the region of the radial nerve (with the exception of the supinator longus), supplied by the musculo-spiral nerves, brought on rather as an effect of fatigue of the muscles involved than as an effect of local action of the poison through the skin. This hypothesis explains the greater frequency of the
paralysis in right-handed persons and of the left in left-handed. The hand drops, the middle and ring fingers are half flexed while the index and thumb are raised. The wrist drop may be complete and may reappear even after all contact with lead has been given up. The paralysis may also be generalised accompanied by functional disturbance of the muscles, developing slowly and affecting different areas in successive stages; generally only the trunk muscles escape.

Loss of power, localised in the extensors of the hand noted by Gilibert in 1906 is rarely an early symptom. Teleky, however (1923), regards this symptom as fairly frequently of early occurrence. Among 711 persons handling lead without obvious distress, the symptom was present in 17.4 per cent.; among 27 cases examined it was present in 52 per cent.; among 271 persons not in contact with lead in 1.85 per cent. only. This question has been studied by many experts. Kojran-ski (1928) has investigated this symptom in the aid of an apparatus contrived for the purpose, in the case of 316 lead workers and 192 workers not exposed to the lead risk. Amongst the latter, the force of extension of the hand exceeded by 72 per cent. that of the left hand whilst in the case of the lead workers this percentage dropped to 48.7. Other experts, however (Hertg, Vighortschik, Gelman, etc.), have not been able to arrive at positive conclusions. Levy and Weiss (1928) have used as a means of control the chronaxie, and it is certain that new methods of research will shortly permit of exact determination of this weakness of the extensor muscles. An important early or late sign is headache, even without the presence of albumen in the urine or retinal changes.

Muscular atrophy is the sequel of the paralysis (Letulle) and occurs in proportion to the degree of the latter. It is accompanied by discoloration (cyanotic); trophic changes, etc.

(b) Sensory (myalgias, arthralgias).

(c) The special senses (amaurosis or blindness which is always accompanied by encephalopathic symptoms: headache, vertigo, optic neuritis, albuminuric retinitis, hallucinations of sight and hearing, delirium, aphasia, etc.).

A complex series of symptoms — known under the name of "encephalopathy" — set up by lead in the central nervous system, comprises epileptiform convulsions, trembling, delirium, coma, amaurosis, blindness, and collapse.

This form, reported fairly frequently in Great Britain, has been less frequently noted in France, Italy and Germany, although cases affecting the brain have been described after two or three months only of contact with lead. Convulsions are most likely to affect young women workers soon after their first exposure to large doses of lead salts.

The cerebral attacks have been classed under three classical types (Grisolle): delirious, comatose and convulsive. Tanquerel des Planches was the first to distinguish them under the name of "lead encephalopathy", being accompanied by almost particular cerebral phenomena: convulsive crises, isolated or in series, almost always with fatal issue, sometimes supervening after a period of coma and at times affecting the victims of lead poisoning from the commencement of absorption.

Certain authorities regard them as a toxic meningo-encephalitis, while others are inclined to pronounce them hypertensive paroxysmal strokes.

Levy and Weiss (1928), who recently took up the study of this morbid manifestation, incline to the latter view, basing their judgment on the fact that lead acts as a poison by inducing anaemia and acting as a hypertensive agent and poisoning the nervous system, especially the periphery.

Hypertensive attacks of eclampsia as noted amongst victims of lead poisoning are to be distinguished from exceptional attacks of eclampsia, etc., affecting invalids. The term "encephalopathy", according to certain authorities, is restricted to this hypertensive crisis, usually of fatal termination, phenomenon of a hypertensive cerebral vaso-constriction. They suggest grouping the injuries resulting from these crises, such as deafness, amaurosis and transitory aphasia, under the heading "slight encephalopathy" and retaining for lead eclampsia the term "severe encephalopathy". The first group often constitutes the premonitory symptoms of the fatal attack of eclampsia.

In 1929, Niederland, of Aquisgrain, had an opportunity of reporting 11 cases of encephalopathy amongst victims of chronic lead-poisoning; 3 of the cases were typical lead encephalopathy; in 2 the encephalopathy was of the Jakssonian type; there was 1 case of chronic lead encephalopathy and 2 of a slight form with rapid evolution; another 2 of a type with retarded evolution and lastly 1 chronic nephritis with uraemia and possible previous encephalopathy.
The respiratory system is also affected, presenting various forms always terminating in sclerosis. Probably supervening on this, in certain individuals tubercle develops as a result of the special conditions of environment and life of such individuals. As a matter of fact, writers agree that tuberculosis does very frequently attack persons suffering from plumblism, and in any case that lead absorption predisposes to it. Asthma is also of fairly frequent occurrence.

Changes in the blood vessels, high tension pulse, arteriosclerosis, etc., which in the opinion of some authorities are early symptoms of lead poisoning (on this point opinion varies greatly), are considered by the majority as late symptoms of chronic lead poisoning.

Nevertheless, James Lasius (1930), who engaged in research into hyper- tension in lead poisoning, considers that, apart from cases of nephritis, there can be no question of increased pressure amongst workers who have absorbed small quantities of lead, even over a period of thirty to forty years.

The elimination of lead by the kidneys is not unattended with danger to that organ so important to the animal economy, and its injurious action upon the secreting epithelium is to be detected early in the stage of poisoning. Later the damage extends to the connective tissue and to the vessels so that the slow and almost continuous changes pass on relentlessly to the condition of chronic interstitial nephritis — the small atrophic kidney.

According to some German and Dutch writers, presence of haematoporphyrin in the urine is said to be an important sign of lead poisoning — at least when in excess of a certain minimum quantity. The porphyrin is thought to be formed in the intestine starting with haemoglobin and helped by the action of aerobic and anaerobic bacteria.

It is hardly necessary to insist on the harm done to the organs and functions of generation both of man and woman as they are now well known and admitted. Of the endocrine glands the suprarenal capsules resent most the action of lead. In consequence the important endocrine functions are disturbed and the effect of this upon the clinical picture presented by the patient can readily be imagined.

The organs of sense do not escape the disastrous action of lead. Five cases of ocular injuries due to lead were noted by Pedley (1930), who found them amongst 100 cases of lead poisoning studied in the course of the four previous years. The injuries consisted in optic atrophy (2), neuroretinitis (1), probable retrobulbar neuritis (1), sub-hyaloidian haemorrhage (1). Whilst lead might be considered as the probable etiological agent, it cannot, however, be recognised as the certain cause in these cases, in the absence of direct proof.

These various clinical symptoms are not in themselves characteristic, with the exception of colic, and their presence can only be determined by reference to the history of the case and the presence of lead in the urine. For reasons still unknown, individual predisposition favours in different individuals occurrence now of this, now of that clinical picture, and while colic, nephritis and the mental symptoms may appear, even after a short exposure to the action of lead, the changes in the vessels and kidneys are always an indication of late and terminal effects. Even colic is at times the expression of an episodic absorption of a larger quantity of the poison, and at times of a peculiar reaction of the subject to the action of lead.

Blood.— Among the alterations of the blood, diminution of the haemoglobin, of the number of the red blood corpuscles, and inversion of the leucocytic count are certainly, from the point of view of early diagnosis of plumblism, of less importance than certain changes in the red blood cells themselves.

Diminution of the haemoglobin in severe cases may be remarkable (40-50 per cent.), the number of red cells may fall to 3½ millions or even to 2,800,000. The picture of pernicious anaemia, however, is never seen.

Further, lessened plasticity of the red cells, polychromatophilia, punctate basophilia, the bodies of Jolly and Cabot in the red cells, are cited as early symptoms. Polychromatophilia and punctate basophilia are now recognised as an indication of disturbed regeneration, if not of an embryonic or pathological reaction of the blood-forming tissues, which direct into the circulation a more or less large quantity of immature red cells, or, at any rate, of cells with embryonic characteristics, rather than the result of a degeneration of these cells following on action of the poisons, as was the view previously held.

The frequent presence of punctate basophilia in the blood, in the absence of other symptoms, should be regarded as a note of warning and evidence of latent poisoning. The value of this
LEAD POISONING — 131 —

indication is sufficient to confirm diagnosis based on other symptoms (see article "Blood: Changes due to Occupation").

Punctate basophilia considered characteristic by Schnitter, Grawitz, Schmidt, Hamel, Moritz, Embden, Schoenfeld, Sellers, etc., is held, on the other hand, by other authorities as not characteristic because it is observed in other diseases and forms of poisoning and even occasionally in the blood of healthy persons. Further, it is said to be absent in 50 per cent. of cases of plumism (Linenthal) or even 80 per cent. (Harris). Others mention smaller percentages: 25 per cent (Teleky), 27 per cent. (J. Russel); and 17 per cent. (Lutolawsky). But though, according to Nægeli, punctate basophilia is found in healthy persons, the number is very small, while in persons suffering from lead poisoning they represent a fairly frequent change and are sometimes present unaccompanied by anaemia.

While admitting the value of the presence of punctate basophilia in the early stage of lead poisoning, Thomas Oliver is not however willing to ascribe to it the great value placed on it by certain authorities as a guide to diagnosis. In certain cases presenting very clearly-marked symptoms of lead poisoning punctate basophilia was absent, and the same was found to be the case amongst animals fed on lead for several weeks.

A comparative study made by Trautmann (1908) brought to light the fact that while punctate basophil red cells were found in 14 per cent. of anaemic subjects examined and in 21 per cent. of healthy persons, they were found in 56.2 per cent. of lead workers undergoing periodic medical examination, and in 70 per cent. of painters examined. Taking as a minimum standard for punctate basophil red blood cells 100 per million, he showed that only 2 out of 10 anaemic subjects (1 only if 200 per million were adopted as minimum standard); and 2 of the 100 healthy persons (not 1 if 200 were the minimum standard) gave this blood reaction, while it was positive in 20.6 per cent. of the lead workers (11.2 per cent. with a 200 standard), and in 33.3 per cent. of painters (21.7 with a 200 standard).

Very interesting observations have recently (1925) been made by W. Blair, W. R. Williams and L. Cunningham on the toxic action of lead administered intravenously for the treatment of cancer. The intravenous administration of lead gave rise to punctate basophilia some hours after the first dose of lead was given. Anaemia and polychromasia (also very frequent), anisocytosis and poikilocytosis were of later development. The authors do not share the opinion that punctate basophilia of the red cells occurs in normal blood. Of 117 patients 76 showed punctate basophilia, 24 punctate basophilia accompanied by nucleated red corpuscles, 3 others showed other pathological changes. The remaining 14 cases only showed polychromasia. As regards the white cells, the authors report that leucocytosis is common while leucopenia is rare, but there is nothing specific or definite in regard to these changes observed in the white cells.

The blue line is of uncommon occurrence when lead is administered intravenously. On the other hand, colic is of frequent occurrence, especially after heavy doses. Psychopathies are rare,
but the retina and the kidney are often affected. The action of lead on the latter is so frequent and so intense as to require the greatest precaution in administration of the drug.

But though the value of this line of enquiry has become somewhat less apparent from a medico-legal point of view, seeing that the number of punctate red cells does not run parallel with the severity of the poisoning, and though the red cells affected with polychromasia are more numerous than those with punctate basophilia, it must be remembered that these pathological forms appear where there has been quick absorption of large quantities of lead, or when already much lead has been absorbed into the organism and begun to act. They indicate the imminence of lead poisoning, especially in particularly sensitive individuals, and, from this point of view, their presence has a practical importance of even greater value in that it enables us to suspend or transfer to other work the persons running the greatest risk.

Though, according to Teleky, an increase in the punctate basophil red cells is a rather capricious sign, their presence is found almost without exception in cases which have later developed grave symptoms.

In regard to the leucocytes, even in mild cases there is a tendency to a leucocytosis, although slight, and in the more severe cases of anaemia a rather marked neutrophil leucocytosis; a mononuclear leucocytosis with morphological changes in the white blood cells has been observed by Biondi, Legge, Goadby, Seitz (1923, amongst composers), and Thiele (1921, among painters), even in the absence of punctate basophil red cells.

**Technique**

**Vital staining.** — To bring out the presence of punctate basophilia in the red cells, a small quantity of a 10 per cent. solution in absolute alcohol of brilliant cresyl blue (or other azidine stain) is spread out by means of a glass rod on a slide previously slightly warmed. The alcohol evaporates immediately and the slide remains faintly stained blue (only visible when looked at against a white background). A drop of blood received on a coverslip is then placed on the slide without exerting any pressure, so that the drop spreads slowly and gradually gives rise to little bluish arborisations at the periphery. On examining (with the oil immersion) the central portion of the preparation, the filamentous substance of the red cells is seen to be coloured blue and the granular red.

**Dry staining.** — After securing a good smear on a slide (without having the red cells in rouleaus or superimposed one on another) and after drying the smear, it is stained with two or three drops of a solution of May-Grunwald for about 3 minutes. A few drops of water are then added to dilute the solution (in the proportion of 1 to 2) and it is allowed to act for 2 minutes. Then without washing, the slide is passed into diluted Giemsa solution (1 drop in 1 cub. cm. of distilled water) for 5-10 minutes. The slide is then washed under running water and dried with blotting paper (Biondi). The polychromatic red cells and the basophil granules come out blue, the azurophil granulations, Jolly bodies and Cabot rings in violet red. At the same time, if desired, the mononuclear leucocytosis can be demonstrated. Gilbert fixes the smear in absolute alcohol, stains for two minutes with an alkaline solution
of methylene blue (2 grm. of blue, 12 grm. of bicarbonate of soda in 200 grm. of distilled water) and washes until the colour disappears.

Schnitter (1919) uses Manson's methylene blue; Godby (1912) uses Romanowski's stain as modified by Wright; Hayhurst uses Harlow's solution which is the method used by the Division of Industrial Hygiene of the Provincial Health Office of Ontario. This method is really only a double stain with the one liquid (eosine and methylene blue), which also serves to fix the preparation as the colours are dissolved in methyl-alcohol.

In 1922, Schwartz proposed the method of the dense drop and staining by methylene blue and Manson's borax. But the presence of basophil red corpuscles obtained by this method must be interpreted very critically to avoid inexact conclusions. Koch (1924) used a solution of Giemsa Blue II of 0.05 per cent. strength (for two minutes).

The view, however, expressed by Lehmann is endorsed, viz., that it is far better to make several examinations than to pay too much attention to a minute count; also that of Teleky that the same method should be persisted in throughout an enquiry so as to avoid different results. Thus, for example, he has shown that in 20 cases of lead poisoning clinically established the number of red cells showing punctate basophilia varied from 38.6 to 100 according to the method adopted.

DIAGNOSIS

As in all diseases, the physician will not base the diagnosis of lead poisoning on one symptom alone, but once the action of lead or its compounds is suspected, he will diligently seek all the effects on the organism which the poison is capable of inducing. The characteristic signs are mainly: the blue line on the gums, colic, loss of power or paralysis of the muscles. The necessary steps to confirm the presence or absence of lead are examination of the urine or blood.

Though, as is the view of several writers, the blue line on the gums is the sign most constantly present (in 90 per cent. of cases according to Marvin Shie, 1921), it may certainly be lacking in undoubted cases of lead poisoning, especially when the persons exposed have bestowed careful attention to dental hygiene. The line is frequently preceded by a red line with a violet tinge. Other authorities consider that the line is present in only a third of the cases.

If it is not very marked it can be brought out by touching the gums with a 5-10 per cent. solution of monosulphide of sodium; oxygenated water, on the other hand, bleaches it. It has to be distinguished from other staining round the gums by such toxic substances as bismuth, zinc, copper, silver, mercury, etc., more especially as lead may be present without its presence being expected. Thus Koelsch describes the case of a brassworker who showed a deep blue line which, although apparently due to copper, was in reality due to lead as the dust showed 10 per cent. on analysis.

Whatever view is held, the blue line shows that the worker and his companions are exposed to the action of lead dust and that lead poisoning is imminent if they continue to work under the same conditions.

Colic is usually associated with constipation (more rarely diarrhoea) and is characterised by intermittent attacks, by its situation (the lower part of the belly), by slowing of the pulse, and by the relief given on pressure over the abdomen.

Loss of power, or paresis, localised most frequently in the hands (wrist and fingers), may also be an early sign of early poisoning in some persons.

The absolute value of the finding of punctate basophilia in the diagnosis of lead poisoning, as it was originally viewed by Grawitz, has had doubt cast upon it by other authorities. Its presence, however, has always the value of a note of warning which is not denied by those who will not go as far as Grawitz, e.g. Naegeli, who says: "The presence of punctate basophilia has a quite special value in the diagnosis of lead poisoning". The search for it must be carried out on very strict lines (see above); authorities are however not in agreement as to the necessity of basing diagnosis on a minimum number of basophil cells. Among those who hold this view, Schnitter would consider it advisable to transfer to other work every person employed showing more than 100 per million and considers as suffering from lead poisoning everyone with more than 500 per million. Schoenfeld bases a positive diagnosis on a count of 100 per million; Schmidt considers as suspicious every case showing this number, but would not suspend under 500. This proportion has been accepted in Germany. Though, as some writers say, it is wise to accept the view that 100 to 300 basophil red cells per million is an indication of latent lead absorption and 500 of active poisoning, others
are of opinion that this method is too much under the influence of subjective factors.

Kretschner (1924) considers that the presence of punctate basophilia is proof of serious poisoning when this is not accompanied by other symptoms, and Koch (1924) proposes to regard the total number of basophil red cells and polychromatophil red cells (which he calls granulo-polychromasia) as an indication of the gravity of poisoning. He fixes 100 granulo-chromatic red cells per million as the minimum limit for denoting suspicion and 500 per million for denoting cases of recognised lead poisoning.

In the course of a long enquiry in German lead colour factories, Lehmann recommends for consideration as signs of poisoning: punctate basophilia (250 and over per million), the blue line, haemoglobin (below 80 on the Talquist scale), high arterial pressure (above 100/50 for the age and sex of the individual), presence of albumin in the urine (even a trace), weakness of the extensors of the wrist. The presence, of only one of these signs is in Lehmann's opinion sufficient ground for looking upon the individual as "normal". Presence of 2 as slightly suspicious, of 3 to 5 as slightly affected, In the first group figures principally punctate basophilia and less frequently the blue line and anaemia; in the second group punctate basophilia and the blue line followed by punctate basophilia and diminution of haemoglobin. In the third group punctate basophilia (89 per cent.) and the combination of punctate basophilia, blue line and diminution in the haemoglobin (75 per cent.).

Opinion is very divided as to the practical value as a test of the resistance of the red blood corpuscles (Liebermann test) utilising saline hypotonic solutions.

Examination of the blood must be carried out by experts, and when this is the case it is of valuable assistance and cannot be dispensed with today, especially in doubtful cases. It is of the greatest assistance in deciding whether or not the suspension of a worker is necessary and urgent.

Questions of diagnosis are of special importance from the medico-legal point of view. If the symptoms which are really characteristic of lead poisoning (blue line, colic, paresis of the muscles supplied by the musculo-spiral nerve with the exception of the supinator longus) are not accompanied by proof of lead in the urine (even when assisted in its elimination by the administration of iodine) a definite diagnosis of lead poisoning could not be made. This position is still very important in the presence of other morbid symptoms attributable to lead but less characteristic, such as arthralgia, small atrophic kidney, etc. Such lesions, indeed, could not be proved to be due to lead, even if lead had been found in the urine. Moreover, punctate basophilia, and finally presence in the red blood cells of the Jolly bodies and Cabot's rings, although not characteristic of this form of poisoning, may, however, help in confirming the diagnosis.

In conclusion, it may be said that, though absorption of lead by the individual can be proved (by finding lead in the urine, and even in the blood serum by presence of a blue line, etc.), it is not possible, from the medico-legal point of view, without such investigation to assert absolutely, with the exception perhaps of cases of colic, that a given syndrome is saturnine in origin. It is not at present possible in a particular case to assert of certain symptoms that they are known to be the sequelae of chronic lead poisoning (arteriosclerosis, small kidney, etc.), that lead is the cause, and that it is the sole cause, even though it can be proved that there has been exposure to lead absorption.

**DEMONSTRATION OF LEAD**

(a) In the air, see article "Lead".

(b) In the organism (liquids, tissues, etc.).

— Every enquiry as to the presence of lead must always be preceded by a control test of the capsules, filter paper, reagents, etc., in order to be sure that there are no traces of lead in them. Capsules of aluminium can usefully be used, rather than those of porcelain, which may sometimes yield some lead.

Organic matter must especially be destroyed (by the method of Fresenius and Babo, etc.). In the case of urine, for example, the following procedure may be adopted: 150-200 grm. of urine (of the 24 hours' collection) are acidified slightly with nitric acid and concentrated over a bath marie and then completely decomposed directly over a fire. The dry residue is then treated with pure ammonium nitrate and the calcined product taken up in warm distilled water, slightly acidified with nitric acid, and submitted to the action of a solution of hydrogen sulphide or of a current of hydrogen sulphide gas. If lead is present a black precipitate is deposited. To control the reaction, collect the precipitate and dissolve it in nitric acid, dry a portion, take it up with distilled water, and colour it with a solution of sodium iodide: a yellow colour, more or less intense, is obtained, due to
the formation of lead iodide; treat another portion with a decinormal solution of potassium bichromate when a yellow precipitate of lead chromate is obtained; treat a third portion with two or three drops of sulphuric acid, evaporate until no more white fumes are given off; after cooling and dilution with distilled water a white powder of sulphate of lead is obtained.

Numerous other methods of procedure have been proposed to demonstrate the presence of lead as, for example, electrolytic methods and that with Trillat’s reaction (a tetramethyl base of diphenyl-methane dissolved in pure acetic acid) which reveals the presence of lead dioxide in a proportion of 1 in 3,000,000 and a concentration of less than one-hundredth of 1 mg.

Minot, Denis (1919) and Schumm (1922) have proposed modifications in the electrolytic method, but several experts are of the opinion that the chromate method suggested by Fairhall (1922) is the best, though it requires delicate manipulation and close attention. For research for lead in the urine, Fairhall has also proposed modifications in the method currently used.

Research for lead can also be made in the cerebro-spinal fluid (hexanitrite) method (Weller and Christensen, 1925); in the blood by the micro-chemical method proposed by Schmidt (1928-1929) with spectroscopic control. Walther and Werner Gerlach (1931) have recommended a method based on spectral analysis of emission for detecting lead present in small quantities in small fragments of tissue. Finally, there may be recalled the radio-chemical method of research for lead circulating in the system (Christensen, 1924).

HYGIENE.

On the technical side every effort must be made to stop lead dust and fumes by substituting mechanical methods for hand labour or by utilising automatic methods or wet processes according to the technical possibilities of each process. Every escape of dust and fumes must be prevented by locally-applied exhaust ventilation with hoods over each apparatus, and by effecting separation of dusty and dangerous operations in distinct workrooms, by provision of overalls, respirators, etc. so as to minimise as far as is possible the accumulation and absorption of toxic matter. Whatever possible lead should be replaced by substitutes either harmless or less injurious (e.g. in the pottery industry by the use of low solubility fritted glazes, in painting by the use of varnishes), and finding a substitute for metallic lead used as a weight or support in many jobs (e.g. in cloth-cutting or diamond-polishing, weights for Jacquard looms, etc.).

General measures against lead poison-
on industrial medicine, especially in Germany.

In considering the very serious problem of the transfer or suspension of a worker suffering from saturnism, the surgeon must take into account several conditions having a detrimental effect on health, such as former or recent attacks of lead poisoning, marked anaemia, tendency to hysteria and epilepsy, existence of extensive oral sepsis, mental weakness, careless personal habits, such as want of attention to cleanliness of hands and teeth or of clothing, or biting of nails, unwashed hands, etc., maladies which have induced poverty of the blood (e.g. malaria), short sightedness causing undue proximity to the work; amongst women menstrual troubles and especially pregnancy have to be borne in mind. On commencing work, therefore, every worker requires to be made the subject of careful individual examination and similarly any worker resuming employment after cessation for a time for illness, the object being to avoid taking up or resuming work with symptoms predisposing to lead poisoning. If necessary, the surgeon should consider transference to other work in the factory or to other employment free from risk of lead poisoning. Teleky (1924) advises change of occupation when the clinical picture of lead absorption shows itself rapidly even in the absence of the cardinal signs of plumbism. The association of granulo-basophilia with cachectic appearance should be a signal for transference to other work, according to the same authority. When granulo-basophilia only is present it might be advisable to wait and observe the evolution of the case.

When, however, the symptoms of poisoning appear rapidly among factory workers the management should be at once informed, because the conditions of work obviously require to be improved.

The periodical examination should be carried out so that the greater the risk the shorter the intervening period. Thus, for example, it should be weekly for workers dealing with lead compounds, white lead and lead colours, etc., monthly in accumulator works, smelting, painting, pottery, etc., quarterly in tinning (kitchen utensils, etc.) by means of vitrifiable coating substances, enamelling, etc. (see these articles).

LEGISLATION

Cases of lead-poisoning due to lead and its compounds are subject to compulsory notification in almost all the countries in which compensation is granted as for industrial accidents: Argentina, Australia (Queensland, South Australia, Victoria, Western Australia), Austria, Belgium, Bolivia, Brazil, Bulgaria, Canada (Alberta, British Columbia, Manitoba, North Branswick, Nova Scotia, Ontario), Chile, Cuba, Ecuador, Federated Malay Straits, Finland, France, Germany, Great Britain, Greece, Hungary, India, Ireland, Italy, Japan, Lithuania, Luxembourg, Netherlands, New Zealand, Norway, Portugal, South Africa, Sweden, Switzerland, U.S. S.R., United States (California, Connecticut, North Dakota, Illinois, Massachusetts, Minnesota, New York, New Jersey, Ohio, Porto Rico, Wisconsin, etc.), Venezuela, Yugoslavia.

For details see articles on the different lead industries and the article "Occupational Diseases: Definition and Compensation". For the Washington Convention, see articles "White Lead" and "Red Lead".

Numerous leaflets and instructions as to the medical examination of workers engaged in the lead industries have been published; those issued by the German Government are reproduced below.

Lead Notice

"Any person who in the course of his occupation comes into contact with lead or lead compounds (with the exception of galena) or substances containing lead is exposed to the danger of lead poisoning. This danger is the greater owing to the fact that the poison does not betray its presence to the worker either by smell or by taste (except in the case of acetate of lead) and thus he may take it into his system unawares.

"Lead poisoning is usually caused by lead, which is left sticking to the hands or clothes or beard, being taken into the mouth in very small quantities during eating, drinking, smoking, snuff-taking, or chewing tobacco or inhaled in the form of dust during work.

"The lead gradually accumulates in the body, and symptoms of lead poisoning appear sooner or later according to the quantity of the poison absorbed and the resistance of the worker.

"A blue-grey line on the gums (‘blue line’), close to the teeth, is a sign that lead has already been absorbed by the body in considerable quantities, and this disease due to lead poisoning is about to declare itself. The presence of a blue line should therefore cause the worker to take more care than before that he absorbs no further quantities of lead in the course of his work; it is at this stage possible that he may escape actual illness. On the other hand, it often happens that within a very short time, but sometimes not for some weeks or even months, lead poisoning specifically declares itself, and this is usually very painful, protracted, and in certain cases dangerous to life."
Prevention of Lead Poisoning

"Care and cleanliness are the surest protection against lead poisoning. In particular, the following directions should be observed:

(1) Hands and working clothes must during work be protected as far as practicable from contamination with lead, lead compounds, or substances containing lead. The nails must always be kept short. Smoking, snuff-taking, and chewing tobacco during work must be discontinued. Cigarettes, tobacco, pipes and other smoking utensils must not be brought into the workrooms.

(2) Workers must not take food and drink, or leave the workplace, till they have removed their working clothes and thoroughly washed their hands with soap and nail brush. The face, and especially the beard, must also be carefully cleansed if they have been soiled during work.

(3) The prescribed working clothes must be worn for all work in connection with lead. Respirators, damp sponges or bandages covering mouth and nose must be worn during all work involving the raising of dust, unless the dust is immediately and completely removed by exhaust ventilation, in order to prevent the inhalation of dust containing lead.

(4) The widespread belief that the regular use of certain remedies (iodide of potassium, sulphur tabloids, Glauber salts and other aperients), or milk drinking, is sufficient to prevent lead poisoning, is incorrect. On the other hand, a certain value must be attached to nourishing and fat-forming diets, and to that extent to milk drinking also. The use of alcoholic drinks, especially brandy, facilitates the attack of lead poisoning, and is therefore to be avoided.

(5) Exercise in the open air, gymnastics, baths, etc., increase the resisting power of the body, and should therefore be encouraged as much as possible.

If a worker who comes into contact with lead, lead compounds or substances containing lead becomes ill, he should immediately, in his own interest and that of his family, consult a doctor, and at the same time tell him that he has come into contact with lead during his work."

Instructions for the Medical Examination of Lead Workers (Dated 27 January 1920):

In pursuance of section 17 of the Order dated 27 January 1920 respecting the installation and working of establishments for the manufacture of lead colours and other lead compounds, the German Federal Minister of Labour issues the following service instructions for the medical examination and supervision of the health of workers in these establishments.

I. Examination prior to Engagement

The medical practitioner must examine every worker before he is engaged for work in any of the undertakings specified in section I, paragraph 1, of the Order respecting the installation and working of establishments for the manufacture of lead colours and other lead compounds, dated 27 January 1920, in order to ascertain whether his health is such as to render him suitable for employment in the establishment. The medical practitioner must, before the examination, ask the worker in what kind of undertaking he has worked hitherto, whether he has ever suffered from lead poisoning before, and what symptoms then appeared.

Workers must not be employed in the undertakings specified, except in cleaning the rest room, canteen, cloakroom, lavatory and bathroom, and in washing and mending working clothes; and male workers under 18 years of age must not be employed in establishments devoted mainly or exclusively to the manufacture of lead colours or other lead compounds (section 10 of the Order). The medical examination is consequently unnecessary for these workers.

The medical practitioner must regard as unfit for employment any person who has already suffered severely from lead poisoning (e.g. lead paralysis, serious or repeated attacks of lead colic), or who still shows symptoms of lead poisoning, however slight, or who owing to the nature of his previous employment must certainly have absorbed lead, and in whose case the present medical observations and the blood test—especially the presence of numerous basophil granules in the red cells—indicate that the appearance of lead poisoning in the near future is to be feared. Weakly or sullen persons must also be regarded as not suitable, especially those suffering from pulmonary tuberculosis, from diseases of the circulatory system or of a syphilitic nature, or those suffering from diseases of the kidneys, and persons addicted to drink.

The medical practitioner must, at the close of the examination, instruct the workers found suitable for employment as to the dangers of lead poisoning. His instructions must be based on the popularly phrased Lead Notice 1 issued by the Federal Minister of Labour. They must include due reference to the special circumstances of the works, namely, the way in which the worker must behave in order to guard against the absorption of lead, and to the symptoms of incipient lead poisoning.

The medical practitioner must, after the completion of the examination, prepare for the employer a written statement of his opinion as to the suitability of the persons examined for employment in the works.

1 Reproduced above.
II.—Periodical Examination of the Workers

The medical practitioner must inspect persons employed in the works at least twice a month in the establishments in which white lead, lead sulphate, litharge, or red lead is manufactured, and at least once a quarter in all other establishments to which the aforementioned Order applies; he must observe symptoms of illness, and especially those of any illness connected with lead, and examine thoroughly those cases which seem to him suspicious (section 17 of the Order).

During his inspections, the medical practitioner must ascertain by questioning each worker, whether there are any signs of injury to his health through lead work, or whether he is actually already suffering from lead poisoning. He must thoroughly examine persons whose cases appear to him suspicious in this connection, in a special room set apart for the purpose.

In the course of both the inspection and the examination, the following signs of illness especially must be watched for as symptoms of impending or already existing lead poisoning, viz.: the blue line, pallor, lead discoloration (pale, somewhat yellowish skin, bluish grey discoloration of the mucous membranes, pale yellow colour of the sclerotics), wasting, debility, pains in the head, loss of appetite, constipation and other digestive disorders, attacks of colic, diseases of the circulatory system (arteriosclerosis), arthralgia, disorders of the organs of sense, paralysis, albuminuria haematoporphyrinuria, kidney disease, increased blood pressure, reduction of the haemoglobin content, of the blood (anæmia), appearance of basophil granular erythrocytes (granular red cells) or other blood changes (polychromatophil erythrocytes, increased number of leucocytes together with numerous transitional and atypical forms), saturnine encephalopathy, cachexia.

The medical practitioner must carry out the special examinations for verification of the presence of lead poisoning in accordance with the appended directions.

If the examination establishes the presence of forms of lead poisoning which are dangerous to life or which may become so if long continued, especially saturnine encephalopathy, cachexia, chronic inflammation of the kidneys (not merely albuminuria), or recurrent paralysis, the medical practitioner must send to the employer a written proposal for the permanent exclusion from lead work of the person examined. He shall do the same in a case in which, although only slight lead poisoning is present, it has developed very soon after beginning lead work, or has recurred at short intervals and with increasing severity, and so indicates the presence of unusually high susceptibility to lead. Permanent exclusion from lead work must be proposed, moreover, in the case of those persons who are found to be suffering from pulmonary tuberculosis or alcoholism, even if they show no signs of the influence of lead, or are not suffering from lead poisoning:

In all other cases of lead poisoning, the medical practitioner must propose in writing to the employer the temporary exclusion from lead work of the persons concerned until the symptoms have disappeared.

If only granular erythrocytes (less than one granular cell in 50 fields of the microscope) are detected on examination — and if other diseases are not present, especially other disorders of the blood supply (such as malaria, pernicious anaæmia, leukaemia, cancerous cachexia, nitro-benzol poisoning) — or if a worker is found to have a blue line, lead discoloration, or haematoporphyrin in the urine, these symptoms must be regarded as signs of the effects of lead, but the patient should be regarded as not yet suffering from lead poisoning but rather as a lead carrier (Bleitragere). If it is feared, as a result of the medical observations and the blood test (especially numerous granules in the red cells), that a lead carrier will shortly develop lead poisoning, the medical practitioner must in his case also send to the employer a written proposal for his temporary exclusion from lead work until the symptoms have disappeared, and the condition of the blood has improved.

getting nipped in the door and bruises are caused by the regulating cord. Muscular lesions are not infrequent.

All these injuries should receive immediate treatment so as to prevent possible septic complications or absence from work due to sequelae as far as possible. This is especially necessary after injury to the head and spinal cord, because, in the latter case, long illness may be involved, with slow convalescence, and sometimes, indeed, after-effects lasting for years.

Surgical injuries are frequent enough from thickening of the sheaths of the flexor tendons of the fingers as the result of pressure from the regulating cord; and flat-foot from long standing. Flat-foot will readily yield to early treatment (slippers and special shoes); but in some cases treatment takes longer (application of plaster bandages), or even calls for change of employment. Varicose veins are frequent, and in severe cases may ulcerate. Bandaging may ease the condition. Hernia is not more frequent than in other occupations, and when it occurs may have originated in some previous employment. Glands, pharyngitis, laryngitis, bronchitis, come from exposure to draughts, especially in the aged. Tuberculous subjects should not be employed in this occupation on hygienic grounds (spread of infection). Arteriosclerosis cannot be said to be related to the occupation. Still, when it is present it would appear to increase rapidly among busy liftmen. Nervous and gastric disorders are no more frequent than in other occupations, although young liftmen in busy places show signs of it. Young persons are often subjects of headache and fainting attacks necessitating temporary absence from work. Cases of gassing have been reported when gas has been the motive power for working the lift.

**Legislation**

Generally, fairly detailed measures are enacted for safety of lifts and hoists in coal mines, factories, and private houses. Periodical examination is desirable. As to the conditions of work for young persons, for example, the Netherlands Decree of 10 August 1930, section 8, subsections 5-6.

**Bibliography**

Lignite

Lignite is a kind of coal which, according to its derivation, may be classified between lianthrax and peat. It assumes very varied aspects: black and compact, with a brilliant surface like lianthrax; fibrous, with the form, structure, and sometimes the colour of wood, utilised as a pigment in painting (Cassel and Cologne umber), and sometimes polished and designated "jet" when friable, the "bituminous lignites" or "heavy lignites", which resemble petrol rock in character. They are utilised for their distillation products (paraffin, oils, spongy coke). (See article "Shale Oil Industry").

The occupational risk and the state of health of the workers handling lignite have been very little studied, and this neglect may reflect the inferior origin from the point of view of industrial value.

Lignite

![Diagram of Lignite products]

Tar (specific weight 0.830-0.890)

Lignites constitute the first stage of the combustibles of fossil origin. They are to be found in France, Italy, Ireland, Switzerland, Central Germany, Galicia, the United States, etc.

They are generally classified in three categories: the "fossil woods", recalling in aspect the original wood; the ordinary "lignites", of an earthy aspect containing very often a large quantity of pyrites, also of lignite as compared with other combustibles.

Lignite is found in deposits, in stratified layers, and in veins at very varying depths (attaining at times 200 to 300 metres); it is also met with at the surface in banks; in the latter case it is quarried in the open.

The lignite occurs in solid form, in irregular pieces, the colour of which varies...
from black-brown to blackish-yellow. Its vegetable structure may be seen with the aid of the microscope.

Lignites are used industrially for the production of motive power, electric power, and furnace heating; they are also used for domestic heating.

Lignites burn with a long fuliginous flame, but even once the flame is extinguished combustion continues, liberating dense smoke, soot and gaseous products of combustion, amongst others, sulphurous fumes, which at times are present in such great quantity that they destroy the furnace grating.

The cinders are in the form of fine dust of a colour ranging from grey to reddish brown according to their iron content. They contain chiefly compounds of silica, alumina, oxide of iron, of lime, of sulphuric acid, and small quantities of magnesium, potassium, and soda, etc.

Lignites do not melt, but may be distilled without agglomeration. The dry distillation of lignites produces gases which may be used in special furnaces, oils, water, and gas retorts of refractory material (chain offes), ground paraffin, in the carburation of lighting gas, and in dry cleaning.

Lignites contain more or less extensive quantities (up to 8 per cent.) of a kind of wax which, since the war, has been utilised in Europe for leather polishing, lubricating greases, insulating material for electric cables, gramophone discs, etc.

The distillation of lignite under reduced pressure or in a current of hydrogen is generally replaced by extraction by means of solvents (alcohol, benzine, toluene, acetone, xylois, pyridine, phenol, chloroform, carbon tetrachloride, etc.) The best quantitative results are obtained with benzene-alcohol or toluene-alcohol. The lignite remains, however, impregnated with the solvent, which is recovered by steam.

The crude wax has to be purified and relieved of its resinous content, easily effected by the separation processes proposed by technical experts.

In Germany, bituminous lignite is used in the paraffin industry which, when distilled, furnishes a lignite or bitumen tar containing decomposition products of bitumen in the form of oils and of paraffin. The unaltered bitumen is extracted by means of boiling benzol, and placed on the market under the name of "Montan" wax. The distillation of the ground lignite is effected in vertical retorts of refractory material (chamottes), so placed in a suitable furnace that the outside walls are heated by the normal circulation of the hot gases from the hearth. The furnace is charged from above and the coke is discharged at the foot of the furnace. The raseous products are led by a large pipe at the top, whilst the liquid products (tar) flow out at the foot or along the walls and enter a duct into which the upper pipe also discharges its material.

With the aid of an exhaust device, the distillation fumes are directed into an apparatus for slow condensation; the gases not subjected to condensation are led under the hearth for heating the furnace. The tar is generally manipulated in special factories.

The latest tendencies in regard to the utilisation of lignites favour the so-called "internal heating" system by which distillation is effected by means of hot gases.

Certain qualities of lignite are submitted to agglomeration to facilitate transport and increase output. In this case, the lignites, as well as the dust, are dried (usually by artificial means), finely ground, made into a paste with the addition of an agglutinating substance (pitch, tar, resin, etc.), and compressed in moulds for the manufacture of briquettes. In the operations of transforming into paste or of mixing are left out, and only compression takes place.

Amongst the above operations the most harmful is that of grinding, during which great quantities of dust are liberated. The preparation and manipulation of briquettes are less so, since the material is more or less cohesive. The heating of briquettes liberates irritating fumes, since they generally contain pitch and other bituminous substances.

SOURCE OF RISK — PATHOLOGY

The occupational pathology of the workers employed in the lignite industry is to a great extent similar to that of workers in the coal industry. Here again, it is necessary to insist on the fact that medical experts who have made a study of conditions in the coal industry have not included those in the lignite industry, chiefly because the latter merely represent the former in a more attenuated form.

The extraction of lignite (in galleries or in the open) involves danger and risks which accompany all mining work. This explains why there is met with the same effect of heavy work on the cardial-vascular and respiratory systems. The system in general and the blood in particular show harmful effects due to the absence of daylight, to work in a confined space, to bad posture required by lack of space in the galleries (work effected kneeling or lying on the side, and sometimes even on the back). Other harmful effects are connected with conditions favouring rheumatism, draughts, humidity, or at times work in an atmosphere of humid heat.

The quantity of water contained in lignites being fairly high (it sometimes exceeds 50 per cent.) and the lignites being hydroscopic, it follows that there is little dust in the galleries, even in
the case of xyloid lignites, which are more dusty than black lignites. In any case, the quantity of dust is inferior to that produced by other types of coal.

The dry lignites (dried artificially or naturally) disintegrate and liberate much dust. The same disadvantage accompanies extraction of lignites outside the mine or in sheds when the product is freed by the use of a gas for removing surrounding soil. Dust is likewise produced during the manufacture of briquettes.

In certain mines of xyloid lignite, however, dust is liberated to such extent that after an hour's work the worker is quite black with dust. This dust, though constituted by ovoid or polygonal particles, with clean pointed edges, is not very harmful in itself, but may in practice cause damage due to the presence of inorganic particles such as sand and slate, etc.

It is, however, a question of mixed dusts, the harmfulness of which varies from one mine to another, and is in proportion to the degree of humidity of the lignite.

The respiratory lesions caused by this dust are similar to those currently met with among workers in the dusty trades.

The presence of toxic gases is usual in lignite mines: carbon dioxide due to a fermentation process of the product and capable of causing the strata to take fire; methane (fire damp), rare of occurrence, at least in the Italian mines, where fire damp explosions rarely occur (except in the mines of Ribolla in the Grosseto district). At the ordinary temperature in the galleries the lignites do not liberate toxic gases, but in the blasting and cutting sheds small quantities of carbon dioxide are sometimes met with.

The air of the galleries may further be contaminated by gases given off by used fuses from blasting, which sometimes contain very toxic products. Lignite fires are greatly to be feared as a menace to the safety of the workers, for, apart from accidents due to trauma, these fires may give rise to fire damp explosions, and even explosions of the dust in suspension in the air.

As in other coal mines, the combustible itself may spontaneously catch fire apart from explosion due to fire damp, etc., either by friction between two layers of the coal, or by the action of an unduly strong ventilation current on the salient corners at the gallery crossings.

The varying explosion capacity of the dust from bituminous materials is explained by their varying content in carbon dioxide, methane and its homologues. The recent experiments (1926) carried out in Germany have proved that bitumen in dust form constitutes a very explosive element in lignite, and that its explosive capacity is dependent also on the nature and chemical composition of the gases of distillation.

When the lignite catches fire underground, combustion is never complete because of an insufficiency of oxygen. There is, however, extensive liberation of fuliginous smoke of carbon dioxide, carbon monoxide, and sometimes even large quantities of sulphur dioxide, since sulphur is always present in lignite, and likewise of hydrochloric acid, as well as a series of aromatic substances, certain of which cause severe irritation of the mucous membranes.

Lignites have, on the contrary, the property of absorbing the oxygen from the atmosphere, especially when dried and exposed to the air, in which case they absorb large quantities. This explains why the atmosphere of the mines becomes rapidly unfit for breathing; the impoverishment of the air in oxygen due to this cause, in addition to the exhaustion thereof occasioned by the respiration of the miners and combustion of the lamps, constitute a triple cause. It may also be stated that lignites, according to their origin, contain certain impurities such as sulphuretted hydrogen and arsenic (Biondi).

Lignite mines may be infected by ankylostomiasis. In Italy, however, they are generally exempt from this infection (Pieraccini, Giglioli, Biondi, Mori). This fact has been noted also in the Italian copper mines, mercury mines, and pyrites mines, as well as in the lignite mines, despite the fact that certainly more than one miner who was a carrier of ankylostomiasis has penetrated into these mines, without, however, giving rise to an epidemic amongst other miners. No satisfactory explanation of this fact has been found.

It does not appear that handling of lignite, either in mines or industrially, particularly predisposes workers to tubercular infection. Anthracosis, due to lignite, irritation of the respiratory passages by dust, sulphur or other fumes, is generally accompanied by chronic bronchial catarrh, pulmonary emphysema, and disturbance of the pulmonary circulation.

It should also be stated that workers engaged in the galleries suffer chiefly from forms of rheumatic disease affecting the muscles and joints.
When the miner works with his back bare, the dust causes small contiguous patches on the skin, which favour the outbreak of folliculites and dermatites, sometimes extensive and persistent in character. Amongst the hewers there has been noted a conjunctival neformation situated on the right shoulder and due to rapid blows caused by the special tools employed. This lesion is not very important, though cases have been met with in which it showed irritation and gave rise to ulceration (Biondi).

Workers engaged in distilling lignite are exposed to injuries peculiar to the products described above. Nevertheless, medical literature contains no case of poisoning or of lesions among these workers. Lignite tar, and in particular certain of its distillation products (crude paraffin), have given rise to several cases of cancer. The first was studied in a tar distillery in the region of Halle (Saxony) in 1873; 3 further cases were described in 1875 by Volkmann; and other cases by Tillmanns (1880), Schuchardt (1885), Liebe (1892). The cases in question were designated by these authors as "paraffin cancer". It should, however, be recalled that the paraffin produced at this time was highly impure and contained other tar products which the workers were called upon to manipulate. Kennaway, who in 1923 resumed the study of the occupational cancer problem, revealed the fact that the cases due to lignite tar, and described in literature, amount to 10 (1873 to 1890), 7 of which were situated on the scrotum, 2 on the arm, to -10 (1873 to 1890), 7. of which were tar, and described in literature, amount to manipuJate.

Products which the workers were called paraffin, (Biondi). Other cases by other authors (1880), Schuchardt (1885), Liebe (1892). The cases in question were designated by these authors as "paraffin cancer."

The lesion is not very important, though cases have been met with in which it showed irritation and gave rise to ulceration (Biondi).

In conclusion, work with lignite may be considered as very slightly prejudicial to the health, and at least less harmful than the manipulation of other kinds of coal. The most important risks are those of a general character rather than of a particular order connected with the lignite industry, for it is more a question of the subterranean work causing physiological exhaustion, which is characteristic of workers in this industry. In fact, coal miners present the highest invalidity percentage, higher even than that of the workers in metallurgical trades who, nevertheless, have high invalidity rates. Lignite workers, on the contrary, show the lowest percentage among miners in general (Castellani).

The hygienic measures recommended are those to be found in the article entitled "Mines (Hygiene in)."

Legislation is similar to that for coal mines (see articles "Mines (Hygiene in)" and "Miners' Diseases").

LIME

French: Chaux; Chauv vive; Oxyde de calcium. — German: Kalk; Aetzkalk; Kalkerde. Calciumoxyd. — Italian: Calce; Calcina; Osso di calce. — Spanish: Cal; Protoxido de calcio.

Pure calcium oxide (formula, CaO) is a solid substance (density, 3.4), amorphous and very refractory, which fuses at 2,750° C. and only volatilises at the temperature of the electric furnace. It absorbs moisture with avidity and is converted, in the presence of water, into powdery calcium hydrate ("slaked lime") with much disengagement of heat in accordance with the formula, CaO+H,O=Ca (OH). This is the reason why lime exposed to moist air becomes reduced to powder — "slaked".

Derivatives of lime form the greater part of the earth's crust. From the technological point of view, various kinds of lime are used in industry and for building purposes;
**Fat lime.** — A pure lime, white, caustic, obtained by calcining a pure chalk (containing no clay). It owes its name to the property it has of yielding, with a sufficient quantity of water, a very fine, rich, abundant paste.

**Lean lime.** — Obtained by calcining impure chalks containing from 5 to 12 per cent. of clay or silica, as well as, in general, a little magnesia, oxide of iron, and clay. On contact with water, it yields a short and rather sparse paste.

These two varieties of lime constitute the air-slaked limes which, mixed with water, do not set except on exposure to air by the formation of calcium carbonate from the carbonic acid gas of the atmosphere.

Hydraulic limes are made by calcining chalks containing from 12 to 20 per cent. of clay (natural hydraulic lime) or artificial mixtures of clay and chalks in suitable proportions (artificial hydraulic lime). They are characterised by their property to set under water which is the more rapid the more clay they contain.

**INDUSTRIAL PROCESSES**

**Air-Slaked Limes**

Lime is obtained by calcining chalk or limestone at about 1,000° C. in two kinds of furnaces: intermittent and continuous. Intermittent furnaces, still used in small works near chalk quarries, supply the lime needed locally for agricultural and building purposes. They consist of a chamber in masonry with ovoid cavity and lined internally with bricks of refractory materials. Changing is effected through an upper opening or mouth; emptying at the lower part where the hearth is situated. First there is built a roof of large stones; then stones of diminishing size are introduced through the mouth in order to fill the kiln. The kiln is heated with wood, peat, or coal. The operation lasts about forty-eight hours; at the end of this time the kiln is allowed to cool and is completely emptied with the spade from an eye at the bottom. The continuous kilns allow manufacture to be carried on without any stoppage, charging being done about every twelve hours from above and discharging from below. They are of two kinds, with a short and long flame.

Modern works adopt especially kilns with short flame with certain improvements which, while economising hand labour and increasing output, greatly diminish risk to the health of the workers. In these kilns the charging made through the mouth comprises alternate layers of chalk and fuel. It is set alight from an internal hearth, which is not set in action except at the moment of starting.

Among recent models, the Candiot kiln is provided with a hood and counterforce covering the mouth and being able to slide alongside a chimney, which ensures sufficient draught to protect the workmen against the escape of smoke and hot gases even during charging. The lower part consists of a grill in the form of a basket. Emptying is thus done automatically by the pressure of the materials, the workman only having to intervene from time to time to facilitate the fall of the lime by means of a long rake.

The Maenstaedt kiln, entirely automatic, receives the chalk and fuel by a mechanical transporter, whilst to empty it a valve controlled by a counterpoise is used. The lower grid consists of cylinders of cast iron which by means of a rotatory movement, obtained from an electric motor, allows of automatic emptying and at the same time crushes the lime, which falls on to a mechanical transporting arrangement. Two valves moved alternately prevent direct communication between the inside and the outside of the kiln. The air necessary for combustion is blown in by a fan. These modern kilns allow of the recovery of the carbonic acid gas given off during the reaction.

The quicklime as it leaves the kiln oven (lime in cakes) is placed in barrels in this state or after slaking (see below Hydraulic Limes). It must be kept away from the air because it fixes the carbonic acid gas and regenerates the carbonate of lime.

**Hydraulic Limes**

Clayey chalks or mixtures of chalk and clay are baked in a continuous kiln with short flame.

The chalk and clay, in this case, are first ground by a mill in a vessel full of water. The mash thus formed is allowed to rest; the greater part of the water is removed by decantation; then the paste is divided up into sections, dried in the air, and carried to the kiln.

The Teil kiln is also used. This consists of a great ovoid shaft with a mouth at the upper part and an opening at the bottom provided with a grill, under which is the discharging gallery. A cone made of iron bars (mantle for air distribution) placed in the centre of the grill facilitates the ascent of air and the descent of the baked lime, which falls into the bogeys placed in the gallery underneath.

After baking, sorting of the pieces is carried out to separate the "well-baked" from the "unbaked" (which
go through the kiln a second time) and the "over-baked".

Hydraulic lime is always slaked with the object of making it absorb a rigorously determined quantity of water, so as to cause it to pulverise en masse (commercial form) by converting the quicklime into slaked lime. This operation can be done by hand, either with a sprinkler or nozzle. The lime is generally arranged on the ground in heaps 20 cm. high, which are watered. This method, however, presents so many technical and hygienic defects (disengagement of dust) that for a long time automatic slaking has been done with apparatus (Schultess apparatus, for example) yielding a quicklime in the form of a fine, dry powder easy to sieve.

The slaked lime is then crushed, ground, and finally sifted. The first sifting yields light lime; what is rejected is crushed and yields, after a second sifting, "commercial lime", and as rejected material a non-pulverulent residue, which is left for several months in silos, where it undergoes hydration and becomes pulverised. A final sifting yields "heavy lime"; the residues in this operation are again crushed and sifted to be used in the manufacture of certain cements.

The lime is conveyed to different parts of the works either by means of trollies or mechanically (travelling belt, Archimedean screw, etc.) until it is bagged or packed in heavy sacks (Schultess apparatus, for example) yielding a quicklime in the form of a fine, dry powder easy to sieve. The emptysacks of lime are returned to the factory, where they are again opened, bagging, barrelling, carrying, handling, employed in crushing, grinding, sifting, etc., especially if the work is done by hand.

Kiln chargers, further, have to do arduous work (carrying and handling the raw materials). The slakers are exposed to the action of dust when the work is done by hand. The lime dust is very fine, since with a 4,900 mesh to the square centimeter, 90 per cent, goes through, and is the basis of dust when the work is done by hand.

**Uses**

Lime is used either by itself or in the form of milk of lime.

- **Solid lime** is used in the following operations and industries:
  - Manufacture of cement; building industry (cementers, plasterers, white-washers, slakers of lime, rough casters, paperhangers, etc.); subterranean works; manufacture of calcium carbide by the electric furnace using a mixture of lime and coke); of chloride of lime and chloramines; in tanneries (dehairing of skins by means of a mixture of quicklime and orpiment); in dyeworks (as a decoloriser); in the manufacture of synthetic colours; in electroplastic work (for cleaning the pieces with a brush: mixture of pulverised lime and oil); in metal polishing (to keep the surface of the metal dry); in agriculture as a manure, etc.

- **Milk of lime** is used every time a strong and cheap base is needed in the following industries:
  - Manufacture of soda by the Solvay process, of caustic soda and potash, ammonium, sugar, soap, stearine candles, etc.; in gas-works (for purifying the gas), dye-works, the textile industries (preparation of the textile fibre before dyeing or printing, boiling the fibre in an alkaline solution containing milk of lime), etc.; in agriculture, etc.

**Sources of Danger**

(a) *In the course of manufacture.* — The stokers charged with filling the kiln, looking after the fire, regulating the air currents, etc., are exposed to the action of high temperatures, of brisk changes in temperature, to toxic gases (carbon monoxide, carbon dioxide, sulphur dioxide, arsenuirreted and sulphurretted hydrogen gas, etc.), especially when the draught is insufficient or defective; to dusts, etc.

Kiln chargers, further, have to do arduous work (carrying and handling the raw materials).

The slakers are exposed to the action of dust when the work is done by hand. The lime dust is very fine, since with a 4,900 mesh to the square centimeter, 90 per cent. goes through, and is the common risk for all the workmen employed in crushing, grinding, sifting, bagging, barrelling, carrying, handling, etc., especially if the work is done by hand.

(b) *In the course of its use:* see above.

(c) *In the course of the manufacture, and manipulation of products containing lime as an impurity:* basic slag (which contains up to 20 per cent. of quicklime); Swedish matches (dust with a high percentage of caustic lime); calcium cyanide (see that article), which contains up to 21 per cent. of quicklime (injurious to persons using it, e.g. agricultural labourers); spathic ores (carbonate of iron, manganese, lime), when discharging from the holds of ships (the particles of lime mix with the sweat and irritate the uncovered parts of the skin; they set up also lesions of the mucous membranes).
INJURIOUS ACTION

The action of quicklime is due partly to its avidity for water (dehydration), to the heat given off in its reaction with water, and partly to the peculiar causticity of the alkaline oxides or alkaline earths. Quicklime exerts essentially a local action (on the skin and mucous membranes), irritating and caustic, which is naturally less marked in the case of slaked lime. Milk of lime is a feeble caustic acting only on the mucous membranes. The dilute lyes are only caustic to the skin after prolonged action and especially when they are warm.

In practice it is the dust of quicklime and slaked lime, given off in the course of manufacture and manipulation, which gives rise to the well-known lesions. This very fine dust is deposited readily on the mucous membranes and skin; when inhaled it may penetrate as far as the respiratory tract.

STATISTICS

An enquiry, although not recent, was made by Rota and Finzi (1906) among the workmen in the lime and cement factories of Casali Monferrato (Piedmont). While conditions in the getting of lime-stone were not good: bad ventilation, variable temperature, and humidity of the galleries, etc. The men ran considerable accident risk, and among the maladies to which they were exposed were rheumatism, neuralgia, burns, and respiratory troubles.

Kiln men working in a temperature reaching 1,600–1,900° C. showed a morbidity especially from respiratory diseases (bronchitis, broncho-pneumonia), rheumatism, and, in summer, diseases of the digestive system due largely to the drinking of water to allay thirst. Under certain conditions, especially hereditary influences, morbid respiratory states prepare the soil for tuberculous infection. The workmen most exposed to dust were naturally those engaged in grinding the lime or cement, bagging, barrelling, and loading into trolleys.

According to these investigations, lime dust was considered more injurious than that of cement, because of the chemical and mechanical action it exerts on the skin and mucous membranes.

Morbidity data collected during several years among workmen either at their work or in hospital did not suggest that this class suffered any high morbidity. At the same time respiratory diseases, including tuberculosis, were the most frequent especially among the kiln men. Rheumatism and infections (principally typhoid fever) come second. Mortality figures show that respiratory diseases are the most important cause of death. Pesenti (1906), however, takes the view that there is a form of pseudophthisis, a chronic pneumoconiosis, which might be often diagnosed as tuberculosis.

Rota and Finzi emphasise the fact that many of the workmen they examined had worked from fifteen to thirty years and more in lime and cement factories without having been ill. This resistance to illness, even to lung disease, is a very striking characteristic. It is certain, however, that the daily inhalation of irritating dusts must slowly and progressively damage the air passages and that the effect of this must be to lead to some deleterious effect on the health of the individual. This fact explains why so few workmen reach an advanced age.

These writers were of opinion that from 1906 it would be advisable to exclude from the industry applicants affected with arthritis, epilepsy, and predisposition to respiratory diseases, especially pulmonary tuberculosis.

In Switzerland lesions due to lime or carbide of calcium reported to the National Accident Bureau numbered 14 in 1918, 5 in 1919, 3 in 1920, 5 in 1921, 5 in 1922, 5 in 1923, 3 in 1924, and 2 in 1925 (slaked lime had set up 3 cases of dermatitis).

PATHOLOGY

Lesions of the Skin

Like all dermatites, those set up by lime are favoured by certain individual factors (see article "Skin Diseases"). In appearance they show themselves in many forms and may assume the exfoliative type (the most frequent: it begins with a rash of more or less distinctly follicular distribution, red, weeping, sometimes with patches of fine desquamation, followed generally by a non-irritating papular eruption); vesicular (sometimes confluent and situated mainly on the back of the hand); pustular folliculitis (with thickened skin, dull, cracked, dry, with fine scales, sometimes with fissures at the base of the folds of the skin, especially the joints); seborrhoeic: erythrodermic (more or less generalised), etc.

In the manufacture of carbide, typical ulcers are met with, neatly punched out through the whole thickness of the skin; intertrigo; deformity of the nails (see article "Skin Diseases").

These dermatites always cease when the workman leaves the harmful influence. Usually they are not serious, but cases which relapse are known, so severe as to entail permanent incapacity.

The aetiological diagnosis is sometimes difficult because the patient cannot give precise details of his work, and it is often necessary to study carefully the materials handled in order to determine exactly the nature of the substance with which he has been brought into contact.
Lesions of the Mucous Membranes

The most frequent are those of the conjunctiva and cornea, due either to solid particles or splashes of the liquid entering the eyes.

Caustic action rarely occurs from quicklime because the workmen know the danger they run and take the necessary precautions. Burns from slaked lime are more frequent or from mortar or plaster, the caustic action of which may continue for several days. It is this long contact which explains the gravity of the lesions. It may lead to scarring.

The smallest particle of lime in the eye causes spasmodic closure of the pupils, copious lachrymation, which favour the spontaneous expulsion of tiny bodies from the eye but, in this particular case, is not advisable because closure of the eyelid compresses the particle of lime against the eyeball. The lachrymation, it is true, slakes the quicklime, but the heat given off in the reaction increases the destructive process and may lead to perforation of the eyeball. Cicatrization takes place generally with eversion of the eyelids: entropion or entropion, trichiasis (turning in of the eyelashes), and even syntropion.

Hoppe gives 282 cases of ocular lesions among which are the following: masons 122; cleaners of walls and ceilings, 64; porters carrying lime, 26; makers of mortar and lime, 19. On the buccal mucous membrane the lesion is generally characterised by small ulcers, itching rather than painful, rarely lasting, and appearing as white points surrounded with a red margin. The lesion has a transparent mililiary aspect. These phylctenular ulcers which break leaving an abrasion are situated generally on the anterior pillars of the palate, on the outside of the tonsils, on the uvula, etc. If the workman gives up his work they yield in twenty-four hours to simple gargling with ordinary or alkaline water. If he continues at his work the number of the abrasions increases but more superficially than in depth. Pain, with difficulty in swallowing, accompanies them. The mucous membrane is rarely stripped off and rarely bleeds (Fabri).

Ulceration of the nasal mucous membrane has been described, and, more rarely, perforation of the septum.

The deeper respiratory passages are rarely reached by the dust of lime, which sets up principally cough and sneezing. But cases of pneumonia due to inhalation of these dusts have been described.

Experience and the recent studies of Roessle have equally shown that workmen handling lime are relatively little attacked by pulmonary tuberculosis. Kiln men are said to have a mortality from tuberculosis less than the average. (See above, Statistics.)

The high temperatures, watching the fires, brusque changes in temperature, the hard work entailed in charging (when done by hand) and discharging show their effects in various morbid conditions such as bronchitis, affections of the lungs, joints, circulation (varicose veins, etc.), indigestion (due to the heat and excessive drinking of liquids), etc.

Cases, often fatal, from poisoning by carbon monoxide are described among workmen who have gone to sleep on the top of lime kilns. Severe caustic burns have been described in workmen who had fallen into a lime pit. Death has then resulted from extension of the lesions.

Hygiene

Lime kilns should be built away from centres of habitation and should, if necessary, be surrounded by a wall of masonry to serve as a screen.

Kilns connected to a chimney stack should be provided with strong draught. The charging level should be that of the surrounding ground so as to avoid all accumulation of poisonous gas at levels dangerous to the workmen. Measures should be taken for protection against radiant heat and escapes from the hearth and smoke. If the fuel used is not coke, very objectionable smoke is given off. Premises using lime kilns built with a view to the manufacture of liquid carbonic acid gas generally burn the carbon monoxide, so that inconvenience from these gases is avoided. On the other hand the airtightness of the apparatus and pipes along which the gases travel should be periodically tested and any escape of carbon monoxide, etc., stopped. Good ventilation should be maintained in every works, and all cul-de-sacs, pits, etc., where asphyxiating gases might accumulate should be avoided.

The raising of any dust should be as far as possible avoided by using closed apparatus provided with exhaust ventilation: Davidson's finishing tubes, centrifugal crushers, special kinds of sifters, etc. A slight negative pressure should be maintained round the apparatus, which should be covered with large enough hoods; bagging and barrelling should be done by automatic means (see article "Dusts"). The quantities of smoke which escape from the kilns should be as far as possible
freed of dust, which should be recovered by the different methods in use (bafflers, Beth filters, depositing chambers, etc.). Hand work should be replaced by mechanical work wherever possible.

The lime should be barrelled or removed immediately after it has been cooled. Unnecessary noise and vibration should be diminished or suppressed.

Personal hygiene resolves itself into wearing respirators (moist sponges), plugs in the ears, leather gloves, overalls and caps. The workmen are in the habit of smearing a little fat on the hands and repeating the application on the skin of the hands and arms even during the night, which is an excellent precaution. Personal cleanliness, change of linen and underclothing after work, and bathing are most desirable.

Treatment of burns to the eyes lies with the medical man. The particles of lime should be immediately removed or neutralised to prevent in good time injurious effect. Later treatment (Nedden) comprises daily irrigation for fifteen minutes with a 10-20 per cent. solution of neutral tartrate of ammonium. Nowadays the use of sugar and water, which was formerly recommended, has been abandoned because it came to be recognised that the saccharate of lime formed is extremely caustic.

LEGISLATION

Women are prohibited from work in lime kilns (crushing and riddling the stone) in Argentina; in grinding and sifting in the Netherlands. When the dust created during crushing, sifting, etc., is not removed by a mechanical process young persons of under sixteen years of age are prohibited by law from working in Belgium and Spain; under eighteen years in the Netherlands and France; under fifteen in Italy, as well as employment of women of under twenty-one in Spain, Italy, etc.

Special regulations for work in lime kilns have been issued in Austria (sections 8 and 12 of the Order of 1911 on work in sugar factories). German legislation takes account of the risk from lime in the Order of 1911 on the manufacture of chromates. The French Industrial Code, as well as the Austrian regulations referred to above, prohibit sleeping on the top of the kilns. A Norwegian Royal Decree deals with the processes of grinding and pulverising limestone. Certain statutory preventive measures have been issued in regulations dealing with the manufacture of cement.

ECzema and dermatitis due to lime are compulsorily notifiable in France and in the Netherlands (in premises for slaking and sifting); compensation is awarded as in the case of industrial diseases in Finland and Switzerland. Compensation for these lesions is also given in countries mentioning, in the list of scheduled diseases, lesions of the skin and mucous membrane due to dust or liquids.

BIBLIOGRAPHY

***

Litharge

French: Litharge. — German: Bleiglätte. — Italian and Spanish: Litargiro.

CHEMISTRY

Litharge (crisite, argirite) is a protoxide of lead (PbO) which is sometimes found in nature. The name, however, is reserved for the refined product, that of "massicot" (Germ. Bleigelb) is given to the calcined but unrefined product.

These substances are fusible at a red heat (880° C.), insoluble in water, readily soluble in dilute acetic and nitric acid as well as in the gastric juice. They dissolve in hot caustic potash, from which they crystallise out on cooling in the form of rhombohedral crystals.

Litharge has a yellow, sometimes a reddish colour, and is crystalline and laminated. According to the shade of colour it is known under the name of golden or silver litharge. Massicot is a soft amorphous powder of yellow colour.

MANUFACTURE

On heating metallic lead in contact with air, according to the temperature either litharge or massicot is obtained. The former is the important product of the cupellation of silver, and is obtained also on roasting galena and treating it then by soda or by calcining the carbonate or nitrate. Industrially, litharge and massicot are obtained during the melting of lead. This operation is carried out on the floor of a reverberatory furnace heated to 450-500° C. in contact with air. The lead is introduced in pigs of 50 to 100 kg. weight, and as soon as it melts the surface is constantly kept stirred to increase the oxidation and the layer of oxide floating on the surface skimmed off. This rabbling is done with a rake either by hand or mechanically. It would seem as though mechanical methods would altogether replace those by hand.
Dangers. — The great heat of the furnace predisposes to poisoning from lead fumes, but their injurious effect can be lessened by hoods with exhaust draught and provided with a pipe, allowing a spray of water to be projected between the workman and the furnace door. This latter precaution, however, is not always practicable. The workers, further, should be protected against the lead dust escaping from the furnace when the pigs are introduced, during fusion, and when the layer of oxide formed is removed. The amount of dust removed is very considerable.

Emptying the furnace. — This is a very arduous task and one of the most dangerous. The oxidised dry material is removed from the furnace by shovels or rakes and emptied into a trolley, which conveys it to the cooling bins.

The lead fume given off in great quantity from the extruded mass should be carried away by a hood arranged above the opening of the furnace door connected with a duct going above the roof. Such protection seems efficacious. Analysis of 90 litres of air in an Austrian works taken at the time of emptying showed traces of lead (less than 0.1 mg. estimated as oxide of lead).

The trolley when filled is ready to be moved; its contents are moistened with water poured carefully on them, the workman should wear a wet sponge over the mouth. The wearing of a respirator is always difficult to secure.

The deposition of dry matter on the floor in the cooling bins should be prohibited.

The dry material is then ground and washed to separate the protoxide from the metallic lead. This operation is carried out in vats under a stream of water either by hand or mechanically. The product is next dried again, is pulverised, sieved, and packed. All these processes are naturally attended with great risk because of the lead dust raised as they are done. All necessary measures ought to be taken to prevent the escape of dust into the atmosphere of the workroom.

Use

Litharge and massicot are used in the manufacture of red lead, of nitrate and peroxide of lead, of nitrites, white lead, in glass, in optical glass, in crystal, in paste, in pottery glaze (decoration); as a flux in painting on porcelain and on glass; in the manufacture of putty and varnishes; for accumulator plates, in rubber; as a drier of oil varnishes; in pharmacy for making lead plaster; in the manufacture of painted papers, and in the form of plumbite (compounds of alkalis with peroxide of lead); as mordanting agents.

TOXICITY

Massicot and litharge, being soluble in the gastric juice, are among the most toxic of lead compounds. Experiments on animals show that small quantities produce fatal results in a short time (a few weeks). While the minimal fatal dose for white lead is fixed for animals at 10 grm., that for the oxides is a little higher, but not more than 20 grm. The toxicity depends evidently on the form in which it is taken. In laminated form it is less toxic than as powder, because the former is less readily absorbed.

Statistics

Statistics are not available for workmen employed in making these two substances. Generally, they are classed with persons employed in melting lead. As to those engaged in using litharge in various industries, it will suffice to cite the case of a woman in a scent factory in Germany in 1913, who used a paste made of litharge; of a workman making electric insulators in Austria, 1913; and a case among workers in Great Britain making electric accumulator plates and rubber articles. (See the Medical Inspector's reports for Great Britain, 1914-1918 and following years.)

Lithopone

TECHNICAL DATA

Lithopone, also known as zincolith, Griffith’s White or Charlton’s White, is a mixture of zinc sulphide and barium sulphate, obtained by the hot precipitation of barium sulphide and zinc sulphate solutions.

Unlike white lead, it is not toxic, and is not affected by sulphuretted hydrogen.

Barium sulphide is obtained by bringing to red heat barytes or heavy spar, mixed with coal, in revolving furnaces. The mixture of sulphide and barium oxide formed is dissolved in filtered water, and the filtrate is treated by sodium sulphate. Barium sulphate is thus precipitated and caustic soda remains in solution. The process can also be effected by stirring with barium carbonate which is dissolved in hydrochloric acid. It is precipitated by sodium sulphate or dilute sulphuric acid in a cold state.

The Chemical Service of the Dutch Factory Inspectorate found traces of arsenic in samples of barium sulphate.

Preparation of zinc sulphate. — Zinc oxide in the form of powder, produced from all kinds of waste, mixed with water in closed mixing troughs till it has become a thick fluid mass, is poured into a stirring tub, in which, by the addition of sulphuric acid, zinc sulphate is obtained. After neutralisation of the excess of sulphuric acid, the mixture is filtered in filtering presses. The residuum, which contains a considerable amount of lead (17 to 40 per cent.), is washed out, dried up to the point beyond which it would give out dust, and sold for the manufacture of lead. The zinc sulphate solution is again purified twice in stirring tubs: with potassium per-manganate for the removal of iron, etc., and with zinc powder for the removal of arsenic, etc. The zinc sulphate dissolved in water is then filtered in filtering presses.

Instead of oxide of zinc, crude zinc sulphate is sometimes used. This contains amongst other impurities lead, 30-40 per cent. of which remains in the residue.

The Chemical Service of the Dutch Factory Inspectorate found about 1 per cent. of lead and traces of arsenic in a sample of zinc sulphate.

Preparation of lithopone. — A hot solution of zinc sulphate is precipitated with a hot solution of barium sulphate, the white precipitate is filtered, and there is added thereto a freshly precipitated hydroxide of magnesium. The mixture passes to the filtering presses, is thoroughly washed, dried and pulverised. It is mixed with ammonium chloride, brought to red heat, and, while still hot, cold water is poured on it. It is then filtered, dried, and finely ground. The mixture obtained contains, according to the kind of lithopone, 11 to 42 per cent. of zinc sulphide. There are other processes of manufacture which it is not necessary to describe here. The Chemical Service of the Dutch Factory Inspectorate has found traces of lead and arsenic in a sample of the lithopone.

No injuries to workers engaged in lithopone factories are known, save those reported by the German factory inspectors: one worker attacked by gastric pains and hemiplegia of the right side died after having handled a mixture of barium peroxide (44 per cent.) and barium carbonate (56 per cent.); the post-mortem examination revealed the presence of barium in the organs (0.5 grm. in the stomach and intestines). Hygiene experts have drawn attention to the strong toxic effect of the peroxide, which is readily soluble in water and effects its action without the necessity of the presence of a dilute acid as is the case for barium carbonate.

In 1924 in a factory of chemical products several workers engaged in handling the residues from lithopone manufacture in preparing cadmium were poisoned by the fumes. The enquiry revealed that the fumes in question were cadmium fumes rather than arseniuretted hydrogen. Of the ten workers attacked one died.

In 1925 cases of poisoning were met with under similar conditions in another German factory: of five workers affected one died. In this case the enquiry proved that poisoning was due to arseniuretted hydrogen, the arsenic being present either in the zinc or in the sulphuric acid used.

HYGIENE

In shooting the powdered zinc oxide from sacks into the hoppers of the stirring tubs, a considerable amount of dust is raised, which, by reason of its lead content (1-5 per cent.) and traces of arsenic (see these articles), constitutes a danger to the worker.
Requisite measures should therefore be taken to avoid liberation of this dust. The cleaning of the empty sacks should be carried out in a closed apparatus by means of suction.

The raw zinc sulphate is conveyed in tip-trucks from the store rooms to the tubs. A considerable amount of dust is produced in loading and unloading, especially in dry warm weather.

In filtering the zinc sulphate in the presses, a dust is left in the press-cloths, which contains about 30 per cent. Pb SO₄. Formerly these cloths were scraped with a small shovel. The new filtering presses are now provided with a rinsing arrangement by which contact with the hands is avoided.

The conveyance of the barium sulphate to the revolving furnaces is carried out automatically in a closed apparatus, as also is the conveyance of the barium sulphide.

The sulphuric acid is conveyed by *morte jus* from iron boilers by leaden pipes into the stirring tubs. In cleaning these reservoirs the worker, before going in, introduces marl (clay+lime), which is afterwards forcibly syringed with water.

**Prophylaxis**

Attention should be drawn to the wearing of gloves and respirators as a protection against contact with dust containing lead or arsenic.

**Legislation**

See article "Zinc."

(The Hague)
Malaria

French: Paludisme. — German and Italian: Malaria. — Spanish: Paludismo.

Malaria is a widespread disease in many temperate regions but especially in tropical countries. It is characterised by intermittent obstinate fevers which have a tendency to become chronic, and is accompanied by grave general disturbances and organic lesions which make this infection an important cause of physiological and economic misery in many centres of population.

There are three types of malaria: benign tertian, quartan and malignant tertian, and these three types are caused by three kinds of parasite: *Plasmodium malariae*, *Plasmodium vivax*, and *Plasmodium falciparum*.

These parasites are protozoa and, more precisely, protozoa working out their cycle of development in two different hosts: man and mosquitoes of the genus *Anopheles*.

In man the sporozoites, inoculated by the bite of the mosquito, undergo a sexual evolution which provokes the access of fever, recommencing periodically and finishing by the formation of sexual elements or gametes which can only continue their evolution in the body of the mosquito. When this has sucked them in with the blood of the malarial subject the sexual evolution commences by the fertilisation of the gametes, with which is associated the formation, in the intestinal wall of the mosquito, of an egg or zygote, which passes through the walls of the digestive tract and has been given the name of "oöcyst". Inside it are produced "sporozoites", that is, very small parasites which, on the rupture of their cyst, later invade the salivary glands and from there, when the mosquitoes bite the man's skin to suck the blood, they pass via the proboscis and enter the human organism with the saliva.

It is impossible to describe these phenomena in detail here. It will suffice to remark that wherever malarial subjects exist, whose blood contains sexual organic elements and at the same time the anopheles are able to suck the blood, the evolution of an epidemic of malaria is possible; but this possibility is not always realised because it demands the presence together of several circumstances such as: a temperature sufficiently high; a certain surrounding humidity to enable the sexual cycle of the parasite to develop in the mosquito (hence there is a seasonal condition for this in temperate climates which, on the other hand, does not exist in warm countries, where the disease is observed all the year round); a number, and that not too small, of malarial subjects and anopheline mosquitoes.

The disease is not effectively transmitted unless the malarial subject has gametes at the point necessary for development passing into the stomach of an anopheles mosquito which can live sufficiently long to allow of the evolution of the sexual cycle and inoculation of a healthy man with a sufficient number of parasites. The well-known factor of the presence of anopheles and malarial subjects in certain localities without the occurrence of an epidemic makes these regions become known as areas of "anophelism without malaria". There are, however, some districts where the generalisation just given does not appear to be sufficient because the anopheles may have adopted different modes of life, no longer caring, or unable, to bite men; but it is necessary to add that these are only hypotheses which require proof.

The anopheles (females) do not necessarily require human blood for the evolution of the eggs in a normal way; they can gorge themselves with blood of other mammals, the presence of which near man may thus be able to prevent his being bitten by mos-
quites and thus diminish the chances of malarial infection.

Although this malady can be conveyed by different kinds of anopheles, the most formidable are those that are called "domestic", because they pass a part of their lives in houses where excellent conditions exist for biting man. The wood-haunting species, as well as other domestic species, have fewer opportunities of biting man except when he is sleeping in the open air; furthermore, even those which infect themselves as just on the multitude of others and there is consequently little probability of their succeeding later in transmitting the malady to healthy men.

All the inhabitants of a malarial locality are exposed to occupational risk which is greater among certain classes. Those in easy circumstances, having relatively good accommodation, are less affected by anopheles. They live generally in the upper floors which are less accessible, and they can protect themselves against the bites by means of netting on the windows or mosquito curtains round the beds.

The risk is still less if the houses are remote from stagnant water or if the latter has been properly treated.

On the other hand, the peasant class inhabiting slums infested by the anopheles, who are sleeping as other workers may do in the open, or having to spend night hours outside their houses, and, lastly, many other persons whose organic resistance has been lowered by poverty, are more susceptible to contract the disease. Shepherds, soldiers, railwaymen and workmen engaged on sanitation enterprises, miners and generally all those who are badly housed, badly nourished and employed on arduous or unhealthy work are rendered the more susceptible in consequence. An important role is played in their case by ignorance and prejudice, which constitute an obstacle to many measures of social and individual reform.

The disease, of which the average incubation period is ten to twenty days and even more, is characterised by attacks of fever in which the temperature rises to 40-41° C. for some hours, but it recurs, according as the fever is quartian or tertian, at regular intervals of four or three days. The attacks recur at irregular intervals of three days or even less in tertian, malignant or tropical fever; the regularity of the attacks is not always maintained and may be absent because of the simultaneous presence in the patient of two kinds of parasite or of different generations of a single species, which have been developed by multiple and successive infections. Two other important symptoms are anaemia and enlargement of the spleen.

Malaria is a tenacious malady. Often, even in cases which have received adequate treatment, the fever reappears with all the other symptoms after a certain period of apparent health.

It is the frequency mainly of such relapses that characterises chronic malaria accompanied by increasingly severe anaemia bringing in its train profound organic debility (malarial cachexia). Malaria does not always present itself in the recognised typical clinical picture; more or less severe and atypical morbid phenomena affecting different organs then predominate in the clinical picture.

Finally, in certain cases the disease appears with symptoms of such gravity and so suddenly that the life of the patient is immediately in danger (pernicious attack).

A complication of malaria which may entail high mortality and which deserves mention is haemoglobinuria. It is said to appear sometimes as the result of an intolerance towards quinine or other remedies administered to the patient; it may also occur in direct relation to malarial infection or may be a morbid condition in which malaria is active as a predisposing factor.

No certainty exists of any real congenital or acquired immunity to malaria, but several facts nevertheless tend to show that the inhabitants of malarial regions resist the consequences of the infection better than immigrants from other countries. It may be that there are exceptional cases of complete immunity.

Diagnosis should be based normally on microscopical finding of the parasites. If they are not numerous or practically absent, recourse may be had to different methods of observation — examination of large drops of blood instead of the usual films; stimulating the passage into the blood of parasites which may be embedded in internal organs, a method which, however, has not yet been applied in a satisfactory manner, etc.

The prophylaxis for malaria is extremely complex and difficult, especially in cases where conditions are favourable to widespread dissemination of the virus. The principal bases for this prophylaxis are as follows:
(a) Direct Measures against Human Infection

(1) Radical treatment of the sufferer until a complete cure is effected, which is the easier the earlier treatment is begun. Availability of all means of treatment; very close control in order to reveal as soon as possible new cases of infection rendering infection by mosquitoes less and less frequent.

(2) Mechanical protection of houses by means of netting and mosquito curtains, periodical capture and destruction of mosquitoes in houses where this mechanical defence fails.

(3) Quinine prophylaxis which should be welcomed confidently; but it should be noted that if it is not well and regularly administered, as is often the case among a large population, it is not a sufficient safeguard.

(4) Combating by all means physiological and economic poverty, as these constitute conditions favourable to the occurrence and aggravation of malaria: improving the living conditions of the population; giving them clean and well-ventilated homes, etc.

(5) Enlisting the whole of the exposed population in the effort to combat malaria, with, as a consequence, the necessity for instruction and education in this sense.

(b) Direct Measures against the Mosquito

The existence of anophelism is linked up with local conditions, represented principally by stagnant water or water courses where the current is not sufficiently strong or clean and contains vegetation. The life of the mosquito varies according to its species; while certain mosquitoes can develop in pools of water formed by the rain, in the trunks of trees or in receptacles that have been thrown away, others prefer fresh and more abundant water. The fight against anophelism therefore demands a precise knowledge of the species in each region, as well as of their special habits; a well-distributed water supply; suppression of stagnant water by assuring a regular and sufficiently rapid flow in watercourses; combating plant growth; which is the cause of obstruction in the flow; and finally the control of river banks so as to prevent the formation of marshy land. All this is comprised under the name of "good drainage". The majority of the large-scale measures for improving sanitation only assist indirectly in improvement of the country from a sanitary point of view, by tending especially to restore the agricultural value of land hitherto uncultivated as a result of bad distribution of water. An economic improvement follows and conditions of life of the agriculturists improve, enabling a more or less extensive gain, according to numerous concomitant conditions, to be made on the malarial enemy.

These indirect benefits, often slow to show their effect and so often incomplete, become more marked and of greater importance if, in their execution, account is taken of the sanitary aspect as well as of the general principle laid down as to the distribution of water.

A host of useful measures, which may be designated matters of detail, include activities of less importance and of various kinds, the object of which is to favour the drying up of small reservoirs or expanses of water, especially around villages, or of modifying river banks, channels, ditches, etc., in such a way as to avoid hindrance to currents and formation of marshes. In this connection mention ought to be made of chlorination of dangerous water to a limit above that supported by malarial larvae, its treatment with petroleum or other toxic substances in solution or powder, destruction of surface-feeding fish, periodical emptying of irrigation reservoirs, periodical drying of ditches, etc.

LEGISLATION

Discussion on the question of whether malaria is an accident or an industrial disease has caused much ink to flow in Italy. It is true that the report on the Accident Compensation Act stated that malaria was excluded, but, on the other hand, interpretation of the Act has been rather different. As a matter of fact, during the war (in 1916) sufferers from malaria received compensation if they had been working in the military zones, and Appeal Court decisions awarded compensation for malaria as an accident even if it had been the indirect cause of the death of the workman.

Discussion mainly centres around the question of whether the inoculation point for the disease is "sudden" and "occurs in the course of employment". The question has been raised whether several inoculations are necessary. It is admitted that a single inoculation may be sufficient to cause the disease and that the number of inoculated parasites does not affect the question, or the duration of incubation and the severity of the infection.

Evidently the bite, as the primary cause of the malarial infection, can always be considered as single.
As has been said elsewhere (see article "Occupational Diseases: Definition and Compensation"), infective agents do not act quantitatively, but qualitatively.

The opponents of compensation take the view, on the contrary, that the risk of inoculation exists in every malarial area and that consequently the element of something "abnormal," "unexpected," and "sudden" which characterises an accident does not exist. The difficulty of defining the moment of inoculation and consequent proof that it has occurred "in the course of employment" is also present. While it is true that the risk is bound up with the environment, the limits are too indefinite to be able to admit this risk.

Those advocating claims reply that the risk is indirect, extending over all workers, but especially present in a greater degree for certain classes called on to live and to carry out their work in a malarial region. Discussion arises more in regard to the degree of the risk rather than to its existence. Certain authorities consider that it would suffice to prove that in the course of work the morbid phenomena are strictly connected with the work done, in order to justify the right to compensation.

The Arbitration Commission (Italy, 1930) was of opinion that in cases of malaria it was not possible to say whether the disease was contracted during work or under other conditions. Proof of specific risk was therefore lacking. The Commission pointed out that it has occurred "in the course of employment" is also present. Malaria cannot then be covered by the Accident Compensation Act.

The Central Commission has felt it its duty to resume the study of this question and to support a decision on the above lines.

Ranelletti (1930), who has in his turn examined the different points under discussion, considers that it is an industrial disease rather than an accident, because, he says, the legislature has from the first taken the view that the law on compensation for accidents during employment does not cover "malarial" risks: the element of a "violent cause" is lacking and while amongst some classes of workers it is possible to prove that it occurs "in the course of employment", it is a question in their case of an industrial disease and not an accident.

A Bill, which has not yet become law, was introduced in November 1930, interpreting section 7 of the Act of 31 January 1904, and section 3 of the Decree of 23 August 1917, which states that malaria is not included among accidents caused by violence in the course of work as envisaged by these sections.

Malaria is compulsorily notifiable as an industrial disease in the State of Illinois: Compensation is awarded in Brazil when it affects agricultural labourers.

Manganese

Manganese (symbol Mn) is a grey, hard, brittle metallic element, fusible with difficulty, which is found in various minerals: pyrolusite, managanite or acedese, warvicite, palomelane, braunite, hausmannite, etc. The mineral most used, however, is pyrolusite (manganese peroxide or dioxide), of which the ores contain 30 to 90 per cent.

Pure metallic manganese is obtained to-day by aluminothermy, according to the Goldschmidt process, starting with the calcining of the pyrolusite. It is also prepared by reduction of the oxides of manganese in the electric furnace in the presence of coal.

Manganese is relatively very little used. Its use is mainly in siderurgy as a de-oxidising and desulphurising agent and in the preparation of manganese steel.

The dioxide is the starting point in the manufacture of all manganese preparations. It is much used in the manufacture of accumulators, in the glass industry (decolorising agent), in pottery (as a colouring agent of the glaze), in soap, colours, etc. In chemistry it serves in the manufacture of chlorine or chloride of manganese, obtained as a secondary by-product, which is utilised to generate the dioxide which re-enters again into the cycle. The transformation of the chloride into oxygen compounds of manganese used to be carried out by the Weldon process in order to obtain the regenerated or artificial dioxide.

TOXIC ACTION

Manganese-bearing minerals have caused more symptoms of poisoning
among the workers who handle them than is imagined. Certain persons, it is thought, have a natural resistance to this kind of poisoning, this being assumed from the number of workers who have handled it for years in manganese factories without showing any symptoms.

In 1837 Couper reported the first case of chronic poisoning by manganese dioxide in a worker who was engaged in crushing the mineral; von Jaksch (1901) described three cases amongst workers similarly employed, and Embden (1901) published reports on several cases of the same kind, and these were followed by observations from Friedel (1902), Seiffer (1904) and von Jaksch (1907). In 1913 Seelert collected fifteen cases described by different writers and observers in Europe and at the same time Casamajor reported nine cases which occurred in the United States.

In 1919 Edsall, Drinker and Wilbur gave detailed information regarding three of thirty-nine cases which they had examined. In 1920-1922 the German inspectors of factories described in their reports three cases of neuritis which they ascribed to manganese poisoning. In 1921 Davis and Huey described two cases of poisoning among workmen in an iron and steel works where manganese steel was made; 38.6 per cent. of manganese was found in the coarse dust from the electrical furnace and 18.72 per cent. in the fumes. In 1922 Embden described a fresh case affecting a worker employed in crushing the ore, and the German factory inspectors in their reports for 1923-1926 reported three more cases from manganese mills.

Finally, in 1929 Hilpert read a paper to a medical society on a case which he had studied in 1909.

In Great Britain the first cases of manganese poisoning were described by J. R. Charles in 1922. They referred to three workmen employed in crushing pyrolusite, who presented nervous symptoms. A fourth case was observed by Bridge in a factory where crushing, sieving and packing the washed manganese ore was carried on. Of the three cases described by Charles, one proved fatal and at the autopsy degeneration of the longitudinal fibres of the pons was found. Bridge found that the workers in the factory had been exposed to much fine dust.

Experimental researches undertaken by Handowsky, Schulz and Staemmier bear upon the symptoms of chronic poisoning; those of Lewy and Tiefenbach (1922) on cerebral lesions. Grunstein and Popowa (1929) were able to induce by way of the gastric system degeneration of the nerve cells (brain substance), which was most marked in the corpus striatum and especially in the caudate and lenticular nucleus.

In the monkey, poisoning by manganese salts causes a clinical picture like that produced by lesions of the basal nucleus. Histological examination has shown particularly marked changes in the corpus striatum and globus pallidus of the lenticular nucleus.

According to Schwarz and Pajels (1923) natural pyrolusite provokes in animals an increase during the first months, and a diminution on the other hand in the later months, of the haemoglobin and of the number of red blood cells. So far as relates to toxicity Merck's manganese dioxide appears to be more poisonous than the pyrolusite; on the other hand, the pentoxide and the sesquioxide seem to possess the same toxicity and set up in the course of their administration a marked anaemia. Examination of the blood would thus have a diagnostic value enabling early cases to be brought to light by the anaemia indicating this type of poisoning.

**Sources of Danger**

Besides the toxic action of the mineral, the workmen in manganese mines are naturally exposed to the general risks of such work. Thus, according to the researches of Chmaladze (1928) in the mines of Tschiaturi (Georgia), the conditions of work leave much to be desired, the temperature varying between 12.2° and 18.2° C., and the relative humidity between 19 and 100 per cent. But the most important factor is the insufficiency of fresh air entering (defective movement of air in the shafts). The wetness of the mineral prevents the raising of great quantities of dust, of which the amount varies between 16 and 30 mg. per cubic metre. The conditions of work of those engaged in washing the mineral affects health adversely, as the work is effected in places where the temperature is below that of the outside atmosphere and the relative humidity very high; hence frequent illness from cold occurs.

The work of crushing, sieving, etc., exposes the worker to inhalation of dust, and danger from manganese fumes is present during furnace work. Baader and Mosheim (1932) have both published reports containing particulars of cases of poisoning by man-
ganese which occurred in the manufac-

**Pathology**

The symptoms of the first case observed by Couper consisted of a paralysis, progressively affecting the lower limbs in walking, accompanied by a certain "paresis" of the arms and difficulty in speech. The clinical picture was completed by excessive salivation, but there were no symptoms affecting sensation or tremor, colic or digestive trouble. Comparative analysis of this case of intoxication provides a clinical picture typical of the majority of the cases commencing with difficulty in walking. This is spastic, characterised by rest-

ing the metatarsophalangeal joint against the sole of the foot ("stepping gait") (Hahnertritt) — von Jaksch symp-toms. Nervous symptoms show them-selves regularly, with weakness and

fatigue, a tendency to falling for-

wards when rising and of leaning for-

wards when walking; further, spas-

modic laughter and weeping, paraes-

thesia and tremor of the hands. The

voice becomes monotonous and there

is rigidity in movement with loss of the fine movements of the hands. Finally, an increase in the depth of the respirations has been observed.

Abnormal emotional mental symp-

toms have been reported; the mind is

only rarely affected. Irritability and

the onset of emotional disturbances

and persecution mania have been noted.

Objective examination brings out
difficulty in walking, exaggeration of

the tendon reflexes and of the muscular

tonus, combined with a stolid face and a monotonous voice. In no case has the Babinsky plantar reflex or sensory trouble been found, nor has atrophy been seen. The pupils are not altered in size nor in their reactions; the visual field is normal, although ex-

amination of the fundus of the eye often shows retinal anaemia or con-

gestion.

The cranial nerves have never been found to be affected except in the case of those of the face, affected by paresis causing loss of saliva. As cer-

tain sufferers complain of paraesthesia, lesions of the nerves have been sug-

gested. However, exaggeration of the tendon reflexes and the absence of objective sensory troubles or a mus-

cular atrophy are arguments against any alteration of the peripheral nerves.

Examination of the cerebro-spinal fluid yielded normal reactions without a trace of manganese. Salts of manganese have been found in the bile (Wichert and Harnack) and a small quantity in the intestine and in the urine.

The exact pathology of manganese poisoning has not yet been established with
certainty. The analogy between the clinical picture of this form of poiso-

ning and Parkinsonism on the one hand and the Wilsonian syndrome on

the other makes one suspect analogous cerebral lesions. This has been con-

firmed by the observations of Rohuro Ashizawa (1929) in regard to a chronic case of manganese poisoning which was followed by a post-mortem ex-

amination. It was that of a man of thirty-three years employed in crush-

ing the ore. Six months after com-

mencing work he fell ill, with symp-

toms recalling those of lesions of the corpora striata: hypertension, mask-

like features, tendency to fall back-

wards, objective speech, sardonic laugh-

ner. The malady ended by reaching the pyramidal tracts (exaggerated patellar reflexes). In 1923 poisoning became complicated with tuberculosis and death followed in 1924. Micro-

scopic examination showed degener-

ative lesions of the nerve cells and particularly in the globus pallidus, the lenticular nucleus and the caudate nucleus.

The lesions were less important in the brain, the thalamic region, the corpora quadrigemina and the medulla oblongata.

The fairly extensive lesions found in the liver tissue (Embden) make still closer the connection between poi-

soning by manganese and the Wil-

sonian syndrome.

Attention has been drawn elsewhere to the fact that very often, when a case of progressive lenticular degeneration is found, enquiry brings out the fact that work with manganese was as-

sociated with it.

The disease proceeds progressively when absorption of the poison is con-

tinuous. When absorption ceases, the symptoms after having reached their maximum remain stationary for a more or less lengthy period and then tend to diminish gradually. Thus re-

covery has been described in two fur-

ther cases reported by Charles as re-

sulting from cessation of work. Never-

theless, if the intoxication lasts for a sufficiently long time, a definite lesion results which involves permanent in-

capacity for work.

Attention should also be directed to the observations of von Jaksch as to the occurrence of a true "mangano-

phobia" among workers with man-

ganese. A morbid apprehension leads to the same clinical picture as intoxica-
tion from manganese, but is differentiated from it by the fact that it is of functional origin: very marked diminution of the visual field for white and red and disappearance of the phenomena as a result of adequate treatment (high frequency current). The presence of manganese in the urine was not found.

HYGIENE

The prevention of poisoning by manganese is relatively simple and can be effected by the wearing of a respiratory mask at all times in the presence of dust or vapour, protection against the dust (working clothes and gloves) of the parts of the skin exposed to its influence, since the occurrence of skin absorption is a recognised fact; personal hygiene on the part of the worker. Local exhaust ventilation should be applied at the furnaces to remove fumes and likewise for removal of the dust given off in crushing, sieving, etc. This measure is attended with the best results, for it was found, when applied in one particular factory, that it removed all risk of poisoning encountered by the workers over a period of five or six years.

LEGISLATION

Injury due to manganese is included in the Workmen's Compensation Acts of Chile, Germany, Great Britain, Switzerland, the State of Ohio (poisoning by manganese dioxide), Switzerland (poisoning by manganese peroxide) and the U.S.S.R. (under the general head of industrial poisonings).

BIBLIOGRAPHY

Matches (Lucifer)

HISTORICAL

Matches were invented by Chancel of Briançon. According to Littré they date back to the fourteenth century; Villon (fifteenth century) refers to them in his will. Whether that be so or not, the heads of the matches invented by Chancel were prepared with sulphur and chlorate of potash, and they did not light until they were immersed in sulphuric acid. In 1830, "strike-anywhere" matches (which the Germans attribute to Kammerer, the French to Saunier, and the English to Walker) made their appearance. The sulphur in these matches was covered over
with chlorate of potash, antimony sulphide, and gum; they lighted by friction on glass paper. They were soon improved by replacing the antimony sulphide by phosphorus, which enabled them to ignite more readily. In order to avoid the danger from the use of chlorate of potash, which produced a little explosion at the moment of ignition, Trevani, of Vienna, in 1835, used as an oxidising agent a mixture of red lead and peroxide of manganese, and Preschel, in 1837, peroxide of lead and a mixture of red lead and saltpetre. In 1844, 1860, discovered phosphorus; in 1847, Schröter, of Vienna, suggested replacing the white phosphorus by the red as being non-toxic, less inflammable, inodorous, and more resistant to moisture.

In 1852 Bottcher prepared safety matches without phosphorus which ignited by friction on a surface containing 50 per cent. of red phosphorus.

In 1857 Canouil similarly suggested non-phosphorus matches prepared with dextrine, chlorate of potash, peroxide of lead, pyrites, iron or sulphide of antimony, and a colouring substance. He was followed by Ghigliano, Kummer and Gunther, Jetter, Wiedeshold, Craveri, and others, but without appreciable results. Towards the end of the nineteenth century the French monopoly adopted a paste of Sévene and Cahen composed of 90 parts of sesquisulphide of phosphorus, 200 parts of chlorate of potash, 110 of peroxide of iron, 60 of oxide of zinc, 140 of pulversed glass, 100 of glue, and 290 of water. But the sesquisulphide, proposed by Puscher in 1860, discovered possessing certain advantages, had the disadvantage of containing impurities. At the same time the brothers Purgotti, of Périgueux, placed on the market safety matches of red phosphorus which have been definitely adopted by the industry.

The manufacture of matches is the industry presenting the greatest danger of industrial phosphorus poisoning. It thrives chiefly in Russia, Japan, Norway, Sweden, Finland, Poland, and in Italy.

Manufacture

(a) Making the splints.—The manufacture of matches comprises that of the splints, the heads, and of the boxes. The splints can be either of wood or wax. For wooden splints Russian aspen has generally been used, sometimes poplar (Belgium, Italy) or pine (for sulphur matches: Switzerland).

The wood is cross sawn either by hand or the machine into blocks of a certain length which are then divided into strips and these again into uniform splints, each of about 2 mm. in thickness. The rods are then divided into little pieces of the length of matches. They are inserted in an iron frame, and dried in a room heated by steam. In some workrooms forced drying is used; the splints are laid on hurdles or drawers which are introduced into a closed box through which hot air is drawn by a fan. When completely dry they are placed in a revolving drum where they acquire a certain lustre from friction with a little paraffin.

The sorting or straightening of the splints is done on a table slightly inclined and divided into a series of longitudinal channels. The bottom of this table is latticed and pierced crosswise by a series of slits the size of which is equal to half the length of a match, thus allowing the unduly short splints to pass through these slits.

(b) Impregnating.—The splints are next dressed. Safety matches are impregnated before drying, that is, are dipped in a bath of phosphoric acid and ammonium phosphate often containing, in addition, some colouring substance. The process is carried out in a barrel or a vat of cemented masonry. Its object is to prevent the matches from showing any point of ignition as soon as the flame is extinguished.

Preparation of the paste for the heads is done in a separate workroom. The ingredients are mixed cold, except when the composition contains phosphorus, in which case the vat is heated to liquefy the mass. Above the vat is a hood with exhaust draught to carry away the poisonous fumes. This process can be done in special apparatus, hermetically closed and kept in a bain-marie. A duct carries the fumes into a chimney.

The substance composing the paste varies in different factories. For ordinary matches, formerly, white phosphorus, sulphate of lead, powdered glass, and glue were used. In addition, they may be dipped in a sulphur bath.

In England the paste used consisted of white phosphorus (60 per cent.) mixed with an aqueous solution of glue, powdered glass, and an oxidising solution: chlorate of potash and zinc white with chalk or kieselguhr or peroxide of lead, red lead, and a colouring substance (aniline, fuchsine, lamp black). A paraffin bath followed.

For safety matches use was made of the following: flowers of sulphur, chlorate of potash, zinc white, ochre, powdered glass, glue, gum arabic and colophony.

At the present time matches are used made of sesquisulphide of phosphorus, the paste for which consists of sesquisulphide of phosphorus, chlorate of potash, zinc oxide, red ochre, powdered glass, strong glue, and water.

The application of the paste to the splints is done by machinery. This process can be carried out in two ways: in the "Seebold" method the splints are arranged in parallel lines by means of
a mechanical device, and are then introduced into frames which keep them in position. In the "Lagneau" method the sticks are introduced into the frames anyhow without preliminary arrangement. The frame is formed of a perforated plate with holes into which the splints fit. It must be kept in a vertical position to prevent the splints falling out.

In order to make the head, one extremity of the splint is dipped into a bath of sulphur or paraffin and then into the phosphorus paste. At the present time the bath which obliged the workman to plunge his hands into the phosphorus paste is no longer used; the frames are dipped vertically into the first bath of sulphur and paraffin (kept melted by the heat from a burner, or by a coil of pipes through which steam is passed) and then into the inflammable paste which is spread out in a thin layer on a table. The paraffined matches have the whole splint impregnated. In well-managed factories each table is provided with a hood for removing fumes. Obviously, however, the operation is much less dangerous when dipping is done mechanically and the paraffining by steam.

(c) Drying.— After having been soaked in paraffin or sulphur and then dipped in phosphorus paste the matches must be dried before they are boxed. The drying is done in stoves, generally heated by steam. Each match contains on an average 3-5 mg. of phosphorus on heating by steam.

(d) Boxing.— Match boxes can either be of cardboard or wood. The former are only used for phosphorus matches and are made either in the factory (by machinery) or as a home industry. They are made from a single piece of cardboard; the different operations reduce themselves to folding the edges and application of the starch paste. Wooden boxes are habitually used for safety matches. The manufacture of these boxes comprises two series of operations: the preparation of the veneers of wood, then the fashioning of the boxes, done by hand or by machinery, the whole followed by drying in a cabinet through which passes a current of hot air, and into which the boxes pass one after the other on an endless band.

Filling the boxes is done either by hand or by machinery. Application of the rubbing strip made of powdered glass or iron fillings fixed with glue is done last in order to reduce to a minimum the risk of explosion or spontaneous firing of the contents. The rubbing surface in English matches consists simply of a layer of glue on to which sand or powdered glass is applied.

The boxes are, lastly, made up into packages. The frictional surface of safety matches is an inflammable composition containing red phosphorus mixed with powdered glass, manganese dioxide, or sulphate of antimony.

Probably 90 per cent. of the matches made to-day in Great Britain, America, Sweden, and some other countries are made in remarkable continuous machines, in which practically blocks of wood entered at one end pass through all the processes of impregnating, dipping, drying, and boxing mechanically, except for the final regulation of the number of matches per box.

Logs of wood are placed on a peeling or veneering machine, by which long thin veneers of wood are peeled off. These veneers—the thickness of a match—are piled on top of one another and fed into machines containing a guillotine and subsidiary smaller knives, which cut the veneer into match lengths. One such machine will make 56,000 splints a minute.

The match splints are boiled for five minutes in the impregnating solution and subsequently, for the next two hours, are rolled round and round drums for polishing and drying purposes. They then pass through screens to collect the matches so that they lie the same way, and they are fixed in slowly moving flexible metal bands. The serpentine coil of plain splints carries the matches through a bath of paraffin wax, then over a roller covered with the igniting composition of sesquioxide, etc., and after that they travel up and down the serpentine coils over heated drums, while fans assist the drying by the extraction of air.

Finally the matches drop automatically into steel slots the size of the match boxes and the boxes are brought opposite to these slots and filled. It is only at this point that hand work comes in, to prevent unduly tight packing and to detect any irregularity, or any imperfect boxes.

(e) Special kinds of matches.— Some kinds of matches differ from safety in certain particulars. Thus, for example, "repsticker" matches are matches of a new type, of which the head is prepared not only with the mixture of substances entering into the composition of the heads of safety matches, but also containing other substances used to form the frictional surface. This paste contains red phosphorus which
MATCHES (LUCIFER)

explains why it will strike on any slightly roughened surface.

Paraffining is done after the head is made so that the inflammable material is protected by an impermeable coat. The "reptstickor" matches are consequently less affected by moisture than ordinary safety matches.

Wax matches differ from the ordinary "strike anywhere" matches in that the splint is made up of cotton threads saturated in, and enveloped with, wax. Their manufacture comprises two series of operations; first the spinning of the thread, next cutting to length, sorting, pressing, trimming and mounting. Dipping and drying are done in the same way as with wooden matches except that the head and rubbing surface is rather different. In these the splint portion is generally white and the head red.

**DANGER**

At all stages of the operations involving contact with phosphorus, the workman is exposed to phosphorus fumes, and to the white fumes of which the acid and piquant smell is due to the formation of nitrate of phosphorus, which, in combination with oxygen, forms hypophosphorous, phosphorous, phosphoric, and phosphatic acids. According to Thorpe, these products are present in the following proportions: 20-25 per cent. phosphorus, 10 per cent. phosphoric acid, and 70-78 per cent. phosphatic acid.

Thorpe found the following results on analysis of the air in a lucifer match factory in London: In the largest workrooms, ventilated by open windows, there were present, at a point 35-40 cm. above the liquid phosphorus mass, 0.00002 grm. of free phosphorus or of the oxide per 100 litres of air; and in the small and less well ventilated rooms, where boxing was done, 0.00012 grm., as well as noticeable quantities of visible fumes produced whenever the matches fired accidentally in boxing — a very frequent occurrence. Calculating that on the average 1,800 respiratory movements are made per hour, the quantity of phosphorus inhaled can be estimated at 1 mg. in the rooms where mixing of the paste is carried on, and 6 mg. in the boxing rooms.

This same expert found that 22 workmen, after working four hours, showed on their hands about 1.7 grm. of phosphorus, and the water in which these workers washed their hands contained 0.0373 grm., although they had washed with soap and a nail brush before commencing work.

The specially dangerous processes are the preparation of the paste, dipping, drying, and filling the boxes. When white phosphorus was used, Teyxeira estimated that 60 per cent. of the workers in match factories were affected by it.

Use of the sesquisulphide can also set up lesions of an eczematous character. Legge, in 1906, reported the occurrence of such an outbreak on the skin of some dippers, but not those employed in the mixing. In 1920 he described cases of conjunctivitis and was of opinion this was due to hydrogen sulphide given off in the process.

Paraffin can also set up eczema (especially on the hands) in the women engaged in boxing.

In addition to the effects peculiar to phosphorus poisoning (see article "Phosphorus") other fairly characteristic eczematous lesions are met with among match makers. Burns (of the first, second, and third degrees) are especially common among those releasing the matches from the frames prior to boxing. They are localised on the palm of the right hand, especially about the hypothenar eminence, and the first phalanx of the ring and little fingers. The character of these burns varies, however, with the kind of paste used. They are very painful with paste containing chlorate, but in this case the burn is relatively limited and heals fairly rapidly. On the other hand, if the paste contains red lead, the lesion is very painful, widespread, and heals more slowly.

Mention should be made of the danger from lead compounds, chrome, etc. used in making the paste, but which are not known to have caused serious damage except in the case of chrome compounds — ulceration of the skin and perforation of the septum of the nose (Moritz and Röpke, etc.).

In some Swedish safety match factories chrome salts are used to the extent of 3-4 per cent. in the paste (about half a milligram per match head). Wodt has reported 84 cases of chrome ulceration, some severe, either on the fingers or nasal mucous membrane, with perforation of the septum. Lastly, the manufacture of Danish matches has caused localised skin irritation on the hands of dippers, etc. Rasch in his opinion (1918) that 6 to 7 cases coming to his knowledge were due to traces of white phosphorus on the rubbing surface which had been carried by the fingers to different parts of the body.

Machinery has led to the disappearance of traces of certain lesions—teno-synovitis and whitlow—described by Arnaud, which formerly troubled the persons making the sticks.
A vicious position of the fingers (especially of the little finger) has been observed among the boxers, more commonly when they are young persons, in applying the metal stick for opening and gumming on the labels, etc. They do the various operations with the thumb and index finger, keeping the others in a position of forced flexion. This position induces a permanent spasm of certain groups of muscles or a contraction of the palmar fascia due to small multiple and repeated injuries, or to synovitis of the permanent spasm of certain groups of tendons of the flexor muscles of the fingers due to the same slight localised multiple and repeated injuries.

**STATISTICS**

The first case of phosphorus necrosis in a match worker — Moritz — was described in 1845 by Lorinzer. The data do not enable one to follow the extension of this malady in the early years after the industry was established.

In Germany 49 cases were reported in 1847. Moritz and Röpke, in a report in 1901 dealing with 64 workers in a match factory at Hitdorf (Solingen), reported 14 cases of pyorrhoea alveolaris, and 19 of ulceration of the septum with perforation in two cases. The first case of phosphorus necrosis reported was in 1896, and in the period 1896-1902 on 48 in the clinic at Neustadt-Jena. Hölze in 1905 cited 947 known cases of phosphorus necrosis in Europe, but recognised that his figures were not complete.

In Austria between 1866 and 1875 the hospitals of Vienna treated 126 cases. For the period 1896 to 1905 the cases numbered 350 to 400.

In Belgium, for the years 1904, 1906, 1908, and 1910, not more than one case was reported yearly, but the medical inspectors, taking account only of these persons 65 per cent, were exposed under the age of 16 (121 boys and 195 girls). Of these persons 65 per cent. were exposed to the risk of phosphorus poisoning — women and children to a greater extent than the men. The Report describes more than 150 cases, with 4 deaths.

In Great Britain, according to the Annual Report of the Chief Inspector of Factories for 1899 (p. 318), the total cases of phosphorus necrosis in the match industry in the previous 20 years (including cases also in the manufacture of phosphorus) of which there was definite record numbered 102. Prior to 1896 there were 92 cases; in 1898, six; and in 1899, four. Three other cases were reported in 1899, but they did not reach the stage of necrosis and were included among the suspected cases. Nineteen of the 102 cases were fatal.

Between 1900 and 1904 there were 9 cases (3 fatal), and between 1905 and 1908 8 cases (2 fatal). Subsequently no further case has been reported in match factories. This happy result in British factories was largely due to willingness on the part of the holders of the patent rights of the non-phosphorous paste to allow other manufacturers to use it.

In Italy, 100 cases occurred between 1877 and 1913, but the wide development of match making as a home industry makes it probable that this figure ought to be higher owing to unrecognised cases.

The monograph of Vallavatta, published in 1914, states that 5 cases of necrosis were treated in 1912-1913 in the Industrial Diseases Clinic of Milan, and gives a list of 58 cases for the period 1874 to 1905, for which had not been published hitherto. Of these, 6 had occurred in the match factories of Lombardy, 18 in those of Piedmont, 9 in those of Tuscany, while 21 had been reported between 1904 and 1913 in the factories of Rome and Venice.

The morbidity percentage for Italy for some years before 1913 was about 1.4, while statistics from other countries before the abolition of the use of white phosphorus show, for Great Britain 1 per cent., for Switzerland 1.6—3 per cent, and for France 2.3 per cent. These percentages are reckoned on the number of cases and the number of workpeople, but without regard to the fact that quite half of the latter are not in contact with the toxic agent even in the most dangerous factories.

A more methodical enquiry carried out in an Italian factory, taking account only of the workers exposed to danger, gave 2.76 per cent. of cases of phosphorism,
distributed according to the different departments, with a maximum of 10 to 12 per cent. for the workers employed in mixing the paste. Introduction of machinery has certainly improved the hygienic conditions, but in spite of that phosphorus necrosis seems still to be pretty frequent, as in the space of two years 11 cases were treated by the Industrial Diseases Clinic of Milan. Between 1914 and 1918, 12 cases (with 1 death) were reported in a single factory.

In Norway, since 1913, when the law prohibiting the importation, manufacture, and sale of matches made with white phosphorus came into force, no case of phosphorus poisoning has been reported. (See also article "Explosives": Fireworks.)

**Hygiene**

The main safeguard is careful examination of persons seeking employment and rejection of those with defective teeth. At the same time periodic medical examination must be arranged for, so as to detect at an early stage dental defects. Should a workman have undergone dental treatment for an extraction he should not be allowed to be re-employed until the wound has completely healed. The dental examination should be in the hands naturally of a dentist, but even this measure does not suffice to guard against all danger of phosphorus poisoning.

As regards the hygiene of the different processes, these should be conducted as far as possible in well-ventilated workrooms: each process in a separate room, and the walls and floor should be carefully and regularly cleaned. Of first importance is locally applied exhaust ventilation as near as possible to the point of generation to remove the fumes to the outer air. The fumes have a tendency to spread from their point of origin, and if the hood is placed too high the atmosphere of the workroom is vitiated. A case in point illustrating this was an Italian factory where cases had been very few, yet on installation of a bad system of exhaust ventilation, which dispersed rather than extracted the fumes, 5 cases of phosphorus poisoning occurred.

Mixing the paste should be done in iron receptacles capable of being tightly closed.

The dipping table should be provided with a series of exhaust hoods situated at its posterior end so as to draw the fumes away from the worker. Further, a powerful fan should be placed in the roof of the room where paraffining is done.

Good ventilation should be provided for the trimming and drying rooms, and entry into these should not be allowed until this has been carried out. Through ventilation should be kept up in the drying stoves so long as the workers have to enter them, and a thermometer should be hung in these stoves which should not show a higher reading than 35° C. Hands labour here should be replaced by mechanical means rendering entry into the stoves unnecessary.

Packing should be done in large well-ventilated rooms separate from the other workrooms. The windows should be provided with metallic screens of very fine mesh.

The quantity of raw materials in hand should be limited and waste (shavings and everything likely to cause risk of fire, etc.) removed every day. All suitable precautions must be taken against fire (in construction and installations, etc.). Special precautions should be taken to protect the workers engaged in mixing (danger of load, red lead, nitric and chlorate of potassium). Working hours should be limited and workmen instructed as to the professional risk they run.

In Germany the following measures have been suggested since 1884: prohibition of work with phosphorus paste; exclusion of women, young persons, and children from the following processes: dipping, drying, boxing, and preliminary packing; limitation of the hours of work; complete separation of the rooms in which the most dangerous processes are carried on; special installations of ventilating fans, etc., for preventing toxic fumes entering the workrooms; rooms of sufficient size for ample cubic space and a sufficient volume of air per person so as to reduce the proportion of fume as much as possible; good mechanical ventilation; maximum temperature of 38° C. in the drying stoves in order to avoid excessive evaporation of phosphorus; daily cleaning of the floors, machines, and trimming rooms; repainting of the walls every six months; provision of overalls, and of separate cloak rooms and of washing accommodation for the face and hands; evaporation of turpentine vapour in rooms where much phosphorus fumes are given off; compulsory cleaning of the teeth with a dentifrice or permanganate of potassium at the cost of the employer; submission of plans of new and of alterations in existing, factories to the Factory Department; medical examination before taking up employment and at periodic intervals with exclusion of all persons suffering from dental caries and phosphorus poisoning, etc.
LEGISLATION

Whether the preventive measures had not been constantly enforced or whether they had not been adequate, it is clear that no sensible diminution in cases had been achieved up to the time when a beginning was made with the prohibition of the use of white phosphorus, although technical progress allowed the carrying out automatically of almost all the processes.

The first country to pass a law prohibiting the use of white phosphorus in the manufacture of matches was Finland in 1874, followed in 1879 by Denmark. For four years no case of phosphorus poisoning has been reported in these two countries. Switzerland prohibited, provisionally in 1879 and definitely in 1898, the use of white phosphorus. In 1901 the Netherlands followed suit.

In Germany a motion presented to the Reichstag on 27 June 1879 demanded the prohibition of white phosphorus in the match industry, but a Committee of Enquiry contented itself with the recommendation of Regulations, although acknowledging that prohibition was the simplest and most effective solution. The law of 10 May 1903, however, prohibited, as from 1907, the use of white phosphorus in the manufacture of matches as well as their importation and sale. As the prohibition hampered exportation — the very high price of red phosphorus placed the countries using it in a position of inferiority in international markets — a Convention (Berne, Convention of 26 September 1906) was signed by France, Germany, Italy, Luxemburg, the Netherlands and Switzerland to prohibit on their territories the importation and exportation of such phosphorus. Some delay in the execution of the agreement, however, was recognised as necessary for the industry to adapt itself to the changed conditions and the alterations in the cost of production. This was fixed at three years for the countries signing the Convention and at five for those which might subsequently signify their adhesion to the Convention. Poland (14 January 1921) and China (6 December 1923) have thus subscribed.

The following States have since then signed their adhesion to the Berne Convention: Austria in 1909, Great Britain, New Zealand and New South Wales in 1910, Hungary in 1911, Mexico in 1912, Canada in 1914, Japan in 1921 (to come into force in 1922), Belgium, Bulgaria, Estonia, Finland, India, Irish Free State, Palestine, Rumania, South Africa, Spain and Sweden.

The United States, by a law in 1912 (enforced in July 1913), imposed a tax on white phosphorus matches, and since 1 January 1913 and 1914 prohibited interstate importation and exportation of such matches.

It is worth noting that, as no industrial disease resulted from the use of sesquiphosphide of phosphorus, Switzerland, after 30 years' experience, abrogated the provisions of the law requiring special measures for the workers such as preliminary medical and subsequent periodic examination.

Young persons were prohibited from dipping, drying, and packing under a certain age, which differed in the regulations of different countries. This exclusion, however, has become purposeless in view of the prohibition of white phosphorus.

Regulations relative to match factories were issued in Finland (1924) and in Portugal (1926).

As regards notification of and compensation for necrosis see the article "Phosphorus".

BIBLIOGRAPHY

See the articles "Phosphorus", "Amorphous or Red Phosphorus", and "Phosphorus Compounds".

Dr. L. Ferrannini (Naples).

Mechanical Engineering and Metal Work

Under this title have been grouped all industrial operations following metallurgical extraction and serving to transform the products furnished thereby into finished objects adapted to the multiple needs of industrial or social activities.

Mechanical engineering comprises roughly all static constructions, i.e. all metallic parts for the building trade and public works intended to constitute fixtures (bridges, frame-works, etc.), mechanical apparatus for general application and characterised by the fact that in contrast to the above they constitute essential parts of moving machinery (motors, haulage apparatus, etc.), mechanical material and machine tools varying infinitely in accordance with the material manipulated and the products to be obtained, the construction of transport material (land, sea and air), and operations of maintenance, repair and demolition (breaking up of ships, for instance), which constitute in themselves highly specialised industries. Along with mechanical engineering may be considered a certain number of other industries. For instance, the large-scale and small ironmongery trades (manufacture of various instruments midway between large forged articles and small objects made by wheelwrights; utensils of medium and small dimensions, principally household goods), ironwork; edged tools, tinsmiths' goods, and certain special types of manufacture, such as the manufacture of arms, for instance.
The raw materials are many and varied in form, and are generally delivered in their crude state by metallurgical factories.

The following metals are used: iron, steel, cast iron or steel in the crude state or moulded, copper, zinc, lead, aluminium, brass, bronze, various alloys, etc.; numerous products of mineral, vegetable or animal origin, serving especially as accessory material (flint, grindstones, wood, cardboard, paper, leather, animal hair, etc.); various products such as rubber, vulcanised fibre; colours and varnishing materials (as means of protection of the metal against external agents and for imparting to the finished objects a more agreeable aspect and facilitating their maintenance); red lead or minium; iron oxide: oil colours, varnishes, enamels, etc.

The principal operations may be summarised as follows:

**Shaping** (subsequent to foundry work and circular brushing or allied processes; stamping, sheathing with metal, rolling, wire-drawing, drawing, plate-bending, cutting-out, etc.); rough shaping; work on machine tools; effects this operation by means of processes formerly done by hand by means of machines which are partly or totally automatic: lathes, boring, drilling, threading, screw-cutting and grooving machines. The articles are then adjusted, fitted and inspected. During this phase of production the articles in question are sometimes subjected to operations which modify their hardness or malleability: tempering (by water, oil, molten lead, cyanides, etc.), followed by annealing.

**Finishing** comprises a series of operations amongst which are included scouring and other chemical (cold bath) or mechanical (sand spray) — grinding and polishing, sharpening, etc. Scouring with a sand spray is becoming more and more widely utilised in foundries as well as for metallic objects prior to enamelling; nickel-plating and hard soldering, etc. For this operation there is used a spray consisting of a fluid (air, steam or water) projected under pressure and at great speed against the surface to be treated and carrying with it a mass of sand or other substance having similar properties (carbon-bondum, lead shot, etc.). The pressures and the products utilised vary in accordance with the technical needs, and may be applied by means of a free spray, generally under a hood, or in special apparatus or in chambers provided for the purpose, or by means of a spray which is completely enclosed.

**Polishing** of objects is effected by files or brushes on a polishing lathe, by a wooden grindstone covered with buffalio leather, and by the application of various products: rouge, pumice, emery, whiting, etc. (see articles “Metal Grinding and Polishing” and “Abrasives”).

**Assembling and fitting** consist in grouping together the different elements for machine construction, and comprise various operations, such as, for example, tightening, cold and hot riveting done by hand or by means of a pneumatic hammer, smoothing, white soldering, autogenous welding, hard soldering, etc.

The fitting of metallic constructions involves the erection of scaffolding, hoisting of parts, fixing and erection properly so-called. Mention should also be made of the work of ship-breaking.

The operations of galvanisation, plating with zinc, lead or nickel, chrome-plating, etc., with a view to covering the metal with a protective coat, are generally effected prior to fitting. The latter operations comprise finishing, scraping, pumicing, painting and varnishing. Many of these operations have been made the subject of special articles.

Apart from the above operations relative to the manufacture of metals in general, mention should here be made of a long series of special industries such as metallic rope works, manufacture of screw nails, bolts, nails and lattice-work, etc.

Finally, the working up of raw materials of all kinds may be remarked, practised in certain cases (manufacture of rolling-stock, for instance). Similarly, there should be included mention of certain work carried out by other occupational grades: wheelwrights, cabinet-makers, harness-makers, etc.

**SOURCES OF RISK**

In view of the numerous and very various operations dealt with in this article, it is obviously difficult to summarise all the possible sources of risk met with during such work. On the other hand, there is a danger of repeating here matter already dealt with in other articles (“Abrasives”, “Metal Grinding and Polishing”, “Copper-Boiler Making”, etc.). For this reason attention will be confined to enumerating the most important causes of danger without attempting to provide a complete list of these.

The material handled may constitute a source of risk by reason of the dust liberated during the numerous operations referred to in preceding paragraphs. These dusts are generally of mixed origin: mineral, animal or vegetable; and may comprise coal, sand, abrasives, metal, as well as dusts of animal or vegetable origin: from the accessory products utilised, such as buffallo leather, cloth, sawdust, etc.

Reference should also be made to the sand projected by the sand spray, since this sand contains silica, calcium carbonate and various impurities (iron, iron oxide, lead, etc.). Thus, for instance, attention has been called to the presence of considerable quantities of lead which have given rise to cases of lead poisoning (J. Werner, 1928). The lead content of the sand was reduced after usage demonstrating the passage of lead in the form of dust: a variety
of sand, the lead content of which was 0.52 per cent., prior to use in the sand blast, only contained 0.34 per cent. of lead after the operation. In all cases sand particles exert a harmful effect on the worker's health by reason of their irritant effect on the respiratory passages.

As regards the effect of pumicing and dry scraping of metallic surfaces painted with lead colours, reference should be made to the investigation conducted by McNair and Price (1927). A true epidemic of serious cases which occurred at Detroit (1921-1924) in the motor industry has been described by Donald and Dean.

The use of certain cements with a minium or white lead basis exposes workers to the lead risk. Thus lead poisoning was notified as occurring amongst riveters engaged on coating the interior of the riveting-hole with minium prior to the introduction of the hot rivet, and amongst workers engaged in the construction of locomotives while effecting the particular operation of levelling the wheels on their axes (use of white lead). Paints for protecting metals, and in particular those for protecting constructional metal work, have a minium basis, especially for the basic coats. At the present time in many cases rapid drying paints are utilised (with a benzol basis), or cold enamels.

Acids are used for cleaning and scouring. Tempering baths have a cyanide basis. For the oiling of machine tools use is made of mineral oils (see articles "Petroleum" and "Fatty Substances"), with a view to preventing heating and seizing of the metal and accelerating expulsion of metal turnings and shavings. In certain work use is made of vegetable or animal oils and very often of an emulsion of fatty substances in an alkaline solution (soap). It is important to recall in this connection that the waste used for cleaning machines until it is completely impregnated with oil or blackened grease, not only favours the harmful action of these products, but further, having undergone neither washing nor disinfection, often represents a means of transmitting various pathogenic microbes (infection of wounds). It should further be recalled that such rags constitute also, in the absence of adequate precautions, a cause of fire.

The use of red hot baths and tempering baths is becoming much more extensive, especially with baths containing a mixture of nitrates of potassium and sodium heated to 500° C. The dangers of explosion and fire have induced the workers to demand an enquiry into the causes of very serious accidents which have occurred on several occasions. It was at first thought that organic material was to blame, then a light metal "electron" inadvertently admitted to the bath. It was, on the other hand, proved that the real cause was water, the accidental penetration of which into the nitrates in a molten state gave rise to explosion. The particles projected, when coming into contact with organic substances, cause instantaneous ignition (Gremp).

Certain operations in which there is exposure to the combined action of dusts and lubricating products are particularly dirty.

Gases, fumes and smoke coming from the hearths of furnaces, as well as from the metal in course of manipulation (melting, forging, welding, etc.), constitute a fairly frequent cause of contamination of the atmosphere. There may be cited as an instance the acid, sulphuric and nitrate fumes liberated during scouring and burnishing, the droplets from the baths, which are thrown off in steam and disseminated in the surrounding atmosphere, the hydrocyanic acid (found to be present in small quantities by Leschtschinskaja, 1927), the carbon dioxide and also monoxide coming from the hearths and from poor gas used for heating, etc. Attention has also been drawn to the possibility of poisoning by arseniuretted hydrogen during scouring of sheet-iron plates by means of sulphuric acid containing traces of arsenical substances (case of Barker in 1864; seven cases in Great Britain in 1902; three cases reported by Gerbis, one of which was fatal, in 1925; one case in the United States in 1928; in regard to which, however, the subsequent enquiry showed doubt as to its professional origin); by lead (Legge), etc.

The manufacture of beryl, a light metal which in small quantities enters into the alloys of other light metals such as aluminium, gives rise during melting to hydro-fluoric acid fumes. These fumes have caused fairly serious injuries amongst workers, and particularly a cutaneous eruption lasting several days. Even certain persons inhabiting the neighbourhood have suffered from illness as a result of the toxic and evil-smelling gases liberated.

There must not be overlooked certain injuries due to the use of polishing, lacquering and painting products used on metals (alcohols, ether, acetone, various solvents) as well as the operations of repairing vats, boilers, cist-
erns, especially when these contain heavy oils, petrol spirit or other toxic products.

The conditions of work may also constitute sources of risk. Where the work is carried out in the open air, there must be taken into account the influence of the inclemency of the weather on the system (damp, great heat, rain, wind). Likewise work undertaken in partially open sheds may involve exposure to heat rays (radiant heat from the ovens, forging of metallic objects at red or white heat) and luminous rays (during welding, for instance), certain of which are very rich in ultra-violet rays. It is also necessary to remember the effect of noise on the hearing and on the nervous system.

There are besides certain operations which, were they not effected by means of mechanical or automatic apparatus, demand a very great expenditure of physical energy, and which are liable to cause strain and exhaustion. On the other hand, whilst many machines economise the physical labour of the worker, they make on him at the same time other heavy demands: rapidity of movement, close attention, dexterity, visual concentration, etc. During other operations work has to be accomplished under special conditions and requires special selection of the workers: for instance in metallic construction of buildings (skyscrapers), in the course of which the worker is obliged to work on a framework and to accomplish at times highly dangerous balancing feats; in marine construction, on scaffolding of temporary construction above the water, or within the holds, etc.; on ship-breaking (danger of lead poisoning).

The working posture peculiar to certain types of work (see article “Metal Grinding and Polishing”) may represent a source of danger when combined with an unduly long working shift, thus favouring the outbreak of phenomena of fatigue and exhaustion. Thus, for instance, there has been reported amongst certain workers obliged to work in a standing position on account of the inclemency of the weather on the system (damp, great heat, rain, wind). Likewise work undertaken in partially open sheds may involve exposure to heat rays (radiant heat from the ovens, forging of metallic objects at red or white heat) and luminous rays (during welding, for instance), certain of which are very rich in ultra-violet rays. It is also necessary to remember the effect of noise on the hearing and on the nervous system.

Apart from certain old statistics prepared by Sommerfeld and Hirt and quoted by Zadek, no important statistical data exists relative to morbidity amongst workers engaged in mechanical engineering and metal work.

Based on an analysis of cards belonging to the Austrian Sickness Funds and relating to metal workers in Vienna, Adler and Herzmark has drawn attention (1921) to the great frequency of tuberculosis amongst these workers, especially amongst young persons — affections of the pulmonary apex, and more particularly still amongst women between twenty and thirty years of age who appear to be much more frequently affected than the male workers. Amongst locksmiths and mechanics the percentage of days of sickness due to tuberculosis diminishes with advancing age.

In Germany amongst workers engaged in a ship-breaking yard (Kiel) Engelsmann found in 1923 that 32 workers out of 39 engaged on cutting sheet iron coated with zinc by blow pipe suffered from affections similar to zinc funder's fever. The action of lead being eliminated, the author ascribed the troubles to absorption of zinc. In another shipyard 22 out of 41 workers showed symptoms of lead poisoning. Analysis of the air gave a lead content of 5.6 mg. per 100 litres of air.

In Great Britain from 1920 to 1927 the medical inspectorate received reports of 265 cases of lead poisoning — 138 cases only in 1924 — one of which was fatal, due to lead fumes volatilised by the action of the oxyacetylene flame used for cutting metal (painted with red lead!): enquiries by Legge, Bridge, etc.

Riveting also involves a risk of lead poisoning. In 1928 Fraenkel recorded a case of poisoning due to a cause so far unknown. The piercing of rivet holes having been effected, minium is introduced into these and heated to 100° C., and the rivet is thereupon hammered with a compressed-air hammer. Under the action of the heat the minium liberates lead fumes.

Finally, there should not be overlooked the risk of accidents due to traumaism, splashing (molten metal, acid or alkaline drops), especially afflicting the hands and eyes, falls of the worker or of objects on to the worker, etc.

### Statistical Data

Apart from certain old statistics prepared by Sommerfeld and Hirt and quoted by Zadek, no important statistical data exists relative to morbidity amongst workers engaged in mechanical engineering and metal work.

Based on an analysis of cards belonging to the Austrian Sickness Funds and relating to metal workers in Vienna, Adler and Herzmark has drawn attention (1921) to the great frequency of tuberculosis amongst these workers, especially amongst young persons — affections of the pulmonary apex, and more particularly still amongst women between twenty and thirty years of age who appear to be much more frequently affected than the male workers. Amongst locksmiths and mechanics the percentage of days of sickness due to tuberculosis diminishes with advancing age.

In Germany amongst workers engaged in a ship-breaking yard (Kiel) Engelsmann found in 1923 that 32 workers out of 39 engaged on cutting sheet iron coated with zinc by blow pipe suffered from affections similar to zinc funder's fever. The action of lead being eliminated, the author ascribed the troubles to absorption of zinc. In another shipyard 22 out of 41 workers showed symptoms of lead poisoning. Analysis of the air gave a lead content of 5.6 mg. per 100 litres of air.

In Great Britain from 1920 to 1927 the medical inspectorate received reports of 265 cases of lead poisoning — 138 cases only in 1924 — one of which was fatal, due to lead fumes volatilised by the action of the oxyacetylene flame used for cutting metal (painted with red lead!): enquiries by Legge, Bridge, etc.

Riveting also involves a risk of lead poisoning. In 1928 Fraenkel recorded a case of poisoning due to a cause so far unknown. The piercing of rivet holes having been effected, minium is introduced into these and heated to 100° C., and the rivet is thereupon hammered with a compressed-air hammer. Under the action of the heat the minium liberates lead fumes.

In Great Britain Middleton has studied (1923) working conditions and the state of health of workers engaged in metal grinding and removing of sand from castings.
His enquiry, which is very complete, comprises a technical section (analysis of the operations, composition of the grindstones, etc.), a medical part (examination of 1,153 workers), and a third part dealing with hygiene (analysis of air samples, means of protection, etc.). Despite the fact that for some time back the composition of grindstones has been considerably improved, unfavourable working conditions still exist in certain factories, more especially in the town of Sheffield.

Without scrutinising in detail this interesting study, it is sufficient to recall that 4.7 per cent. of the workers examined showed obvious signs of pulmonary tuberculosis, 9.3 per cent. suspected tuberculosis, and 19 per cent. bronchial catarrh.

Analyses of 123 dust samples collected with Owen's konimeter revealed a quantity of dust varying from 496 to 26,377 particles per cubic centimetre of air during wet grinding on grinders made of sandstone and metal polishing.

The proportion of dust particles exceeding two microns in diameter varied between 0.7 and 34 per cent.

In the United States Brown (1926) met with 83 cases of lead poisoning.

In the U.S.S.R. several investigations have been effected in the mechanical engineering industry. A brief reference may be made to that of Marschak (1923) concerning 7,815 workers who showed a number of days' sickness four times as high as that recorded for the year 1914, but half that for 1920, even though the number for 1923 had increased as compared with that for 1922; likewise the enquiry of Gleserow (1928) dealing with cases of ocular traumatism amounting to 5,769 over a period of four and a half years. Occupational traumatism accounted for a fifth of the total. The left eye was most often affected (52.1 per cent.), this being due to the position of the worker's head, which is generally turned to the right. Diminution of natural lighting during autumn and winter were said to explain the increase of accidents met with. Metallic particles and splashings of molten metal most frequently account for these accidents, amongst which serious forms were however rare (0.7 per cent. of the total). Ter Gasaroff, of Baku, in examining (1927) 136 blacksmiths in a large factory, found chronic lesions of the mucous membrane (conjunctivae, upper respiratory passages, emphysema, serious derangement of the circulatory system, and even in certain cases modifications of the blood count (increase in lymphocytes).

As regards mortality, recent figures taken from the Registrar-General's report for England and Wales (1923-1925) and dealing with the mortality for various occupations in the metallurgical industries, show the following returns:

Metal moulder, who, together with the unskilled foundry workers, form the large majority of wage earners in foundries (61,329 moulders out of 166,001 wage earners), show the mortality rate for all causes exceeding the comparative mortality figure (C.M.F.) by 13.7 per cent. for all ages, with the exception of the group between twenty and twenty-five years of age, the mortality rate for which only amounted to 95 per cent. of the general average, contributing to an excess which mounts gradually and reaches 34 per cent. for workers aged over seventy. The most frequent causes of death are influenza, cancer and respiratory troubles (bronchitis and pneumonia). These results thus cause moulders to rank amongst the most affected (135th, 162nd place) out of 178 groups, the latter figure designating the most seriously affected category.

Blacksmiths and mechanics, fitters, boilermakers and unskilled workers helping the latter show a mortality rate slightly under that of the general average, without however any exceptional rates for any special age group or any particular causes of death. Figures for plumbers and gasfitters are relatively high for chronic nephritis and cerebral haemorrhage. This high mortality is said to be due to lead poisoning, and the mortality due to lead amongst these workers is only exceeded by that for workers in the pottery industry.

Cutlery workers sometimes engaged in grinding and at others in polishing, are to a certain extent exposed to the inhalation of silica dusts. Their comparative mortality figure for all causes of death is 28 per cent. above the average, especially for the group aged thirty-five to fifty-five. The diseases which cause the greatest number of deaths are: syphilis, cardiac valvular troubles, accidents and pneumonia.

For file-cutters, see article "File-cutting".

Metal polishers show similar mortality rates, under which the outstanding causes are notably cancer of the stomach, influenza, pneumonia, etc. The phthisis rate is 2.12, and that for bronchitis 1.96 times the average figure (see also article "Metal Grinding and Polishing"). Riveters who work chiefly in the open air and are exposed to all weathers have a comparative mortality figure which exceeds the average by 6.2 per cent. It should be noted that amongst the causes of death the highest figure is that for syphilis, followed by bronchitis (excess of 60 per cent.), pneumonia (excess of 35 per cent.) and phthisis (excess of 15.7 per cent.).

Workers engaged in naval construction show a mortality rate which only amounts to 934. The unskilled workers in this occupation, however, show on the contrary a rate of 1,253, the most frequent causes of death being: influenza, phthisis, syphilis, cancer and especially cancer of the stomach, respiratory troubles and accidents.

Pathology

Amongst general troubles should be mentioned first of all those arising from fatigue, heart-stroke, exhaustion, cramp, anaemia, premature senility, etc., troubles due to cold (extremely
frequent: tonsillitis, acute or chronic rheumatism, respiratory affections, etc.; forms of poisoning due to products handled or to substances liberated during the various operations (lead, carbon monoxide, cyanide, nitrates, etc.).

Forms of illness similar to those caused by brassfounders' fever, and which are attributed to zinc fumes, affect very frequently workers engaged on cutting metal by means of a blowpipe. The incidence of lead poisoning among these workers attained very high figures after the war at the time when shipbreaking was frequently engaged in. Cutting painted metallic plates by blowpipe, where the ground coat consists of red lead, involves volatilisation of lead and causes inhalation of the fumes, giving rise to acute poisoning amongst the workers.

The use of red lead cement heated to 1,000°C for riveting in the construction of a metal bridge was the cause of poisoning amongst the workers who completed about 30 to 40 rivets per hour (Fraenkel, 1928). The use of a red lead cement heated to 1,000°C for riveting in the construction of a metal bridge was the cause of poisoning amongst the workers who completed about 30 to 40 rivets per hour (Fraenkel, 1928).

Reference should be made to the article "Nitrous Fumes" for information regarding the risk connected with red fumes liberated during scouring of metals with acid.

Forms of dermatitis occur on the uncovered parts of the skin and are manifested by pigmentation and erythema (in the case of exposure to the action of radiant heat and often in contrast with pallor of the mucous membranes) and are especially amongst blacksmiths (pigmentation of the mucous membranes and nodules) and amongst milling machine operators, due to small metal particles (Kober and Hayhurst). Blisters and carbuncles on the hands have a characteristic situating amongst certain occupational categories, for instance file-cutters. Horny callosities of this kind when neglected may develop into painful scars and even suppurate. Small traumatic lesions favour the formation of ulceration, and when they become infected may develop into subcutaneous cellulitis, whitlows, etc. Forms of dermatitis due to lubricating oils, and especially that known under the name of "oil acne", should also be mentioned (see article "Petroleum"), as well as "wearing" away of the nails encountered amongst workers removing sand from castings. The skin is often subject to ulceration which at times is extremely painful and is caused by certain products the action of which is accelerated by pre-existing skin lesions (broken skin, scratches, etc.).

The use of water and lubricating oils containing dichromate induces ulceration of the skin (see article "Chromium and Chromates").

In France in 1927 a case of papillomatosis of the forearm with cancerous degeneration was recorded as affecting a worker in a factory for making small metal balls. This lesion known as "turners' disease" led to amputation of the arm. The disease was attributed to the action of the tars (or mineral oils) used for lubricating.

Types of deformation of the bones have for long been known and described. Whilst in pre-war times knock-knees have been reported amongst file-cutters, turners and boring machine attendants who operate their machines with their feet, later deformations encountered are said to affect especially the thorax of workers engaged on turning machines. These deformations have been studied by several experts, amongst others by Sternberg. The right anterior and lateral part of the thorax reaching from the fifth rib downwards is pushed inwards, whilst the posterior part takes a convex form with the result that the right nipple is lower than the left. The muscles on the right side of the thorax, especially the large dorsal muscle, are more developed than those on the left side.

Metal workers also suffer from muscular curvature, especially in the lumbar region (blacksmiths), spasm, cramp and forms of paralysis of the muscles of the hand and forearm, amongst workers utilising compressed air tools: see article "Pneumatic Tools"). Certain workers engaged in making metallic lattice-work present, according to Dravet (1928), acute or chronic lesions of the tendons and synovial sheaths of the extensor muscles of the thumb and external radial muscles at the level of the anatomical snuffbox. This teno-synovitis is mostly bilateral. In cases where it is unilateral the left wrist is more often affected. Acute forms of this affection resemble in their clinical characteristics creeping teno-synovitis. Relapses are encountered especially as an effect of strain and exhaustion which is to blame for the first acute attack. The chronic form with chronic development from the outset causes partial permanent incapacity, and lesions of this kind develop very slowly without any acute symptoms which might serve as a warning.
A caustic or irritating local action has often been noted during several operations on metal work, and especially during welding. Lesions due to the fumes of the solution utilised (hydrochloric acid, zinc chloride, etc.) affect not only the mucous membrane of the eyes, but also of the mouth and upper respiratory passages (Koelsch) (see also article "Welding (Auto-genous)"). For injuries due to nitrous fumes, see article "Nitrous Fumes".

Whilst pathological manifestations affecting the digestive system are fairly frequent in foundries (gastralgia, gastritis, etc.), those of the respiratory system are more frequent. There has been noted irritation of the respiratory passages and bronchitis amongst metal grinders, obliterating bronchitis amongst workers handling metal hooks (Frederkel, 1908), pneumonia and forms of pneumono-coniosis (moulders, sand-spray workers, grinders, polishers), and sometimes even pulmonary haemorrhages due chiefly to metallic dusts (Kober and Hayhurst), tuberculosis amongst workers using the sandspray, yet isolated observations made lead to the conclusion that it is possible to find workers who have worked for fifteen, twenty years and over in occupations which include ocular fatigue, blepharitis, conjunctivitis.

No statistics are available relative to pathological conditions amongst workers using the sandspray, yet isolated observations made lead to the conclusion that it is possible to find workers who have worked for fifteen, twenty, twenty-five years and over in occupations which include ocular fatigue, blepharitis, conjunctivitis.

Valvular lesions and cardiac hypertrophy as well as derangement of the venous circulation due to prolonged standing or to strain have been described by several medical experts as occurring amongst founders, blacksmiths, brass-workers, mechanics, etc.

Ocular troubles encountered include ocular fatigue, blepharitis, conjunctivitis and in the case of certain occupations, cases of furunculosis due to obstruction of the sebaceous glands of the external auditory meatus have been noted, also deafness caused by noise and vibration. Ocular troubles encountered include ocular fatigue, blepharitis, conjunctivitis and in the case of certain
occupational categories, cataract and lesions of the retina (autogenous welding by the action of ultra-violet rays, etc.). Hirschberg has described under the designation "electrical ophthalmia" a syndrome characterised by lesions of the conjunctivae, the cornea and the retina. Crzellitzer quotes similar cases and Apfelbach in 1914 described about fifty cases of ocular lesions which he had met with in the metallurgical industries in Illinois and which were characterised by conjunctivitis, photophobia, abundant lachrymation, transitory blindness and, more rare, keratitis of the retina, forms of scotoma and alterations in the pigmentation of the retina, etc. In 1921 Roberts studied cases of cataract amongst English workers engaged in chain making. Cridland in 1923 made a study of similar cases amongst puddlers and Schnyder in 1928 amongst iron-workers.

Samoiloff (1926) has reported diminished sensibility of the cornea amongst metal-workers. The possibility of burns due to hot metal splashing has been already referred to.

Finally Lederer (1929), basing his observations on extensive statistical data, has arrived at the conclusion that workers employed in front of furnaces suffer from premature presbyopia more frequently than other categories of workers. As has been stated in regard to cataract, accommodation is more readily affected on the side most exposed to the action of the radiant heat.

Accidents amongst metal-workers are very varied in type: burns, crushing lesions, contusions, cuts, fractures, etc. Complications are also of frequent occurrence especially in the case of skin wounds, which are very liable to infection.

Though not quite recent, the data collected in 1909 by Peri comprising 4,014 metallurgical workers and mechanics who were the victims of industrial accidents, provides nevertheless some idea of the incidence of various medical and surgical forms of injury which occur in this occupational category. (See article "Iron, Pig-iron and Steel Industry.") More recent statistics prepared by G. L. Ron-lando (1923) deal with 27,426 accidents which occurred amongst the workers in the Spezia Arsenal during the period 1913-1922.

Certain authors refer to the high rate of alcoholic poisoning amongst these workers as said to be favoured by working conditions inherent to certain processes (radiant heat, etc.).

It seems of interest to refer to certain Russian studies on fatigue amongst metal-workers and in particular to those effected by Efimow and Zibakov (1925) in Moscow and Efimow and Itina (1925) which insist on the value of short rest periods throughout the working day as a means of prevention of fatigue amongst metallurgical workers; those of Feinberg (1925) who enquired into conditions amongst workers manufacturing rolling-stock and in particular amongst workers exposed to heat, his conclusions seeming to point to the fact that injuries encountered were largely due to variations in the surrounding temperature, to the action of radiant heat in the course of certain operations and to that of carbon monoxide (0.15 to 0.57 mg. per litre), sulphur-dioxide (0.10 to 0.14 mg. per litre) and to strain (muscular fatigue).

Hygiene.

Metal-working establishments are generally classified as dangerous trades on account of certain offensive features connected with them: smoke, steam, noise, vibration, etc. Certain legal requirements consequently demand that windows opening on to public highways or neighbouring properties should be kept closed, that machinery should not be installed alongside the common partition walls, in order to protect neighbours against noise and vibration, and that smoke, fumes and dust (sand-spray) should as far as possible be collected and removed.

Workrooms should be so constructed as to permit of satisfactory installation of the machine-tools, etc., of adequate ventilation and lighting of the workrooms, which should further be maintained in a satisfactory state of cleanliness. With this in view it is essential to have even uniform flooring and lime-washed walls.

Problems of ventilation and lighting receive in general adequate consideration from the technical managers of the factory, who are now increasingly aware also of the advantages which accrue from rendering factory conditions healthy as regards the problem of withdrawal of dust, smoke and fumes. The reader is referred to the various articles dealing with these problems. Brief reference may, however, be made to certain improvements which have been obtained in a number of factories as regards measures of general hygiene (dust exhaust, cooling of furnaces, lighting for hygiene) as applied to certain special operations (scouring of metals, etc.).
In work on ordinary metals it is essential to have arrangements for collection and evacuation of the abundant dust produced in the course of several operations (fig. 26).

As an instance may be quoted the operations of removing the moulds, fettling and rough-shaping the metallic articles in a dry state. For a suitable means of collecting the dust in accordance with the types of apparatus and the kind of process, technical experts have occasionally recourse to automatic precipitation of the dust, which is inadequate, and at times to ventilation by means of steam, compressed air, blowing or exhaust. See in this connection articles "Abrasives (Artificial)," "Metal Grinding and Polishing" and "Dusts, Fumes and Smokes".

Sandspray machines, the use of which has at present become increasingly extensive, require the adoption of minute precautions more especially by reason of the fact that the sand used is hard and siliceous. These measures vary slightly in accordance as to whether the article which is presented to the sandspray is fixed or whether the worker is obliged to direct the spray on to the articles. Respiratory masks of a good type give favourable results. It is, however, necessary to take into consideration the serious inconvenience of this protective appliance when the connection between the head-piece and the piping for provision of compressed air is badly made or becomes disconnected. In the event of this happening there is immediately a violent entry of a cloud of dust in suspension in the atmosphere and the worker is then perhaps obliged to breathe an atmosphere more injurious in its results than if he had been unprovided with a mask.

Fettling of small foundry pieces is generally done by hand with the aid of brushes. To overcome the inconvenience caused by inhalation of the dust liberated it would be advisable to effect this operation on benches provided with downward exhausts for withdrawal of the dust. Amongst the measures proposed by Middleton may be mentioned the installation of sandstone grinding by a wet process in a special chamber; abundant provision of water for the grindstones; wearing of respiratory apparatus; good general ventilation of the workshops together with adequate localised ventilation, where work is carried out in a dry state; and changing of shifts in order to ensure that the workers are not always exposed to the same dust. In the closed apparatus the heaviest grains of sand fall back into a sieve and from there into a reservoir. The lightest particles which have become extremely fine by a wearing down process fly about in the atmosphere and are usually withdrawn by localised ventilation and cast outside. It is, however, preferable to direct these dusts on to filters or on to a sheet of water or a layer of coke kept damp by a fine water spray (Frois). The best protection is obtained by the adoption of apparatus furnished with automatic devices (sandspraying machines in the bronze factories, closed apparatus preventing the worker from coming in contact with the dust), by utilising wet sand (mixture of water and sand in given proportions by means of compressed air at high pressure) and by the use of fine metallic shot (a costly system).

Scouring with acid should also be effected in such a manner as to prevent dispersion of acid fumes and the projection of droplets. The waste water should not be discharged until it has been neutralised, when it should be evacuated either by drainage or by discharge outside the factory and this only after every precaution has been taken to prevent stagnation and likewise every possibility of any inconvenience likely to be caused for those...
in the neighbourhood, and of any possible pollution of the water supply.

In workrooms adequate measures should be taken to prevent liberation of harmful steam, fumes, gas or dust. Acid fumes may be collected under excellent hygienic conditions even in closed workrooms by means of the device indicated in figs 27 and 28 (Association of Industrial Employers, Belgium).

On the upper surface of the three walls of the scouring vat there is arranged a wooden case closed on all sides except towards the interior of the vat. On its surface and as low as possible small exhaust apertures of a rectangular form are arranged. The long wooden cases are connected up by means of piping to an exhaust device which has the effect of withdrawing by exhaust as they form any fumes liberated at the surface of the bath and casting them outside through a chimney. A uniform rate of exhaust is obtained by giving the ventilation piping a cross section which increases from the furthest distant point up to the point at which it joins the exhaust piping. Another system of elimination of acid steam is composed of hoods placed above vats and connected up with evacuation piping. Ejectors fed by a steam pipe withdraw the gas towards the outside. Condensations produced in the evacuation piping are led back to the rinsing vats by means of purifying agents; vats and edges of hoods are installed in a box with glass windows balanced by means of counterweights; lattice work is furnished on the floor in front of this installation with a view to preventing the worker from treading on acid solutions.

Bachrach, of Rostov, who has made a study of conditions relative to metal scouring by acids in Russian factories, insists (1930) on the necessity for having rational ventilation of the workshops and on the advantage of adding to the solution in the vats certain special substances ("Sparbeize", "Adacid", "Antra", etc.), said to be of advantage from the hygienic and also from the technical point of view, and finally on the advisability of replacing chemical scouring by mechanical scouring (Tereschtschko), which would result in rendering the work in question perfectly healthy.

The best fire extinguisher for tempering baths is absolutely dry sand. The introduction of any water into nitrate baths should be avoided. Workers should be instructed as to the risk involved; no wooden articles should be allowed inside the workroom, which should be provided with safely doors opening outwards, and there should be ample provision of boxes containing very dry sand. It must be remembered that burns caused by molten nitrates are extremely painful and slow in healing, it being therefore necessary to adopt every possible precaution to prevent these (Grempe).

![Fig. 27.](image-url)
It is hardly necessary to insist here on the advisability of replacing wherever possible hand transport of articles of manufacture by lifting apparatus. Similarly, attention has on several occasions been called to the advantage of rest intervals, judiciously interspersed throughout the working shift with a view to preventing fatigue, and in this way to improving production both as regards quantity and quality.

The question of purification of waste waters in the metal industry is of capital importance and at the same time extremely complicated.

Amongst measures of personal hygiene should be included the provision of working clothes, aprons and leather leggings for workers (particularly those obliged to work under conditions of great heat), of gloves, glasses, head-gear and, where necessary, respiratory masks, etc. Washing accommodation, douches, baths, etc., as well as canteens, where these are required, should also be provided. An interesting account of social progress in the French metallurgical industry is that published by Pinot in 1924. See also the article "Social Welfare".

In all processes requiring scaffolding or in regard to all work effected in a dangerous position, adequate safety measures should be taken with a view to assuring on the one hand the solidity of the construction and on the other to preventing workers falling from heights.

Transport and first-aid for injured and sick workers should be assured by adequate means and entrusted to trained personnel.

The above measures should be completed by propaganda work amongst the workers in order to keep them informed of the dangers and risks to which they are exposed and of the requisite precautions to be adopted. Their attention should be drawn especially to measures of personal hygiene and graphic presentation of facts will be found to play an important part in this scheme of propaganda.

Legislation

Women are excluded in France from operations of scouring, pickling and galvanisation of iron in workrooms where acid fumes are liberated, or in which acids are handled and similarly from workrooms where grinding and polishing of metals are effected.
Young persons under fourteen years of age are excluded in Belgium from grinding operations, from polishing on mechanical grindstones articles intended for the manufacture of firearms, and, in Great Britain, from operations connected with dry grinding in the metallurgical industry. Young persons under sixteen years in Belgium are excluded from operations connected with coating iron and cast iron with zinc (in workrooms for scouring and coating with zinc); in South Africa from dry polishing; in several of the United States from work where abrasives are used in polishing articles made of non-precious metals on wheels or grindstones; young persons under eighteen years of age are excluded in France from work on sheet iron and painted metals when the use of toxic products is involved; and in certain of the United States as mentioned above.

Boys under fifteen years of age are in Italy excluded from operations on metal works or in Japan from any work in connection with metal where dust is liberated; boys under sixteen years of age are excluded in Canada (Quebec), from the cutlery trade (grinding) from dry polishing of metals and from vanishing of metals dried in a furnace and from the manufacture of nails, in Spain from polishing, grinding of metals and the preparation of painted metals wherever toxic substances are used.

Girls under seventeen years of age are excluded in Canada (Quebec), from similar operations to those given above in reference to boys; those under twenty-one years of age in Italy, Japan, Spain, under conditions similar to those already mentioned for boys.

Apart from general hygiene regulations which may be applicable to the metal industry certain legislatures contain special regulations relative to the industry in question. In Finland an Order of 1927 contains safety measures for metal shops; in France the Act of 19 December 1917 dealing with dangerous trades lays down conditions regarding the opening and running of workshops for metal scouring (with sand and acids), in regard to which provision is likewise made under Italian legislation.

In Germany instructions issued by the Ministry of Labour relative to the protection of the health of workers engaged in dismantling ships were issued on 26 April 1923. Orders of 2 February 1921 and 12 May 1927 deal with painting inside the holds of ships; they fix the length of the working shift for painters (shifts to last for half an hour separated by intervals of two hours on work in the open air); constant supervision of the workers; the number and size of the manholes in relation to the dimensions of the place in which the work is effected; adequate measures for the rapid and easy withdrawal of workers; prohibition of entering into freshly painted places prior to adequate ventilation; etc., are included.

Similar prescriptions have been issued for workers engaged in operations of welding and cutting by blowpipe.

General measures with a view to prevention of risk from lead colours (in course of painting operations) in shipyards are contained in the Order of 27 June 1905 which is from time to time extended and completed in the sense of more frequent examination of the workers.

In the case of repair of tank ships which have contained mineral oils, German legislation demands supervision by a responsible engineer or master of works, likewise preliminary emptying of the tanks by the introduction of air or steam to drive out any inflammable gases present therein; testing, prior to work, to ensure absence of toxic or inflammable gas, etc.; permission to descend into the tanks only to be granted in the presence of an engineer; constant ventilation of the tanks whilst workers are engaged therein; lighting of the tank by electric light and by a system excluding the possibility of risk from explosion, etc.

In Great Britain an Order of 5 October 1917 deals with the protection of workers engaged in making tin wares or ware with a tin coating. A further Order of 12 October 1917 deals with ambulance and first-aid work in metal factories, foundries and other metallurgical factories. An Order of 3 July 1918 lays down measures of protection for workers engaged in turning shells or shell cases, whilst a further Order of 31 December 1921 is devoted to the protection of workers engaged in the manufacture of tinware and galvanizing. A Regulation of 2 September 1925 deals with grinding and polishing of metals.

In Greece the prevention of accidents in the metal industries is dealt with under the Act of 23 December 1925.

In Norway a Royal Order dated 29 October 1920 contains hygiene regulations relative to polishing of metals, and a further Order dated 30 October 1919 deals with work in foundries.

In the U.S.S.R. several regulations are devoted to safety in workshops in the metal industry (forges, rolling-mills, etc., 1923), likewise.

Cases of dermatitis (eczema, etc.), pulmonary affections occurring amongst metal polishers, inflammation of the joints and of the subcutaneous cellular tissue and synovitis of the knee amongst workers in shipyards for maritime engineering as well as forms of teno-synovitis amongst blacksmiths, pulmonary affections and cataract affecting foundry workers and metallurgist's cramp are subject to compulsory notification in the Netherlands.

Compensation is granted for cases of poisoning (by lead, mercury, cyanides, asbestos, etc.), as well as for cases containing the list of diseases for compensation or covered by the definition of industrial accident or again by a list of
substances (Finland, Switzerland); likewise cases of silicosis or phthisis amongst metal sharpeners and polishers (Germany, Ontario, Alberta), where siderosis and lithusis are also compensated; cases of poriatis of the palm of the hand amongst the same workers (Japan); cases of deafness and hardiness of hearing (Germany); cases of cataract amongst metal founders (Germany); cases of cataract and retinitis amongst metallurgical workers (U.S.S.R.); cases of poisoning due to metals (Queensland, Western Australia); cases of neuralgia and neuritis of the extremities due to fatigue and pressure of tools, etc., amongst blacksmiths (U.S.S.R.). See also the article "Occupational Diseases: Definition and Compensation".

Medical and Allied Professions
(Occupational Pathology of)

Doctors and Physicians

While more fortunate than men of letters in that they are not obliged to lead an entirely sedentary life, doctors are on the other hand forced to spend much of their time under conditions which are bound to exercise a pre-judicial influence on their health. In lecture halls or hospitals, in the midst of epidemics or with the army during campaigns — in fact everywhere where the doctor is exposed to infection and contagion. His whole life, divided between the claims of science and humanity, is sacrificed to duty; and in his concern for the health of others he has neither the time nor the inclination to look after his own (Layet).

At the present day, however, the doctor's sphere of activity is very much more extensive. He engages in general practice in the town or country or as specialist in chemical, serological, physical or pharmaceutical laboratories or works in röntgen-ray or radium centres (either for preparation or treatment), or in public service, in schools, factories, etc., and each and all of these activities may offer particular sources of injury to his health.

The traditional reluctance of the physician to heal himself is reflected in the fragmentary and inaccurate information to be had regarding the health conditions or even concerning the morbidity and mortality of the medical and allied professions.

1 Figures in italics indicate years of exposure and rates for partial disability for policy holders eligible for partial disability benefits.
No extensive data are available regarding morbidity among physicians. It seems unlikely that they can have an abnormally high incidence of incapacitating illness. The principal causes of death, apart from a portion of the cardiac group, are not associated with long periods of disability.

The combined experience of a large number of American insurance companies writing personal health and accident insurance, published in 1926, shows, however, a relatively high financial loss ratio for physicians and surgeons. The following table presents data relating to the four most prevalent types of policies issued which, for all occupations combined, included over 97 per cent. of all years of exposure.

According to this experience, total incapacity among physicians and surgeons is 36 per cent. greater than for other occupations combined, 88 per cent. greater than among lawyers and 28 per cent. greater than among a general group of officers of corporations. Similarly, partial disability is 28 per cent. in excess of that of other occupations combined, 42 per cent. greater than among lawyers and 8 per cent. greater than among corporation officers. The greatest excess among physicians, however, is in connection with one type of policy providing for full disability irrespective of house confinement, and if this type be omitted from consideration, the total disability is but 19 per cent. in excess of that for other occupations combined, the partial disability 26 per cent. greater. This experience among physicians, apparently moderately unfavourable, must be in part explained by the fact that a liberal attitude is maintained by companies adjusting the claims of physicians. Age distribution figures little as policies are rarely in effect after the age of sixty.

An enquiry made by Kunzig deals with the hospital staff in the infectious diseases departments of the Düsseldorf hospitals for the period 1907-1927 and has provided the following data:

Amongst the doctors: 6 cases of diphtheria and 5 of scarlet fever, 2 of influenza accompanied by laryngitis, 12 of bad sore throat, 4 of typhus and typhoid jaundice, 1 of whooping cough, 1 of parotitis, and 1 of acute enteritis.

Amongst the nurses: 48 cases of diphtheria, 29 of scarlet fever, 13 of acute enteritis, 23 of bad sore throat, 184 of influenza, 3 of typhus (1920-1927), 1 of chicken pox, 3 of parotitis, 3 of whooping cough, 2 of influenza accompanied by laryngitis.

In 1928 Mignon published the results of research effected in studying the archives of a mutual aid society for French doctors for the period 1894-1924. The various groups of diseases with a duration exceeding four days are as follows:

Diseases of the heart and blood vessels and then tuberculosis most frequently affect the medical profession. As regards age, the greatest number of cases of sickness fall within the period between the ages of forty and fifty and at fifty years of age there is recorded the greatest number of diseases. From twenty-five to forty-five the morbidity rate is stationary round about 2 per cent., it oscillates about 3-6 per cent. from forty-six to sixty years and above that age it mounts rapidly in a striking manner since the morbidity rate passes from 6 to 100 per cent. in twenty years (effect of old age).

Mortality statistics for physicians are subject to some degree of error because of the inclusion under the title of a great variety of occupations allied to that of the practice of medicine. The profession in all countries includes not only active practitioners, but also many who have retired or who are but casually engaged in practice, and those in laboratory research, in public health work and medical and institutional administration.

The deaths of physicians reported in the United States in 1923 amounted to 2,570, which, adding 2 per cent. for omissions and delayed reports, makes...
Mortality per 1,000 Male White Physicians in the United States, 1925, Compared with That for All Occupied Males, 1920 (U.S. Census Bureau), and for Physicians, 1910-1912 (Report of Registrar-General for England and Wales)

The death-rates at the several age-periods for American physicians in 1925 given above are certainly conservatively low as the data upon which they are based were obtained from the files of the American Medical Association. In comparison with these, the rates for physicians and surgeons as reported by the registration states in 1920 perhaps err in being somewhat high.

The crude death-rate of 19.0 per 1,000 males, compared with a rate of 12.6 among all occupied males suggests a serious situation which does not, as a matter of fact, exist. A very much larger proportion of physicians than of professional groups or other occupied males lives beyond forty-five years of age. Physicians enter upon their work later in life than do most men and they do not figure in mortality tables at all until twenty years of age.

² From U.S. Census, 1930, Vol. IV, Ch. 4.

It is the very longevity of the profession which is responsible for the high crude death-rate. Casper, writing in 1884 upon the expectancy of life for physicians, was extraordinarily pessimistic regarding their longevity and his views have long influenced those who have written upon the subject. Layet in 1875 reported the average age of physicians in England to be 45 years. Ogle in 1886 found the average duration of life of English physicians to be 59.3 years. De Wilde in 1925, reporting upon a group of Dutch physicians who have died since 1861, found the average age at death to be 50.6 years as contrasted with 64.8 for the average of the whole male population for the same period. The average age at death is not however in itself a valuable criterion of longevity. Unfortunately, life tables for any occupational group are very few.

Hill has computed the expectation of life for English physicians, comparing it with that for all males (see table).

The report of the Registrar-General for England and Wales (1910-1912) shows for physicians 693 deaths in the "standard population" against 790 for all occupied and retired males aged twenty-five to sixty-five, and 695 for the upper and middle social classes. Favourable as this rate seems, it is higher than that for the legal profession (627) or for clergymen (443). These figures are corrected for age distribution, and are, consequently, significant. It should be noted that no deaths beyond the age of sixty-five are included. The death-rates per thousand living are slightly higher for the several age-groups than those found for American physicians in 1925.

Bertillon, summarising extensive mortality statistics for England, Scotland, Paris, France and Switzerland, found the death-rates for physicians, in relation to the general average, to be slightly higher in the earlier English, Scotch, French and Swiss figures and lower in the Parisian and later English tables.

According to Koelsch, the mortality rate for German doctors and veterinary surgeons exceeds that for other professional classes, but does not exceed the general average. The excess mortality is manifested especially in cases of circulatory disease, infectious diseases, and diseases of the nervous system.

With good reason, diseases of the heart and arteries have long been considered the great cause of death among physicians. Harvey, Hunter, Jenner, Bright, and Ramazzini are but a few of those whose deaths were due to cardiovascular disease, such as angina pectoris or apoplexy. Statistical data from many sources indicate that cardiovascular disease is the outstanding cause of death of medical men.

An analysis of 2,534 causes of deaths (United States, 1923) gives the following results:

**EXPECTATION OF LIFE OF ALL ENGLISH MALES BASED UPON MORTALITY: (1) 1838-1854 AND (2) 1910-1912, AND (3) EXPECTATION OF LIFE OF PHYSICIANS, SURGEONS, AND REGISTERED PRACTITIONERS BASED UPON THE MORTALITY OF 1910-1912**

If the several forms of cardiovascular disease, excluding nephritis, be considered as a group, they account for 609.4 deaths per 100,000, 32.1 per cent. of all deaths. A similar proportion was evidenced by the mortality tables of the U.S. Census for 1909 — 31.3 per cent.

Comparing the mortality of physicians for important causes at the several age-periods with that of all occupied males, and particularly with that of males over twenty-five years of age, a number of striking facts are disclosed.

The excessive mortality of the medical profession from heart disease and the pneumonias is evident. Relatively very low rates may be noted, however, for cancer, nephritis and pulmonary tuberculosis. In the U.S. Census figures for 1900 cardio-vascular disease was dominant, but the pneumonias did not occupy so prominent a place, relatively.

English mortality statistics, quoted by Lowy, give the following rates: 10.5 pulmonary tuberculosis, 12.5 respiratory diseases; 13 circulatory diseases; 10.9 digestive diseases; 7.9 uroepithelial affections; 4.3 tumours; 12.3 diseases of the nervous system; 1.4 alcoholism; 4.4 suicide; 3.7 accidents and 16.1 other causes. Statistics for 1910-1912 present for doctors a tuberculosis mortality rate per thousand persons from fifteen to sixty-five years of age of 1.21 and a total mortality rate of 8.03. The percentage of the tuberculosis rate as...
compared to the general mortality rate is 15.07.

Out of 4,354 persons belonging to the medical and dental professions who were members of an insurance society there were during the year 59 cases (1.3 per cent.) of rheumatism distributed as follows: arthritis 12 cases, sciatica 13 cases, lumbago 15 cases, muscular rheumatism 13 cases and acute and sub-acute rheumatism 6 cases (Willcox).

In Italy the mortality rate for men of fifteen years and upwards from the most common diseases was for the years 1915-1917 as follows (figures relative to 100 deaths from all diseases for the same professional class):

The low mortality from pulmonary tuberculosis among physicians has long been noted by Ogle and others. Recently Löwy expressed the belief that among younger physicians (from twenty-five to thirty-four years of age) there is the same incidence of tuberculosis as in the general population, and he stated that Teleky concluded from statistical evidence that in this age-group the mortality from tuberculosis was approximately that of the general population.

Hamel found that among the physicians and nurses employed in hospitals, university clinics and tuberculosis sanatoria the rates of infection were relatively low.

A relatively large number of doctors have sacrificed their lives to scientific research or in the humanitarian task of prophylaxis. Martyrs in this cause include, amongst others, the following names: Daniel A. Carrion (verruga Peruana); Jesse W. Lazear, Hideyo Noguchi, Adrian Stokes, Col. Guilliet, William A. Young (yellow fever); Alexander Yersin, Herman Franz Muller (plague); Tito Carbone (undulant fever); Allen MacFayden (undulant fever and typhoid fever); Thomas B. McClintic (Rocky Mountain fever); B. Siccardi (haemorrhagic spirochosis); Ahmed Bey and Rudal Bey (glanders); Ottokaro Horak (tuberculosis of the skin); Pirrie (kala-azar); Howard Taylor Ricketts, Bacot (typhus); Moreschi (smallpox); Snyder (rattlesnake poison), etc., without taking into account the still greater number of doctors who have sacrificed their lives in research on X-ray work and radio-active substances.

### Pathology

Doctors are liable to all skin affections, and in particular to the anatomical tubercle and dermatoses due to iodoform, disinfectants used in preparation for surgical operations and to handling plaster of paris, and which are of frequent occurrence. In earlier times, before the wearing of rubber gloves to protect the skin, eczemas due to carbolic acid, sublimate and iodure solutions often even prevented surgeons from pursuing their careers. Erysipelas or some form of mycotic disease is secondary infections.

Schosserer reports from a surgical clinic, 1914-1921, 618 cases of skin infection contracted by members of the medical staff while treating approximately 144,000 patients, giving a ratio of 4.3 per thousand, which ratio diminished during the war years only to increase to 5 per thousand in 1919-1924. Medical students, some of whom contracted wounds during dissection, were however included, while about one-third of the cases affected nurses; 155 cases were by direct contact (hands, clothing, etc.) and the rest were secondary infections.

A very serious occupational malady developed by certain members of the profession has resulted from excessive exposure to röntgen rays and radio-active substances (see articles “Röntgen Ray Operators” and “Radium and Radioactive Substances”). Treatment with an arc lamp is said to expose the doctors handling it to poisoning by nitrous fumes (Dallex, 1927). The manipulation of radium and radio-active products is said to have caused cataract affecting a doctor (Elschnig,
1929. Naujokas in 1929 studied the action of X-rays on the reproductive function amongst assistants in radiological laboratories (for details see article "Röntgen Ray Operators").

Infection is certainly the gravest occupational risk for hospital staffs. Hamel found that the probable infection rate per annum and per hundred exposed was 0.14 for doctors of general hospitals, 0.35 for those in university clinics, and 0.08 for those engaged in tuberculosis sanatoria.

At the St. Ladislaus Hospital for Infectious Diseases, Budapest, from 1918 to 1924 there occurred 12 cases of infection (4 fatal) amongst clerks, and from 1910 to 1925 630 cases of infection (30 fatal) amongst nurses and 78 (9 fatal) amongst servants, laundry-women, cooks, etc.

During thirteen years up till 1929 the incidence of infections amongst persons occupied in scientific laboratories was, according to Kisskalt, as follows: 19 cases due to pure typhus cultures (confirmed cases); 13 cases of infection (probable cases); 22 cases of probable infection by cultures, contact with faecal matter or urine; 3 cases of infection (confirmed); 5 cases (probably by contact with faecal matter or blood); 8 cases of infection into the system by bacteria but without resulting disease. Amongst the cause or causes of infection there are found to be noted para- typhus A, cholera, diphtheria, anthrax, strepto-cocci, etc.

Infections amongst doctors are generally caused by wounds inflicted in course of handling hypodermic needles, medical and dental instruments, etc. Numerous other cases of infection occur however by direct contact with communicable diseases. It is a tribute to the care taken by most physicians that of the infectious diseases pneumonia alone now plays a prominent role as a cause of death. There are, however, unfortunate exceptions to this rule.

Surgeons, gynaecologists and staffs of bacteriological laboratories, of dissecting rooms, etc., are most exposed to infection. Though Ramazzini believed in the relative immunity of doctors as regards infection, and though it may be considered that doctors, by reason of their medical knowledge possess a strong protection against infection, yet the history of medicine reveals instances which prove the contrary, as in the case of Müller, of Vienna, who in 1898 died a victim to the plague which he had been studying in detail; or again in the case of four doctors and ten veterinary surgeons who were victims of glanders in a total of 106 cases, while a number of doctors have suffered from infections of the following order: tularemia, melitensis, spirochetosis, ictero-haemorrhagia, sittacosis (1930), etc. Doctors have also suffered from such infectious diseases as measles, scarlet fever, diphtheria, typhus, typhoid fever, malaria, and, amongst diseases transmitted by animals, anthrax, foot and mouth disease, etc. Cases of septicaemia, often fatal, are also frequent resulting from infection in dissecting rooms (Bichat, Legros, Papillon, etc.). These were formerly known under the name of "anatomical mephitism".

Throat specialists are specially exposed to infections, for example conjunctivitis; pathologists to the anatomic tubercle, typhus, typhoid fever and relapsing fever, etc.; bacteriologists to typhoid fever (Widal's reaction), typhus (case of E. Weil), spirochetosis, ictero-haemorrhagia (Siccardi), etc.; oculists to trachoma, ictero-haemorrhagia, etc. There should also be mentioned cases affecting medical scientists who have had themselves inoculated with pathogenic germs or have swallowed substances in order to study their properties.

As regards tuberculosis the highest rate reported by Hamel for university clinics (1.23 per cent.) was about the same as that for the general population. In Bavaria, Koelsch only found 1.92 per cent. as compared with 3.07 per cent. for the whole population. Those cases in which occupational origin could with certainty be affirmed were few in number in the statistics assembled by Hamel. Under present conditions in sanatoria there is practically no danger of infection for doctors (see later for nurses). A case of percussion, periostitis of the phalanges, has been met with in a doctor.

An abundant literature testifies to the frequency of extra-genital syphilitic infections amongst members of the medical profession. Trüb in a detailed monograph upon the subject, in which he analyses 669 cases due to exercise of the medical profession, distributes them in their order of frequency as follows: infection of extremities: finger, hand, arm, 388 times; eyes, 32 times; lips, 12 times; nose, 10 times; cheeks, 10; chin, 6; forehead, 2. (Some of the cases enumerated relate to midwives and 17 to dentists.) The cases of extra-genital syphilis affected in 19.5 per cent. of the instances midwives, in 13.0 doctors, and 11.7 dentists. Gynaecologists and surgeons are particularly exposed to this infection. Doctors are liable to infection
in treating patients (cases of Desmarres, Leloir, Boucheron, Buret, Hutchinson) and also from corpses during dissection (cases of Julien, Lagneau, Rumpf, Taylor). Thirty cases are on record, contracted by doctors and attendants during dissection, but only 5 of these stand the test of analysis and proof (Ullmann). It must also be remembered that doctors infected by syphilis may contract parasyphilitic diseases such as tubes, creeping paralysis, etc. (see article "Syphilis").

Venereal diseases of the eye have been contracted by doctors by rubbing the eye with an infected finger. Statistics of Bulkeley, Fournier, Scheuer, and Münchheimer show that in 1,000 cases of extragenital syphilis — chiefly infection of hands and fingers — 33, or 3.3 per cent., affected doctors. In the assembled statistics of the above, there were 952 cases of arm, hand and finger ulcers, of which 284 affected doctors. Of eye ulcers 40 per thousand, or 4 per cent., of the affected doctors — got by rubbing or by sputum of patients who had coughed in the doctor's face. Infections of lips, buccal cavity and tonsils are much rarer (Trüb). Trüb notes a marked recent decline in the frequency with which such cases are reported, reflecting improved measures of control of the disease and better technique; yet it must be remembered also that medical men frequently neglect to report such infection for fear of injuring their practice.

As an example of cancer infection transmitted from patient to physician, mention must be made of the case of a medical student, reported by Locène and Lacassagne (1926), who in extracting by puncturing a collection of pus which may have existed for months, introduced infected matter when treating patients, and also from corpses during dissection, but only 5 of these stand the test of analysis and proof (Ullmann). It must also be remembered that doctors infected by syphilis may contract parasyphilitic diseases such as tubes, creeping paralysis, etc. (see article "Syphilis").

Irritation of the mucous may lead to bronchitis, etc. Surgeons also suffer from flatfoot and varicose veins. Carbolic poisoning, sometimes fatal, was formerly fairly frequent when, in accordance with Lister's methods, doctors operated in an atmosphere rich in phenic acid fumes.

Pulmonary emphysema is said to be fairly frequent amongst doctors practising in mountainous countries; sclerosis of the coronary arteries with the well-known symptomatology is also said to be fairly frequent amongst doctors (Selig, quoted by Löwy), extra systolic neuritis (Galili).

Neurasthenia, another disease said to be of frequent occurrence amongst medical men, is due to hard and exhausting work and to grave responsibility, added at times by the influence of unduly heavy drinking and smoking, etc.

Doctors sometimes become addicted to drugs (morphia, cocaine) as a result of handling these therapeutically. Lambert has stated that of 1,700 cases of drug addiction in private practice, known to him, 405 were physicians. In 183 of these cases overwork and worry were apparently the causative factors and most of the cases developed in the late twenties or early thirties.

Out of 64 cases studied by E. Meyer, 21 affected doctors, 7 pharmaceutical chemists and druggists, and 2 male nurses; of 18 cases amongst women, 9 affected nurses and 3 doctors' wives. All the victims of cocaine who came under Löwy's observation were doctors or dentists. Usually this habit is met with in large towns rather than in country practices. Bertillon has commented upon the sobriety of the Parisian physician and the relative inebriety of his English counterpart. Whatever the record may once have been, alcoholism is not now notable as a cause of death of physicians in England. It does not figure as a cause of death in current American statistics.

The danger is naturally greater for doctors working in hospitals or laboratories. Hospital doctors are exposed to infectious diseases (tuberculosis, diphtheria, typhus, pneumonias, etc., contagious skin diseases, itch, furunculosis, etc., and venereal diseases). Infection may occur by pollution of water or food, by inhalation of dust, by bites (insects or parasites) or by spraying with infected matter when treating patients, or through open wounds or scratches.

Rist, who examined 349 members of a hospital staff for an insurance com-
pany in Paris, draws attention to current errors in the diagnosis of tuberculosis. He engaged in 1,032 consultations and personally supervised thorough and repeated chemical, radiological and bacteriological examinations with the result that he found amongst those previously suspected as tuberculous 9.3 per cent. really suffering from tuberculosis, amongst those stated to be tuberculous 33.3 per cent., and amongst those said to be suffering from open tuberculosis 86.6 per cent. — in all, 123 cases of tuberculosis, while 20 cases remained for further observation. The affections wrongly diagnosed were for the most part non-tuberculous pulmonary affections (24 cases) and affections of the upper respiratory passages (87 cases).

Special difficulty is encountered by medical staff in combating epidemics in mental asylums and hospitals where patients cannot be relied on to take precautions against infection; it is therefore found that a relatively high percentage of doctors, nurses and attendants contract infection during such epidemics, exanthematic typhus, etc. It has moreover been stated that as a result of the bad influence of mental patients on their attendants, amounting almost to a sort of infection, the working capacity of such attendants is reduced to nothing at the end of six to nine years, but owing to the large turnover in such institutions it is difficult to find absolute proof of this.

Staffs of laboratories, dispensaries, anatomy and dissecting rooms, disinfecting stations and baths, etc., also present special pathological features. Cuts and wounds received in dissecting rooms where infected substances are handled, as well as during post-mortem examinations, pave the way for infection from open corpses. The use of fixing solutions with a basis of formaldehyde, mercury, chromates or other substances may set up irritation — even chronic irritation of the mucous membrane involving risk of throat, nose and lung diseases and conjunctivitis.

The attendants in baths where the water and mud are rich in salts often suffer from irritation of the skin. Thus, for example, at Moinaki (Russia) peat-bath attendants were noticed to be suffering from skin irritation and other troubles ascribed to handling of lye and peat salts, sweat and dirt, and bent attitude sending blood to the head while transporting peat and attending to baths. Hydrogen sulphide fumes were inhaled by these workers, who suffered from trauma, nervous and muscular troubles, headaches and faintness, irritation of mucous — conjunctivitis, blepharitis and bronchitis. Skin troubles on hands and feet suggested an occupational disease, and 55 per cent. of illness was found to be confined to skin affections. It was noted that the workers suffered from loss of weight and reduced disease resistance at the end of the season.

Data regarding mortality and morbidity rates for the dental profession are even more fragmentary than those for physicians. No trustworthy mortality rates for this profession have been found except unpublished figures for American dentists indicating a mortality rate but little more than half that for physicians.

Both dentists and dental hygienists are exposed to the risk of contracting infections of the upper respiratory passages as a result of their professional work. There is also risk from infection (measles, diphtheria, tuberculosis of the skin, lupus, tuberculosis verrucosis cutis, etc.). There is, of course, some opportunity for contracting syphilis (finger infection) from the buccal lesions of patients. Usually it is the first finger, middle finger or thumb of the right hand which is affected. Because of the peculiarly faulty posture long maintained while operating, these groups have a tendency to develop deformities of the spine and shoulders with consequent cardiac troubles. Flatfoot in said to be common, associated with long continued standing, much of the time with practically all weight borne on one foot.

An interesting condition associated with the practice of dentistry is the dermatitis produced upon the hands by novocain or procain widely used by dentists. The condition is characterised by erythema, pruritus, exfoliation and fissuring, occasionally papules or vesicles, either on the dorsal or palmar surface of the hand.
More often formerly than of late dentists developed mild mercurial poisoning from the practice of rubbing up material for amalgam fillings in the palm of the hands. Hippe is said to have found mercury, not only in the atmosphere of a dentist's room, but also in the dentist's urine.

The use of X-rays exposes dentists to the risk of radio dermatitis with all its grave consequences. According to Klein, 17 per cent. only of a group of dentists examined were free of occupational disease; 72 out of 140 suffered from nervous troubles, deformities of the thorax, etc.

Risks of poisoning and asphyxiation from gas is present in operating theatres, dispensaries, disinfected and chemical laboratories and hygienic, pathological and anatomical institutes. The staff in these places are also exposed to danger from fire and explosion. Bursting of glass vessels and apparatus has also been the cause of accidents (eye injuries, etc.) in laboratories, dispensaries, etc.; where electricity is used, earthing and short circuits constitute a further danger.

Medical and Hospital Staff (Nurses, etc.)

In considering the morbidity and mortality rates of these workers, the part played by certain very unfavourable general factors must be taken into account; these, in a lesser degree, apply also to doctors. These comprise unduly long spells of duty, night duty, lack of sufficient exercise and fresh air, anxious and harassing responsibility, danger of infection added, in the case of religious orders, to fasting and strict exercise of religious duties, irregular meals, poor food, poor housing and unsuitable clothing. Amongst the latter anaemic and weak-chested subjects are often found, and not infrequently young nurses are obliged to do heavy physical work such as housework as well as sick nursing. An enquiry in regard to hours of work conducted in Germany showed that among 100 nurses 40.2 worked thirteen to fourteen hours per day, 41.2 worked fourteen to seventeen hours, and only 18.6 less that thirteen hours. Sometimes night duty or part-time night duty is demanded in addition to day duty. In private nursing (serious cases) the nurse is sometimes obliged to work twenty-four hours a day. For the great majority of nurses there is no legal limitation of the working day. All religious orders are exempt from regulations limiting the working week to sixty hours, or ten hours a day (Germany), and it is stated that this regulation where it applies is frequently not observed. The long hours and arduous routine life of the pupil nurses in many hospitals are a disgrace to the medical profession.

STATISTICS

No comprehensive mortality statistics for nurses are to be had. In the United States Census Bureau reports for 1909 the percentage distribution of deaths by causes was much the same as for all occupied females and for those engaged in domestic service. Typhoid fever was slightly higher.
and pulmonary tuberculosis notably lower. Typhoid fever is now, of course, largely eliminated through the use of vaccines. A report of medico-actuarial investigation of the experience of American insurance companies published in 1913 showed the actual mortality of trained female nurses to be 81 per cent. of the "expected", the same as that among unmarried women as a class.

There is no important evidence that nurses in general suffer a notably high death or illness rate as a result of contact with communicable diseases. In many American and European hospitals, however, acute illness among nurses, particularly young pupil nurses, is astoundingly prevalent. It is for the most part of types associated with debility resulting from long continued fatigue.

Despite the arduous life of nurses, most of the American reports relative to morbidity rates amongst them indicate these to be slightly lower than that for the general population, a proportion which might indeed be expected if the high physical standard demanded for this occupation be taken into consideration.

Robert Koch in 1910 carried out the first enquiry into the incidence of tuberculosis amongst German hospital staffs. For the period 1906-1910 the staff of 549 hospitals having a minimum of 100 beds showed a morbidity rate for tuberculosis of the lungs and of the larynx which did not exceed the average for the general population. Not one single group presented a value exceeding 1 per cent. Amongst the nurses in religious orders the morbidity figure seemed to be even more favourable than that for lay organisations of nurses not belonging to organised bodies.

Bräuning in 1910 arrived at similar conclusions; nurses from evangelical sisterhoods were not more frequently attacked by pulmonary tuberculosis than were women in the average amongst the active population. Nevertheless, 15-30 per cent. of the cases of tuberculosis were probably of occupational origin.

The German Council of Public Health decided in December 1922 to repeat the enquiry made in 1910 into the incidence of tuberculosis amongst the hospital staff. The enquiry will cover the period 1928-1931. In 1929 Harmsen studied the morbidity and mortality rates of nurses in evangelical sisterhoods. His enquiry covers a ten-year period.

In Italy, very interesting sickness and mortality statistics for nursing staffs have been furnished by G. d'Este and Chincarini. The former studied pathological conditions amongst nurses in Florence, and the latter those of the nursing staff in the "Maggiore" Hospital in Milan. The data assembled by D'Este cover a period of eighteen years (1904-1921), comprising eleven pre-war years (1904-1914) and three post-war years 1919-1921.

The days of absence for each individual nurse and for each case of sickness are summarised in the following table:

<table>
<thead>
<tr>
<th>Period</th>
<th>Per Nurse</th>
<th>Per Case of Illness</th>
</tr>
</thead>
<tbody>
<tr>
<td>1st period: 1904-1909</td>
<td>32.8</td>
<td>24.1</td>
</tr>
<tr>
<td>2nd period: 1910-1914</td>
<td>22.9</td>
<td>15.9</td>
</tr>
<tr>
<td>3rd period: 1915-1918</td>
<td>21.4</td>
<td>14.9</td>
</tr>
<tr>
<td>4th period: 1919-1921</td>
<td>18.6</td>
<td>16.2</td>
</tr>
</tbody>
</table>

After analysis of the cases of sickness as regards their duration, etc., D'Este is led to the same conclusions as Dr. Maffei (1914), who after studying absence due to illness amongst nurses in Florence concluded that the permanent staff of the hospitals remained absent from work on account of sickness for a number of days exceeding considerably that actually necessitated by their illness.

In analysing the incidence of diseases in relation to special categories, he found that the staff in the different departments were not presented an actual rate of absence per case of illness highly exceeding that for nurses in the tubercular wards (28.5; 18.3; 14.6; 13.7 as compared with 9.6). The explanation is to be sought in the working conditions for the latter category, which comprised a working day of eight hours in the twenty-four instead of eleven for the other services, and also in the fact that the nurses in the tubercular wards received an attendance bonus which was not paid during absence on account of sickness.

There were 19 cases of death: 11 due to respiratory diseases (6 to tuberculosis and 5 to broncho-pneumonia); 3 due to circulatory diseases; 2 due to digestive diseases and 2 to diseases of the liver, etc.

The mortality percentage was 1.91 per annum.

The morbidity rate per hundred male nurses was 71.1 for the period 1904-1909, 72.7 for 1910-1914; 76.5 for 1915-1918 and 62.8 for 1919-1921. The morbidity rate per hundred male nurses absent on account of sickness was per annum for the same periods 155.8; 151.2; 143.2; 114.9 respectively; each sick nurse having had during these four periods 1.08-1.09 attacks of sickness per annum. The general average sickness rate for Florence was 135 per cent.

The average number of days of absence for each case of sickness during the eighteen years under review was 17.77. As regards female nurses, the author was able to obtain data covering a period of twelve years: 1910-1921. The average number of women nurses employed being about 170 per annum, the number of patients amongst them amounted to 1,08 with 104 cases of illness and 2,744 days of absence, and an individual average of 16.1 days of absence and an annual mortality of 0.68 per cent. These data confirmed those already assembled in 1907-1909 by Guerra-Coppioli and those of Maffei in 1914.

The data collected by Chincarini for the period 1904-1914 and that for 1914-1921 throw very interesting light on the pathology and mortality of hospital workers.
In fact, for the second period the statistics relate to an annual average of 752 nurses (601 women and 151 men). The data may be grouped as follows:

<table>
<thead>
<tr>
<th></th>
<th>Men</th>
<th>Women</th>
</tr>
</thead>
<tbody>
<tr>

<td>17.92</td>
</tr>
</tbody>
</table>

The days of absence increased from year to year; but there must be taken into consideration the influenza epidemic of 1918 and the influence of the war. In comparing the data for the period for 1904-1914 with that for the period 1914-1921, there is noted a diminution in the mortality rate; for the men 1.51 as compared with 1.03, and for the women 1.85 as opposed to 1.03.

Religious orders, which under the hospital organisation of Milan carry out the work of superintending in the hospitals but have very much longer hours than the nurses, have no annual leave and do not enjoy good living conditions (lodging, food, etc.), do not provide (and not without good reason) such accurate morbidity statistics as the other nursing services. Mortality data for these orders are however accurate. From 1914 to 1921 amongst 150 Sisters of Mercy there were 17 deaths (2.12 per cent.), 7 due to tuberculosis, 3 to influenza and 3 to broncho-pneumonia. From 1904 to 1913 there were amongst 107 Sisters of Mercy 18 deaths, 8 being due to tuberculosis and 4 to typhoid fever.

Italian mortality statistics for men over fifteen years of age and for the period 1915-1917 show the following figures (per hundred male deaths from all causes and for the same occupational class):

<table>
<thead>
<tr>

The various causes of death reported by D'Este in Florence were as follows: gastrointestinal diseases due especially to irregular meals; diseases of the locomotor system; infectious diseases; respiratory diseases; traumas; occupational or otherwise, the former being five times as numerous as the latter; diseases of the nervous system, etc.

According to Chincarini the most frequently occurring diseases showed the following values (annual average per 100 persons):

<table>
<thead>
<tr>

In Germany Hamel found for nurses 0.27 cases of probable occupational infections per annum and per hundred exposed in the hospitals and 0.48 in the university clinics and 0.36 in tuberculosis sanatoria. The Protestant deaconesses presented a rate of 0.53, organised female nurses other than those belonging to religious orders 0.29 and female nurses not connected with any association a rate of 0.26.

Cornelius ascertained that of a nursing order of Sisters of Mercy, 61.9-73.8 per cent. died of tuberculosis between the ages of fifteen and fifty. In Prussia 39-43 per cent. of a nursing staff were found on examination to be tubercular, and in Munich 50 per cent. of the deaths of a hospital staff were due to tuberculosis. Official statistics for Bavaria, 1890-1908, published in 1913, show 56 per cent. of a certain order of nurses to have died of tuberculosis. Cornet and Von Maes are agreed, after detailed investigation of the subject, that tuberculosis is the predominant cause of mortality amongst nursing orders. Of 100 deaths amongst nursing sisters the following were due to tuberculosis:

<table>

The rate for the female population over fifteen years of age in Prussia, 1897-1901, was, in contrast to these rates, 15.9. Kossisch found the tuberculosis rate for nurses in Bavaria three times as high as the average rate. On the other hand, the Imperial Health Office characterised rates for doctors and nurses in German hospitals, 1906-1911, as "not unduly high", but the issue of a circular containing measures for combating infections (Ministry of the Interior, 10 October 1920) seems in contradiction with this (for recommendations contained therein see below, Hygiene).

In France, Pissavy (1927) found that doctors belonging to the wards for tubercular patients in the Paris hospitals suffered from tuberculosis during the year 1926 to the extent of 8.8 per cent., whilst male and female nurses in the same wards were affected in the proportion of 3.3 per cent. In hospitals without special wards, Meerbeck, cited by Epstein, states that male and female nurses were affected respectively in the proportion of 3.6 and 1.5 per cent. The higher morbidity rate for students is probably due to the fact that in questioning and examining the patients they are more likely than the nursing staff to come within the zone of projections of virulent tubercular bacilli. Riet has confirmed the importance of position in regard to persons obliged to approach tubercular patients. Thus, for example, attendants on duty at the entrance to the Léon-Bourgeois Dispensary have on several occasions contracted tuberculosis from salivary projections from patients until a protecting screen was erected to prevent this. The same expert has also noted cases of tuberculosis amongst laboratory staff, who were too greatly overwhelmed with work to enable them to observe the necessary precautions in handling infected material.

Hamel has reported the tuberculosis morbidity rate amongst nurses to be as follows per annum per hundred exposed: 0.80 for male nurses in general hospitals; 1.07 for students; 0.42 for those in sanatoria for tubercular patients; 0.58 for Catholic nursing orders; 0.68 for those not belonging to any organised body.

Epstein states that half of the cases of tuberculous infection occurring in hospitals, one-third of those in university clinics and six-sevenths of those in special institutions for tuberculosis can be regarded as occupational infection. For Catholic orders, Storch, cited by Epstein, states that from January 1919 to August 1922, 319 out of 10,692 sisters died from tuberculosis or four times the number for Prussia in general.

According to Chincarini, tuberculosis is very frequent amongst nurses in the "Maggiore" Hospital in Milan. During the period 1914-1921 there were 129 victims, 97 of whom were women, and 23 deaths, 14 of these being women. Per cent. for women, 2.8 per cent. for men and 17.8 per 100 patients). The Hospital Committee in 1919 decided to provide free treatment to nurses affected with open tuberculosis of occupational origin without any limit as to duration and to grant paid leave of three years' duration, at the end of which a pension should be granted unless a cure has been effected.

Certain authorities ascribe the high death-rate to infection, while others incline to the view that the over-ambitious work in the religious orders and bad objective conditions are mainly responsible. Six cases of tuberculosis which occurred among nurses were attributed to insufficient training, inefficient installation for destroying sputum and to nursing of very bad cases.

Typhus infection is specially common in country hospitals and cases of infection caused by bath water have occurred frequently. Schäuber (in Zeitschr. der Hygiene. Infektionskrankheiten) states that 1,797 nurses developed typhus in treating 35,647 patients, or a ratio of 3.3 per cent. of nurses to patients.

A case of epidemic encephalitis affecting a nurse who had nursed a case of post-encephalitic Parkinson disease had been reported by Crouzon and Horowitz in 1929.

Syphilis infection. — Nurses and midwives are highly liable to syphilis infection from syphilitic patients and infants, which may be contracted in a multiple number of ways. Childbirth cases are responsible for the majority of infections.

Skin infections. — Amongst skin infections may be mentioned whitlows and carbuncles, while eczema may be contracted from the use of mercury sublimate. Even the solution of 1:1000 used may give rise to blisters and eczema. Catamin and sulphur ointments likewise cause obstinate eczema and danger is also presented by the use of creosote, lysol, chlorine, lyes and acids, and silver nitrate solutions. Burns are not uncommon in the course of sterilisation.

Female hospital staff not infrequently suffer from strain and displacements caused by lifting heavy patients and from dysmenorrhoea and kidney trouble. Nervous affections and neurasthenia are common among nurses due to overwork, nervous tension and night duty, and a tendency to seek relief in the use of drugs. Overheating in operating theatres, baths, etc., causes rheumatism and cases of pneumonia. Nurses are also exposed to the effects of chloroform and ether fumes in operating theatres, already referred to under "Doctors", and to danger from arsenic and mercury fumes in handling such preparations. It should be recalled here that nurses belonging to religious orders, especially missionaries, are, like military doctors, exposed to exotic diseases and to a higher sickness rate on account of defective hygienic conditions (climate, feeding, etc.).
Children's nurses. — In regard to infections contracted by children's nurses, the most important factor is the very close contact presenting additional risk to that involved in treating adult patients. Children's nurses are exposed to risk from syphilis (see above "Syphilis Infection"), pemphigus neonatorum, dermatitis exfoliativa, multiple skin carbuncle, impetigo contagiosa, pediculosis, pyoderma and blennorrhoea. The risk is greater in private nursing where hospital precautions and often elementary means of taking precautions are absent. Often too the nurses themselves are wholly ignorant of the danger or means of avoiding it.

Mycosis, herpes tonsurans and erysipelas may also be contracted and often the medicaments used present danger, i.e. potassium, hypermanganese baths. Stomatitis mercurialis may be derived from iodine and sublimate. Infectious maladies such as diphtheria, measles, whooping cough, scarlet fever, etc., and also vaccination infections, but adequate care offers protection against such infection. Children's nurses may become carriers (e.g. diphtheria germs) and constitute a danger for other charges.

Hygiene

There is no formula for the improvement of the health of physicians. The old rules of Fodére in great part are still valid, particularly his precepts that the physician approach his task without fear, that he avoid an excessive burden of work and that he secure adequate rest after his labours. Doubtless there is no single measure of so much value in the conservation of health as a periodic physical examination at the hands of an able and understanding physician. Ignorance of impending disease may be blissful, but in such circumstances wisdom cannot be folly.

A doctor should be physically fit for his work and his sense organs should be intact. There is required of him not only a very wide general culture, but he should at the same time possess what few doctors really do possess, the faculty of making a psychological study of his patients. Durig has, however, rightly stated that certain diseases and states of health should not be considered as sufficient for exclusion from the medical profession. It is in fact true, for instance, that a tubercular doctor can practice in sanatoria or on board ship, while there is nothing to prevent a lame man from practising as a dentist, or a doctor with a paralysed hand or suffering from shortsightedness from engaging in therapeutical treatment. An individual whose hearing is affected but whose sight is good may become a good surgeon, whilst a shortsighted doctor whose hearing is good may make an excellent physiologist. Whilst a practitioner in a mountainous district, for instance, must be in good health and capable of long and tiring walks, such qualities are not required of a medical scientist desirous of engaging in laboratory work or in the teaching profession.

All nurses and attendants in hospitals should wear practical uniform, including head-gear and ward shoes, and should be instructed in efficient methods of disinfection. Baths and washing facilities should be provided for the separation of those of the patients. Male attendants should be called upon for lifting heavy patients, mattresses, etc.

Better methods of selection in the nursing profession would, together with shorter regular hours and adequate medical supervision, greatly diminish the professional risk, and efforts should be made to impose regulation of hours and wearing of suitable uniform on all nurses, including those belonging to charitable and religious orders. Comfortable well-ventilated sleeping accommodation should be provided and where possible facilities for physical exercise and recreation.

The habit of dry sweeping in infection wards twice daily should be discontinued and cleaning by vacuum installed. As parasites often transmit infection by bites, dirty patients should be obliged to pass through a delousing station provided next to the reception ward before admission for treatment, and precautions should be taken to keep infection wards free from flies, mosquitoes, etc. All persons with open wounds or scratches should be rigorously excluded from all sources of infection — fever wards, operating theatres, anatomy rooms, etc., and notification of all cases of sepsis through this channel should be insisted on. Infectious material should be transported in specially adapted vessels filled with detachable washable metal linings and lids which should be promptly disinfected after use.

All personnel in contact with infectious cases should be thoroughly instructed in the requisite precautions to take and should be ween nourished and not overworked. Schemes of insurance providing for treatment and compensation should be instituted for staff exposed to infection.

The danger encountered in nursing tuberculosis patients is stated to be not above normal in other occupations.
when every precaution is taken. Patients with infected sputum should be isolated, and spitting receptacles disinfected or special receptacles adopted which permit of incineration. Pre-disposed persons should be rigorously excluded from all contact with tuberculosis. Nursing staff in contact with such cases should be very well fed and their occupation should whenever possible be changed after three months with return to tuberculosis nursing only after lapse of one year. Working hours should never exceed eight per day inclusive of rest intervals with weekly rest of thirty-six hours at least. All vessels should be thoroughly disinfected and sickrooms should be washed down regularly with fluid disinfectants. Wearing of practical uniform and changing of uniform when off duty should be compulsory. All staff should be thoroughly instructed in the danger to which they are exposed and in the requisite precautions. Above all, doctors and nurses chosen for work in sanatoria and hospitals where tuberculosis patients are treated should be thoroughly examined before taking up work and all doubtful subjects excluded, and those admitted periodically; examined thereafter and removed on the first sign of any symptoms.

The Circular, already referred to, circulated by the Ministry for the Interior (Germany, 10, October 1920) makes the following recommendations: separate wards for tubercular cases, exclusion from these of nurses of feeble constitution, previous tuberculosis cases or susceptible persons; all nurses employed to be medically examined and weighed at regular intervals and immediately removed as soon as unfavourable signs are shown, nurses to be taken off duty at once when sick and not readmitted till passed as fit by a doctor; thorough instruction of staff in dangers and precautionary measures and technique of disinfection; provision of nourishing food rich in fats and of messrooms and sleeping accommodation separate from patients; annual leave of at least four weeks in summer and opportunities for rest during intervals between working hours; well-trained and efficient staff to be employed exclusively for tuberculosis; staff to be transferred to other wards after certain time spent in the tubercular wards; special attention to be directed to isolation of tubercular and infectious cases in lunatic asylums.

This Circular was followed by Special Orders in Prussia (1920), Bavaria (1921), Baden, Hamburg, Brunswick, Oldenburg, Anhalt, Bremen, Lubeck, Mecklenburg-Strelitz, Waldeck and Schaumburg-Lippe.

Doctors and nurses in contact with syphilis and skin infections should have their hands protected by rubber gloves when using disinfectants, as strong disinfectant solutions destroy the skin and open a door to infection. More care should be devoted to the training of midwives and children's nurses who engage in private nursing, as the danger is much greater for such persons than for those engaged in medical institutions under good medical supervision. Here again the great importance of compulsory notification of all cases of infection must be emphasised.

Staff exposed to ether and chloroform fumes in operating theatres should have short spells of rest, and be thoroughly instructed in the danger to which they are exposed and the requisite precautions. Above all, doctors and nurses chosen for work in sanatoria, and hospitals where tuberculosis patients are treated should be thoroughly examined before taking up work and all doubtful subjects excluded, and those admitted periodically; examined thereafter and removed on the first sign of any symptoms.

LEGISLATION

Peripheral paralysis occurring amongst employees in chemists' and druggists' establishments, poisoning by arsenic, phosphorus or mercury, and pulmonary affections due to chemical drugs occurring amongst persons engaged in chemical laboratories are subject to compulsory notification in Holland. Infectious diseases occurring amongst nursing staffs are compensated in Western Australia; smallpox, cholera, tetanus, typhoid fever, diphtheria, plague, measles, mumps, scarlet fever amongst nursing staffs in hospitals in Queensland; in Austria infections occurring amongst the staff of scientific laboratories; and in Germany infections occurring amongst the staff of hospitals, asylums, maternity institutes, health services and scientific laboratories. Mercury poisoning in Russia. For legislation relative to röntgen rays, and radium, see articles "Röntgen Ray Operators", and "Radium and Radio-Active Substances".

Medical Inspection of Factories

French: Inspection médicale du travail.
German: Ärztliche Gewerbeaufsicht.
Italian: Ispezione medica del lavoro.
Spanish: Inspección médica del trabajo.

HISTORICAL

Austria was the first industrial country to organise technical factory inspection, promulgating towards the end of the eighteenth century (1786) a series of regulations for the protection of children employed in industry. The action taken was to entrust to the medical men of the district the application of the regulations, with a view to the prevention of illness among apprentices. In 1816 the Government of Lower Austria applied these regulations more rigorously; in 1842 the Chancellor elaborated a Bill on the employment of children, with the object of placing the control in the hands of local authorities, inspectors of local schools and the clergy. In 1869 an important Bill laid it down that inspectors of factories ought to be public officials, quite independent of the employers. This Bill failed, and successive efforts in 1876, 1877 and 1879 suffered the same fate. Thus factory inspection did not attain a legal status until the special Act of 17 June 1883, which remained in force up till 1921.

In Great Britain a Factory Act dates from as far back as 1802, when a law was passed of which the object was to "preserve the health and morals of apprentices and other persons" employed in spinning mills and other textile factories, as well as in cotton mills and other factories (Morals and Health Act, 1802). Its application was placed in the hands of the local authorities, and Justices of the Peace had the duty of selecting either from amongst themselves or ministers of religion persons who were ready to fill, in an honorary capacity, the functions of inspectors (visitors). If they considered that existing conditions were likely to promote the spread of infectious diseases, they could require that the employer should submit, at his own expense, to an enquiry carried out by a medical man, who was obliged to present to the inspector a report on his findings. This law was not observed in practice, and this necessitated successive amendments (1819, 1825, 1883) which led to the introduction of official factory inspection placed in the hands of inspectors who were in possession of sufficient power to accomplish their task. In view of
the numerous abuses arising from the question of fixing the age of admission to factory work, the inspectors would only recognise certificates of fitness given by medical men selected by themselves. This was the origin of the "certifying surgeon" who still plays an important part to-day in English factory legislation (see below).

Conditions of labour prejudicial to the health of the workers could be combated by the Sanitary Act of 1866, the application of which was placed in the hands of the local sanitary authorities. In 1857 clauses were introduced into the Factory Act bearing upon health, the supervision of which was placed in the hands of factory inspectors. Consequently, hygienic conditions in workshops properly so called came under the Public Health Act of 1875, which replaced the Sanitary Act of 1866, the question of the duration of employment alone remaining in the hands of the inspectors. This state of things continued until 1891, when supervision of measures affecting health and workpeople was again entrusted to the local authorities, the inspectors of factories only acting as a sort of "super-inspectorate". Finally, the Factory and Workshops Act of 1901 introduced the procedure as it exists to-day.

In France, the campaign started in 1820 by the Industrial Society of Mulhouse resulted in the initiation of the first law for regulating industry (1841). At the same time, the inspection instituted did not go as far as to subordinate the private interest of the employer to the public interest, as the question of safeguarding did not yet come within the powers of the police. A Bill passed in 1848 by the Upper Chamber proposed the appointment of salaried inspectors to carry out the regulations concerning employment of children in factories, but it was not until the year 1868 that an Imperial Decree imposed this duty on the mines engineers. In 1870 the Government introduced a law in the Senate for the creation of four posts as superintending inspectors and sixteen divisional inspectors. In 1874 a law on the employment of children and female young persons in industry widened the circle of persons under supervision, strengthened protection relating to hours of work and prescribed various measures for the protection of the life and health of the workers. Finally, provisions contained in the laws of 2 June 1892, 12 June 1893 and 9 April 1898 enabled the inspector to intervene in case of factory accidents and led to the organisation of factory inspection as it exists to-day.

In Germany factory inspection has been organised in the different States independently of one another. Prussia was the first to create such an inspectorate. In 1824 the Minister invited the prefects to report to him on the employment of children in the Rhine provinces, about which he had received disquieting reports since 1818. Consequently on this invitation, the Prefect of Düsseldorf proposed the institution of local committees of inspectors (1835), which was followed in 1837, on the initiative of a Rhineland employer, by a proposal to create a regular service of factory inspection. These measures led in 1859 to the adoption of regulations as to the employment of children in factories, the results of which were not too satisfactory. However, the adoption in 1869 of the Industrial Code (Gewerbeordnung) marked a real progress in the development of Prussian and German factory inspection. Later amendments modifying this Industrial Code brought organisation in Germany up to the point where it stands to-day.

In Belgium the origin of protection for the workers dates back as far as the era of Napoleonic domination (1810), when a law prescribed that officials should inspect mines, foundries and similar undertakings. Royal Decrees of 1849 and 1863 subjected dangerous and unhealthy establishments to regulations intended to impede or diminish ill-effects from such establishments, inconveniencing people in the neighbourhood as well as the workers themselves. A Decree of 27 December 1866 required that, if these measures, the execution of which was in the hands of the administrative authorities, be made more stringent and efficacious. Nevertheless, the basic law for inspection of factories was not adopted until 5 May 1888; this provided for the inspection of dangerous, unhealthy or offensive establishments, the supervision of machinery and boilers, and the right of inspectors to enter any factory, etc. A Royal Decree of 1895 prescribed the re-organisation of factory inspection and classification and established measures which are, in the main, still in force at present.

In Switzerland the first law for the protection of workmen was promulgated in 1815 by the Canton of Zurich, but it remained ineffective. Effective inspection of factories for the whole of the Confederation was not provided
for until 1877, as a result of a Federal law for all factories.

In the Netherlands, as a result of a parliamentary enquiry in 1886, a law relative to labour, which provided for the appointment of factory inspectors, was adopted on 5 May 1886. This law was completed by the law on industrial safety of which the most recent form dates back to 1915, and which contains provisions relating to conditions of hygiene in workshops and the prevention of industrial diseases.

In Italy the conception of factory inspection as a public service is only of recent origin, as its organisation dates back to 1912. However, as in other countries, various legislative measures had already assured a control over the employment of children (1886), factory accidents (1898), etc.

Amongst other countries possessing relatively long-established inspection services should be mentioned: Denmark (1832, 1851); Sweden (1889); Finland (1832, 1868 and 1873); Spain (1873); as well as the United States of America (Massachusetts: 1842, 1852; Pennsylvania: 1827, 1848; Connecticut and Maine: 1836, 1852; New York State; 1886; etc.).

The Medical Inspection Service

While factory inspection in the beginning was, in certain countries, placed in the hands of persons who, besides a certain amount of instruction possessed also much tact and good sense, and in other countries was given over exclusively to engineers to emphasise the technical nature of the service, the need had nevertheless been early realised for calling in aid the collaboration of the medical profession in all questions relating to hygiene and the health of the workers. This necessity was felt by most industrial countries and resulted in the organisation of medical services.

The medical inspection department in Australia comprises a Divisional Director of industrial hygiene, a medical adviser attached to the head office and a Chief Medical Inspector for each State. These last positions are not yet filled, but at the present moment two medical inspectors are attached to a clinic in the mining district of Broken Hill.

In Austria factory inspection has comprised, since 1919, a medical department, directed at the moment by a woman. As an official factory inspector, she has the right of entry into factories and workshops, and into the workers’ homes where home work is carried on, places where apprentices are employed, workers’ dwellings, etc. Mines, railways and agricultural undertakings are outside the scope of her duties, and in most cases she makes her visit to unhealthy establishments in conjunction with the factory inspector. The work of the medical inspector forms a special report which appears in the annual report on factory inspection.

In Belgium the medical inspection of factories includes a central department and a provincial department; the former, which is vested with full authority, directs the latter, and is under a Chief Inspector of the department and three medical inspectors, one of whom is a woman, and one an inspector holding a doctor’s degree in science and chemistry. A laboratory for chemical and biological research is attached to the central department. The provincial department comprises nine inspectorial districts, one for each province, each district being under the control of a medical inspector. The supervision of some of the districts is in the hands of certain medical inspectors who are officials of the central office. The duties of members of the medical inspection department are as follows:

1. to organise the protection of pregnant women and nursing mothers in industry;
2. to ensure the protection of the health of apprentices from fourteen to eighteen years old, and to assist in their vocational guidance;
3. to study all branches of industrial physiology and pathology;
4. to bring their special knowledge to bear on all social services;
5. to spread throughout the industrial world a knowledge of the best methods for preventing occupational disease and to promote the use of the most rational health measures;
6. to supervise the application of the official medical regulations.

Performance of the medical inspector’s duties is assured by various legal provisions concerning health and safety of the worker (physical cleanliness, first-aid, smallpox vaccination, etc.).

The medical inspectors of factories can enter freely during the day and night premises under their supervision; they can conduct prosecutions for infringements of the law and may ap-
Medical inspection of factories.

In the course of their visits they make useful suggestions to the employer, but definite instructions must be addressed to the employer through the district inspector of factories, who alone possesses the right of taking definite action. The medical inspectors may be requested to investigate certain questions or to collaborate in regard to enquiries made by the Federal Office of Hygiene. They act on occasion as medical advisers to the Prussian or Federal Ministry on questions of industrial hygiene. They collaborate with insurance offices, with a view to improving sickness statistics, besides giving talks to medical men with the object of disseminating knowledge of industrial hygiene. They deal with vocational guidance. They may not practise or act as consultants for social insurance services except

In France, a medical inspection service has not so far been established. However, during the war, a special branch comprising medical men had the task of informing the Ministry of Munitions as to conditions of health and safety of the workers, and the organisation of labour. Furthermore, during the war, a member of the Superior Public Health Council of France was entrusted by the Consultative Committee on Labour and the Committee on Women's Labour with the examination of the hygienic measures taken or to be taken to safeguard the personnel, and particularly the women employed, against the risks inherent in the different manufacturing processes.

In Germany medical inspection was organised separately in the various States. A service instituted in Prussia in 1921 comprises five industrial physicians (Landesgeverbeärzte) resident respectively at Dorpat, Berlin, Wiesbaden, Erfurt and Breslau, under the authority of the Minister of Social Services. They have to collaborate with governmental and industrial councils in the districts under their charge; they are naturally in close contact with the other factory inspectors, as well as medical practitioners in the district. They have the right of visiting factories, but they are generally required to give notice to the Government department or occupier beforehand, in order to allow them to take part in the visit. They have not the right to draw up regulations, but when there is a difference of opinion between them and the departmental councils and the occupiers on special points, they can be summoned before the President of the district affected or even the Ministry.

The duties of the medical inspectors are:

(a) to advise and assist the factory inspectors and mines inspectors on questions of industrial hygiene;

(b) to study the morbid changes occurring among the workers in their relation to the work effected, methods of prevention and cure of such changes, as well as all questions of industrial hygiene affecting the health of the workers.

In practice their activity is organised in such a way that they are informed by the Sickness Insurance Offices and the workers' organisations of the occurrence of sickness or other industrial injury affecting the health of the workers. Owing to the compulsory notification of certain industrial diseases, brought into line with accidents and the collaboration of technical inspectors, they are kept well informed in regard to all aspects of health and sanitary conditions in industry. In the course of their visits they make useful suggestions to the employer, but definite instructions must be addressed to the employer through the district inspector of factories, who alone possesses the right of taking definite action. The medical inspectors may be requested to investigate certain questions or to collaborate in regard to enquiries made by the Federal Office of Hygiene. They act on occasion as medical advisers to the Prussian or Federal Ministry on questions of industrial hygiene. They collaborate with insurance offices, with a view to improving sickness statistics, besides giving talks to medical men with the object of disseminating knowledge of industrial hygiene. They deal with vocational guidance. They may not practise or act as consultants for social insurance services except

In Brazil the regulations of 5 May 1923 lay down that the medical factory service shall consist of a Chief Inspector and an adequate number of factory inspectors or sub-inspectors.

In Canada an industrial hygiene department carries on its functions under the Ministry of Health, Toronto.

In Finland a Resolution of the State Council of 1927 formed a medical factory inspection service.

In Germany medical inspection was organised separately in the various States. A service instituted in Prussia in 1921 comprises five industrial physicians (Landesgeverbeärzte) resident respectively at Dorpat, Berlin, Wiesbaden, Erfurt and Breslau, under the authority of the Minister of Social Services. They have to collaborate with governmental and industrial councils in the districts under their charge; they are naturally in close contact with the other factory inspectors, as well as medical practitioners in the district. They have the right of visiting factories, but they are generally required to give notice to the Government department or occupier beforehand, in order to allow them to take part in the visit. They have not the right to draw up regulations, but when there is a difference of opinion between them and the departmental councils and the occupiers on special points, they can be summoned before the President of the district affected or even the Ministry.

The duties of the medical inspectors are:

(a) to advise and assist the factory inspectors and mines inspectors on questions of industrial hygiene;

(b) to study the morbid changes occurring among the workers in their relation to the work effected, methods of prevention and cure of such changes, as well as all questions of industrial hygiene affecting the health of the workers.

In practice their activity is organised in such a way that they are informed by the Sickness Insurance Offices and the workers' organisations of the occurrence of sickness or other industrial injury affecting the health of the workers. Owing to the compulsory notification of certain industrial diseases, brought into line with accidents and the collaboration of technical inspectors, they are kept well informed in regard to all aspects of health and sanitary conditions in industry. In the course of their visits they make useful suggestions to the employer, but definite instructions must be addressed to the employer through the district inspector of factories, who alone possesses the right of taking definite action. The medical inspectors may be requested to investigate certain questions or to collaborate in regard to enquiries made by the Federal Office of Hygiene. They act on occasion as medical advisers to the Prussian or Federal Ministry on questions of industrial hygiene. They collaborate with insurance offices, with a view to improving sickness statistics, besides giving talks to medical men with the object of disseminating knowledge of industrial hygiene. They deal with vocational guidance. They may not practise or act as consultants for social insurance services except
when requested by a superior authority. Their activities are recorded in an annual report which is published separately from that of the factory inspectors.

In Bavaria, the position of medical inspector of factories (Landesgesetzeberaetsl) was created in 1908, as a result of the insistent demand from representatives of the working classes and of the medical profession. The medical inspector, who acts under the Chief Inspector, co-operates with technical inspectors and mines inspectors, and is in touch with the medical practitioners in the district, etc.

His duties include the following:

1. acting as referee; giving advice to factory and mines inspectors; making surveys for the Ministers of State, the above-mentioned officials and the higher insurance tribunals;
2. visiting industrial undertakings and mines with a view to inquiring into varying conditions of work and arrangement of plant, studying different methods of work, medically examining the workmen, conducting research into hygienic conditions, etc. ;
3. controlling the activities of the examining surgeons;
4. supervising first-aid provisions;
5. scientific work; making health studies of certain occupational groups doing statistical and clinical research, both in the laboratory and in every department of industrial medicine;
6. preparing reports (literature, etc., on the subject, etc.);
7. doing propaganda work and giving instruction by means of articles in the press, lectures in the Universities and in the higher technical schools, reports to medical societies;
8. organising and maintaining the Social Hygiene Section in the Bavarian Social Museum;
9. studying the various problems of social hygiene which affect the working classes: alcoholism, housing, tuberculosis, and food problems, etc. ;
10. centralising the reports of cases of industrial diseases compulsorily notifiable and elaboration of this material.

In Saxony, the occasional collaboration of the medical practitioners of the district, often impossible without loss of time, was completed by the appointment of a physician attached to the Ministry of Labour and Social Services, and co-operating with the Chief Inspector of Factories. On the other hand, as a result of provisions made by an Ordinance of 12 October 1921, which requires factory inspectors to have a knowledge of economic and medical questions, the medical inspectors have been able to exercise the functions of factory inspectors. In practice, the administrative authorities, in distributing the work, utilise to the greatest extent possible the special capabilities of the medical inspectors, whose essential work consists in supervising the practical application of measures protecting the health of the workers in general. Their activity is particularly concerned with the study of occupational diseases and other injuries to health, the medical examination of particular groups of workers, the effects of certain methods of working, and the peculiar hygienic questions relating to recently-discovered products or methods of production. Besides this, the medical inspectors supervise the work of the factory surgeons and give them any advice calculated to aid them in carrying out their duties and in the study of plans for construction or alteration of industrial establishments, etc.

In the State of Baden, the medical inspector, in conjunction with the superintending inspectors, supervises factories where unhealthy work is carried on. The inspection of mines is independent of factory inspection, but all questions of hygiene are referred to the medical inspector. Like the heads of the other inspection departments, this official is directly responsible to the Ministry. He compiles a special annual report on industrial hygiene, which forms part of the general report on factory inspection. In addition he gives lectures on questions of industrial hygiene, finishing courses for the benefit of medical officers and, in the higher technical schools, courses for the benefit of young engineers.

In Great Britain, towards 1831, when the age of admission of children to factories was first fixed in the textile industries, the service of the "certifying factory surgeon" was first brought into existence.

At present medical inspection of factories in Great Britain is included in the factory department of the Home Office, in which the medical inspectors form an integral part of the general
factory inspectorate, consisting of a Chief Inspector, three deputy chief inspectors, a Senior Medical Inspector and four other medical inspectors (of which one is a woman).

Appointments for medical inspectors are first advertised and then a selection is made, after scrutiny of medical qualifications and previous experience, of a certain number of candidates for interview and final selection. The services of the medical inspectors are, as far as the small number will allow, assigned divisionally, that is, at London (covering the South Eastern, Western, Midland and Eastern Divisions); Manchester (covering North Western, East Lancashire, North Eastern and North Midland); Glasgow (covering Scotland, Newcastle and Gateshead Divisions); and the woman inspector in London (covering the Southern Division). While thus assigned to divisions, if one inspector has special knowledge of a particular branch of industrial hygiene (e.g. silicosis and pneumoconiosis) he is commissioned to visit the other divisions occasion arises.

The medical inspector's duties and powers are in general identical with those of other inspectors of factories. They include particularly: (1) supervision of the work of certifying factory surgeons and appointed surgeons, whose duties are mentioned later; (2) special enquiries into dangerous and unhealthy industries; (3) inspection of works under regulations made by the Home Office under the Factory Act, particularly those enforcing periodic medical examination, and Orders relative to Welfare made under the Police, Factories (Miscellaneous Provisions) Act, 1916; (4) all questions concerning injury to health of workers; (5) supervision of first aid in factories; (6) drafting of new regulations required after enquiry dealing with dangerous and unhealthy industries.

The Factory and Workshop Act, 1901, gave the medical inspectors the right of prosecution, but in practice this is promoted by the factory inspector of the district concerned, the medical inspector only attending as witness.

The certifying factory surgeons, to whom reference has been made above, number some 1,800 and are distributed over the country, one for each district, like the public health officers. Their duties are: to examine young persons of from fourteen to sixteen years of age before employment in factories. They have the power of attaching conditions as to the nature of the work on which the young persons may be employed. Further, they make periodic medical examination of the workers in certain dangerous and unhealthy industries. They report on all cases of industrial poisoning which are notifiable under the Factory Act. Lastly, they grant certificates entitling to compensation in the case of industrial diseases scheduled under the Workmen's Compensation Act. The certifying factory surgeons are appointed by the Chief Inspector of Factories. The duties of the appointed surgeons, of whom the number is very limited, are to examine periodically persons employed in certain dangerous and unhealthy industries under regulations, taking the place of the certifying factory surgeon. Appointed surgeons are selected by occupiers, and their appointment made subject to the approval of the Chief Inspector of Factories.

Further medical services are rendered by:

(a) a special bacteriologist, for the purpose of examining samples of wool and hair for the presence of anthrax;

(b) a specialist chemist for the purpose of research work;

(c) the Government Laboratory, in assisting in chemical analyses;

(d) independent medical officers of health, appointed by county councils, and all local authorities carrying out subsidiary duties as to sanitation of workshops, the administration of the Factory Act in respect of sanitation in them being delegated to the local authority by the Factory and Workshop Act.

No special training for medical inspectors or certifying surgeons is provided at the Universities or elsewhere. Classes are held at London and Manchester Universities during one session on factory hygiene, as part of the course for the Diploma of Public Health, and are open to all fully-qualified medical practitioners. When confronted with difficult questions, the department can have them investigated fully by means of committees. Apart from this, much valuable aid is rendered by a permanent committee (Consultative Committee on Scientific and Industrial Research to the Privy Council) and, as need requires, by the Industrial Health Research Board (formerly the Industrial Fatigue Research Board.)

In Italy, medical inspection is entrusted to medical men with a status similar to that of the technical in-
spectors. Their main duties are:
(a) to ensure the enforcement of all Acts concerning labour and social welfare in industrial and commercial undertakings, offices, agriculture, and, in general, in all localities where work is carried on for wages or salary (the inspection of mines, quarries and peat cutting is carried out by the special body of mining inspectors), and (b) to collect all information and data concerning technical and hygienic conditions in industry, and also concerning the development of the national production and in general all information requested by the Ministry on the subject of industry or labour.

The medical inspectors have the same duties as all other technical inspectors, but they form a special body, ranking as a department, the chief of which resides at Rome and is attached directly to the Ministry of Corporations.

The other medical men are attached to the administrative head of the district in which they work and they can be attached to the service of the Chief Medical Inspector for the purpose of carrying out all duties in connection with the supervision of hygienic and sanitary measures.

The Chief Medical Inspector is entrusted with the duty of co-ordinating and directing all measures for the enforcement of hygienic and sanitary regulations, of giving his views on concessions and measures for the enforcement of such general principles, of carrying out inspections in agreement with the local inspectors in the relative districts, of conducting enquiries into conditions of industrial hygiene and health, and of carrying out any other work which may be assigned to him by the Minister. For the better accomplishment of these duties the Chief Medical Inspector possesses a chemico-physical research and bacteriological laboratory, etc. He may also be authorised to utilise other scientific laboratories for special research work, etc.

His work in supervising hygienic and sanitary conditions of labour is to a large extent assisted by the other sanitary officials in the municipalities.

In Japan, a medical director and three other medical inspectors constitute the staff at the Ministry of Labour headquarters, and there are about sixty regional medical men in different parts of the country.

In Lithuania, medical inspection of factories was organised in 1925.

In Mexico, a department of Social Welfare and Industrial Hygiene acts in conjunction with the Ministry of Industry and Labour.

In the Netherlands, the Chief Medical Officer and five medical men constitute the Central Inspectorate, which is under the Ministry of Labour, Commerce and Industry. These medical men are in the closest contact with the other factory inspectors on all questions relating to hygiene, in order to give them the benefit of their advice and support in giving effect to the provisions of the Factory Acts and Regulations. It is, moreover, their duty to report to the Chief Medical Inspector especially on matters which do not concern the district inspectors.

The Chief Medical Officer acts as the medical expert for the Ministry of Labour, the General Director, and the district chiefs.

The duties of the medical inspectors include inspecting factories, periodic medical examination of workpeople, as well as examination on commencing employment, in certain industries, collection of information on the frequency of occupational diseases, the organisation of first-aid, etc.

In Norway, the medical inspectorate comprises one doctor attached to the Central Inspection Department and medical men attached to the regional staff. The local departments are under the control of divisional inspectors appointed by the State.

In Peru, questions concerning the medical inspection of factories are dealt with by the Department of Industrial Hygiene, which exists in connection with the Ministry of Labour.

In Poland, there is a Central Medical Inspector of Factories, two medical men in the provinces and ten doctors attached to the National Sickness Fund, who are entrusted with the sanitary supervision of workpeople.

In Portugal, the department of Inspection of Factory Hygiene was re-organised in 1927.

In Sweden, there is a central department for Medical Inspection of Factories, with a Chief Medical Inspector; the technical inspectors have further the right of calling in provincial medical men on certain points.

In Switzerland, since the initiation of factory inspection, although there is no special service, medical men may become inspectors. Further, the medical officers of factories, in order to

1 The Chief Inspector of Factories happens at the moment to be a medical man, so that at present there is no doctor attached to the Central Office.
be independent of the employers, are paid by the State, which collects a tax paid by the employers on a basis of the number employed. Lastly, whenever occasion calls for it, resort is had to an expert i.e. a professor of a University (an authority on hygiene or forensic medicine.)

In the U. S. S. R. a Medical Inspectorate for Factories has existed since 1919 attached to the governmental sections of the People's Commissariat and having as its object the task of controlling hygienic and sanitary conditions in industry. Medical inspectors are completely independent of the technical inspectors in everything within their competence. Prosecutions, however, for non-observance of regulations cannot be instituted by medical inspectors, but only through factory inspectors. The duties of the medical inspectors are, among others:

(1) to carry out general investigations, where possible, on the conditions of work affecting health; to compile all scientific, statistical or other information, of use in a systematic effort to combat occupational diseases;

(2) to organise and apply measures of hygienic improvement of production and of conditions and methods of work;

(3) to supervise the execution of legal regulations in the field of industrial hygiene and prevention of accidents.

The medical inspectors have the duty of visiting the various factories, warehouses, etc., either of their own accord or at the request of the factory inspector or the workers' organisations. Professional training of medical inspectors is given in the Universities, all of which provide a compulsory course in industrial hygiene.

Up to the present, it has been principally a question of the appointment of medical inspectors of factories working in conjunction with technical inspectors. But in order to make such health supervision really general and effective, it is necessary to have a large number of co-workers, like the certifying surgeons in England and the appointed surgeons in Belgium, to assist the medical inspectors in their work.

For this reason the Central Labour Organisation would require to have peripheral branches functioning in the various districts. These district organisations could carry out duties which the central office never becomes acquainted with and, at the same time, effect the health work already assigned to the communes as regards industrial hygiene.

In the United States Medical Factory Inspection Services have been organised in several States (New York, Massachusetts, California, Ohio, etc.).

Ranelletti has insisted several times on the efficacy of municipal health offices in the principal municipalities, and he outlines the work of the medical factory inspectors as follows:

(1) Better organisation of the health service for granting certificates of fitness for admission to work of young persons of both sexes, and organisation of the medical department of vocational guidance.

(2) Compulsory periodic medical examination of persons engaged in unhealthy and dangerous industries and in industries where food is prepared.

(3) Collecting and filing information regarding hygienic and sanitary conditions of labour.

(4) Statistics of morbidity and mortality in relation to industry.

(5) Hygiene of factories and supervision of the application of regulations.

(6) Supervision of hygienic conditions, especially among home workers.

(7) Health education of the workers.

(8) Medical, social and charitable organisation work in the field of industry.

To sum up, the duties of the Medical Inspector can be classed under three main heads as follows:

I. — Duties concerning the Factories and Workshops

(a) Examination of plans for building or alterations in the factory.

(b) Right of inspecting the installation, transformation or method of working in any industry or trade.

(c) Right of entry and inspection in industrial undertakings.

(d) Supervision of the application of legislative measures in unhealthy industries.

(e) Investigation of health conditions in factories.

II. — Duties concerning the Workpeople

(a) Examination of young persons entering on employment.

(b) Examination of workers before commencing employment in certain processes.

(c) Periodic examination of children or young persons.

HYGIENE AND PATHOLOGY

The occupation of literary men, or of those following other similar artistic professions (artists, literary, savants, philosophers, barristers, judges, etc.), or again that of public speakers, involves work demanding intense intellectual activity and personal sensibility. Those engaged in such work use up great stores of nervous energy, and draw on their resources to the point of exhaustion. Characteristic of such work is the fact that the nervous system dominates entirely the organic functions. Obviously, therefore, the health of individuals devoting themselves to work of this kind is put to a severe test, and is likely to suffer in the absence of attention to the principles of hygiene.

On the basis of the axiom that a sound mind can only exist in a sound body, it is evident that the physical health of literary men and orators is of pre-eminent interest to the hygienist. In the present state of knowledge and with the ordinary methods available, it is impossible to estimate the expenditure of energy entailed in intellectual work. It may be that there is merely some qualitative change in metabolism which is not reflected in any corresponding modification in the balance of metabolism. This view has led a number of authorities to consider that brain workers do not require such liberal and substantial food rations as manual workers, whose muscular expenditure of force demands considerable quantitative replenishment. However that may be, the contrary has often proved to be the case as might be instanced from the lives of many great writers.

It is true that abundant and heavy feeding by a person engaged in a sedentary occupation engenders troubles commonly known under the name of retarded nutrition, resulting in rheumatism, gout, gravel, arterioskerosis, etc. As a matter of principle, literary workers, in view of their sedentary occupation, are well recommended to confine themselves to a light well-balanced diet, limiting themselves to one principal meal in the day, preferably at midday and followed when possible by exercise to aid digestion. Goethe, for instance, in the effort to maintain his health found that it

(d) Periodic examination of persons employed in unhealthy industries and supervision of conditions under which work is carried on.

(e) Protection of expectant or nursing mothers.

(f) Collaboration with the technical department and the social welfare service.

(g) Vocational guidance and especially study of the physiological demands made by different occupations.

III. — Duties concerning Questions of Organisation and Scientific Enquiry

(a) Study of problems of industrial physiology, research into the causes and effects of occupational diseases and poisonings, and measures for their prevention; forming up scientific progress in the field of industrial medicine.

(b) Study of the best measures for organisation of a medical service in factories.

(c) Advice as to the classification of unhealthy undertakings.

(d) Participation in the drawing up of regulations for industrial hygiene and in the work of departmental committees on industry and hygiene.

(e) Participation in the evaluation of incapacity due to accidents at work.

(f) Collaboration in the drawing up of safety codes and propaganda brochures relative to measures of safety in industry.

(g) Collaboration in the preparation of annual reports.

(h) Propaganda with a view to disseminating throughout the industrial world knowledge of the most effective methods of prevention and the adoption of rational health measures.

(i) Official or unofficial collaboration with Universities, Insurance Funds, School Medical Inspection Services and other institutions interested in industrial medicine and hygiene.

BIBLIOGRAPHY

Prof. A. Ranelletti

(Rome)
suited him to reduce progressively his diet (Michelet). It would seem that intellectual work is not generally conducive to obesity, as is borne out by a long list of names of immortal fame, amongst whom may be cited Demosthenes amongst orators; Leon-Baptist Alberti and Leonardo amongst painters; Beethoven, Chopin, Verdi, Donizetti and Bellini amongst music composers; and from Dante, "of spare build ", to many later famous men of letters. Naturally, however, many exceptions occur since allowance must be made for differences in temperament and constitution. Thus for a subject of retarded nutrition with a tendency to stoutness severe dieting and regular gymnastic exercise may be advantageous. On the other hand, an individual with accelerated nutritional activity (hyperthyroidians, etc.) may be the better for plenty of food and rest after meals. Exercise is, however, generally to be recommended for intellectual workers, who are only too inclined to eschew it and seldom get sufficient opportunity for walking.

The question of the consumption of alcohol in relation to the performance of intellectual work has been much discussed. Alcohol is at present still regarded as a stimulant of the psychical functions and the consumption of drinks containing it in larger or lesser quantity is only too frequently resorted to by those engaged in literary work. Nevertheless, against a long list of men of genius known to have overindulged in alcohol and to have produced their work under its stimulus, must be placed the names of other equally famous men who abstained from its use. It may be argued that the conclusion may be drawn that the brain worker, be he a man of letters or a poet, may very well dispense with alcohol.

Without referring to drug addicts, who have used the most varied substances as excitants, it is useful perhaps to refer in passing to the abuse of coffee indulged in by some writers, certain of whom could not work without the aid of this stimulant. Nevertheless, mental effort should not depend on excitation, since every form of excitement is in the long run exhausting; the necessity being rather for perfect equilibrium since intellectual power is at its maximum under this condition (E. Mouton).

Tobacco smoking is much indulged in by men of letters and to cite only a few great names, Flaubert, Byron, Musset, Racine, Marquis de Sade, Voltaire, etc. were great smokers, though others, such as Victor Hugo, St. Beuve, Heinrich Heine, and above all Goethe, never indulged in the habit. In the opinion of these writers, tobacco did more harm than good, "transforming thought into reverie " (V. Hugo), "clogging activity" (Barbey d'Aurevilly), and has even been characterised as "a murderous pastime, a cruel desire, insatiable and useless" (Theodore de Banville).

So far as concerns the bodily health of mental workers, too much insistence cannot be laid on the value of cold baths, douche baths, etc., which are excellent stimulants.

As regards clothing, it should be comfortable and unconstricted. A writer seated in front of his desk should not, for instance, be hampered by tight, heavy or hot clothing likely to hinder the circulation and cause congestion. Balzac was accustomed to wear a monk's cassock while working, which he found to be thoroughly practical.

The above also applies to oratorical speakers whose work of meditation and preparation is similar to the work of the writer. During public speaking, however, they are obliged to submit to the constraint of clothing which may involve much discomfort.

Besides physical hygiene, men of letters ought to observe principles of intellectual and moral hygiene.

Various expedients have been followed by men of genius, such as reading aloud or declaiming with a view to stimulation of ideas. As regards hours of work no general rule can of course be laid down for such workers. In large towns, as is well known, writers prefer to work at night in the absence of noise and agitation. This may not be an unwise procedure provided undue fatigue is prevented by an adequate compensating period of sleep, provided always that night work does not prove detrimental to the eyesight. The greatest care must be paid to the prevention of ocular fatigue, and it is probably lack of attention to this which brought on blindness in the case of such great men as Milton, Montesquieu, Augustin and Thierry.

Mention should be made of the occupational affection of writer's cramp, from which certain authors have suffered in the production of their works in manuscript.

The introduction of rest periods or interruption of work has been recommended as effective in increasing efficiency in intellectual work. Nevertheless, many authors maintain, as against this view, that in the effort of producing something original, the spell may be broken by an ill-timed interruption. In the case of the majority of writers, the impulse to write is destroyed and its resumption de-
MEN OF LETTERS, SPEAKERS, ETC. — 294 —

Doses a long period of fastidious and sterile effort.

The problem of what attitude assumed by literary men while at work is the most favourable, does not admit of a uniform solution. It is well known that all varieties of attitude from agitated pacing up and down to a peaceful recumbent position have been favoured by different writers. Victor Hugo walked up and down whilst composing his poems and Mistral composed his whilst taking walks. On the other hand, Descartes, Leibnitz and numerous writers of delicate constitution preferred to work in a recumbent position.

Noise is one of the worst enemies of the literary man. Even here, however, exceptions are numerous and certain writers are known to have produced their best work in the chatter of taverns and to have been depressed by solitude (Théophile Gautier), while some like Verlaine courted the stir and tumult found in cafés.

It is an undoubted fact that the rigorous practice of the laws of hygiene must meet with abundant obstacles in the case of literary workers. In the first place, individual variations in will-power and particular attitudes of mind must always be taken into account. Efforts to regulate hours of work or output must remain Utopian measures in a domain where a man's work is the expression par excellence of personal talent. Another consideration to be taken into account is the social status of the writer. Many men of genius have been Bohemians, undisciplined individuals only capable of working under special environmental conditions (in which they are accustomed), however detrimental, and the suppression of which might involve banishment of inspiration. Since literature must be free from all constraint, it is obvious that all individuals, even those differing from normal standards, have the right of authorship.

Early writers in medical literature have devoted chapters to the enunciation of rules for mental work under hygienic conditions, stipulating intermittent activity and rest periods. Yet it would be highly ridiculous for a medical man to prescribe for a writer the time during which he should exert himself and when he should rest. Such advice cannot be taken seriously since it is impracticable, the creative spirit being by its nature free. "It would be a mistake to measure verve by a compass, to try to estimate enthusiasm or dose inspiration" (Réveillé-Parise). Rest and work cannot well be regulated except in accordance with the habitual disposition of each individual, since

the rule of hygiene which is perhaps the most important to observe in sustaining activity and intelligence is the entire liberty of this same intelligence.

So far as relates to the pathology of men of letters, their maladies are caused for the most part by the conditions under which they work. Certain authorities are of the opinion that intense intellectual activity strains the organ of thought and in proof of this quote many instances of writers and speakers who have been the victims of cerebral arteriosclerosis and its sequellae (cerebral haemorrhage, embolism, etc.—Copernicus, Malpighi, Linnaeus, Spallanzani, La Bruyère, Daubenton, Monge, Cabanis, Corvisart and others died of apoplexy (Layet). Without doubt, associated with neuro-muscular fatigue there is also the problem of mental fatigue. Discussion of this will here be confined to mention of the very interesting and original studies of Patrizi on mental fatigue, which he studied amongst speakers and intellectual workers. It is sufficient to state that his studies led him to adopt the view that there exist various individual types distinguishable by their manner of working and by their reactions to fatigue.

Yet, as Gley says, it is essential to avoid confusion in this relation between mental and cerebral fatigue. It is extremely difficult to admit of the possibility of cerebral fatigue because, as the French psychologist says, "the brain is the most complete organ; it is so to speak perfect, it never tires. Men who are accustomed to intellectual activity and who have worked all their lives can often continue work up to the most advanced age, retaining all their mental alertness and cerebral capacity in quite a remarkable degree. How many examples might be quoted! I do not therefore believe in cerebral fatigue properly so called. An individual, sound in body and mind, can work and work effectively until an advanced age and his intellectual output scarcely falls short in value of that shown at the height of his power. But there is such a thing as nervous fatigue especially one of sensorial origin. The sense organs become tired and the central organs (the cerebrum) from which sensations emanate, may be affected by this fatigue of the sense organs.

The sedentary life, a habitual sitting posture, work in a vitiated atmosphere, late and long nights, an unhealthy mode of living and solitude all combine to cause digestive derangement,
retarded nutrition, respiratory affections, nervous fatigue and a state of psychical disequilibrium. Digestive troubles often take the form of gout or gravel, amongst those who have suffered from calculi being Amyot, Erasmus, Calvin, Bacon, Leibnitz, Bos- suet, Newton, D'Alembert, Buffon, Voltaire, etc. (Civiale).

Amongst speakers laryngeal affections are of common occurrence: laryngitis and granular sore throat (inflammation, hoarseness, loss of voice), loss of the power of speech (Jaccoud, Krébier), laryngeal and pharyngeal phthisis, which have come to be regarded as more or less occupational maladies ("clergyman's throat"). Although phthisis cannot really be said to be an occupational disease in this connection, it is nevertheless considered as one to which professions demanding great vocal effort predispose, and at times it first manifests itself after a more than usually strenuous vocal effort (Gueneau, Mussy). A state of pulmonary congestion, at times accompanied by considerable haemorrhage, is paramount, each individual being animated with the urge to stamp his life with the seal of his own personality.

Dr. A. Stocker (International Labour Office).

Mental Hygiene in Industry

Industrial mental hygiene may be defined as that branch of industrial medicine which has for its object to safeguard the moral and intellectual health of the worker. Every factory surgeon practises mental hygiene in a more less conscious way, and often under some sort of cover, for whereas in daily practice the workers accept the help of the doctor in the treatment of physical ailments, they become suspicious as soon as it is a question of examining or protecting the state of health of their minds.

It is certainly in the interest of a firm to pay attention to the mental attitude of the worker with regard to his work, to absenteeism and to waste of time due to causes of a psychic nature, to the problem of fatigue caused by non-adaptation to environment, and to monotony associated with industrial work.

To submit the human body to work on machinery without taking into consideration the elements which characterise the living entity can only have injurious results, and certainly leads to waste of human material, which is as costly to the efficient working of a factory as it is to society.

Modern methods lessen more and more the quantitative importance of the human factor, which may fall as low as 1.9 per cent. in the instance of weaving cotton by automatic machines (Wyatt). Findings
MENTAL HYGIENE IN INDUSTRY

of this kind may give satisfaction to factory owners who are inclined to estimate values according to figures; but, as Buyse has observed, whatever the degree of division of labour and of mechanisation in the most advanced industries, from the point of view of mechanical or manual production, either in mass or in large groups, the human element remains the factor which determines industrial output. It would therefore be wrong to neglect this factor and to apply a materialistic reasoning in a domain where quality outweighs quantity.

As the presence of a man before a machine is a continual necessity, and as the lot of a person performing the work and his mind and body to a particular task cannot be neglected, it is of practical importance for the doctor to take into consideration the whole personality of the worker and to study the best means for ensuring healthy conditions of industrial employment. It must not be forgotten that the psychical reactions of the individual to his work are not the exclusive product of environment, and that no line can be drawn between occupational activity and the private life of the worker. The doctor has in consequence to exercise his influence under conditions which bring him into intimate contact with social service. As Myers remarks, it should always be borne in mind that industrial life occupies less than a third of the total number of hours in the worker's day, and that industrial strife is very often the result of the struggles arising from domestic life, or from inherited tendencies, or from experiences acquired, particularly in infancy or adolescence. On the other hand, as Tanzi affirms, it is not the mental effort required of the worker which exhausts him, but rather emotional disturbances and passionate manifestations. Efforts may therefore be directed towards alleviation of misery and suffering and avoidance of degrading work, rather than to the curtailment of mental activity.

PSYCHOLOGY OF THE WORKER

"For good mental health and the full development of the human personality, satisfaction in work and a good balance between the energy expended in wage-earning and the energy devoted to the wider issues of life are important." (Campbell.)

"Too often one thinks of the factory worker as a stolid automaton, unemotionally working out his hours, trudging home to an equally colourless wife to sup on a smelly stew, spending the evening in sleep, showing the face with occasional riotous celebration and with, never anything approaching thought or emotion." (Dershimer.)

Rather, as a matter of fact, is it exactly the contrary which occurs; and if, for want of education rather than of good intention, the psychic life of the worker does not manifest itself by refinement and intellectual development, it is none the less true that disregard of the rights of humanity injures the lowest grade of workers more than any other wrong. In the intellectual domain, the worker's reactions may be limited in consequence of his elementary instruction, but in his emotional and sentimental make-up there occur the variety and complexity which characterise the soul of a being whose organism is the heir of all humanity. In the case of the worker, his ideo-affective complexes often assume a far larger aspect, because in spite of inborn intelligence, which is often remarkable, his intellectual experience is not more extensive.

As regards the life led by workers there are obviously individual differences. If the degree of contentment, which depends on mental adjustment to the problems of life, is taken into consideration, there may then be distinguished, according to Dershimer, at least three types. He says:

"In industry, as in any other large group of people, it will be found that these degrees of adjustment and their results shade into each other somewhat as follows: at the top, perfect adjustment, contentment and efficiency; midway, restlessness and unhappiness; finally complete failure in adjustment leading to disease and outwardly to revolt."

Myers distinguishes the "surly" type of man who protests against a position, just because he happens to find himself in that position; the "resigned" type, whose personal hopes and aspirations have been destroyed; and the "practical" men who adapt themselves and know how to solve their difficulties.

The "surly" man is very difficult to deal with, and leaves work for motives which are apparently inadequate. The "resigned" man does not interest himself in his daily work; he works mechanically, but he is able to satisfy his aspirations by indulging his imagination in day dreaming; this worker does not feel the monotony of work. The third type is that of the man who satisfies his personal aspirations or his inclinations for leadership by a display of activity, or by filling an important post in social life.

It is essential to detect and evaluate the causes which may have an injurious influence on the psychic equilibrium of the worker.
According to Myers; there are three principal causes that make trouble between the worker and his industrial surroundings:

1. The management may be unsatisfactory;

2. The worker is not in sympathy with the work which is entrusted to him;

3. The worker suffers from a situation which hampers the development of his personal aspirations.

In this connection, Pratt notes that one of the most frequent causes of discontent is found among workers who have to support a family, but are employed on badly paid work, only calling for a small part of their abilities, and cannot find better employment. Their moral equilibrium is quickly destroyed, and their state of mind shows itself by exhaustion and signs of pathological fatigue, or by psychical reactions fostered by ill-feeling and resentment.

In a similar situation is the worker whose modest aptitudes do not come up to the requirements of the process at which he is employed. In this case the individual will react either by depression resulting in annihilation of the few aptitudes which he does possess, or by an increase of his ego which makes him disagreeable to his comrades and difficult for his chiefs to manage.

The duration, physical conditions and the rhythm of the work should also be taken into consideration.

Excessive hours of work may cause, under certain conditions, degrees of fatigue which react on the mental state of the worker, causing psychoses and neuroses; fatiguing work in a very hot atmosphere is an instance, as, for example, in the stoke-holes of large ships during voyages in the tropics (Durig). Excessive rhythm, as in chain work, may cause a state of nerve exhaustion accompanied by depression and uneasiness. The monotonous influences exerted by work should not be judged without taking into consideration the full personality and mental resources of the worker. Monotonous work is not necessarily displeasing to the worker, who may let his mind wander among memories and coming events of social life. In fact it is on the aspect and nature of these last that the healthy or unhealthy character of the interests of the worker and his mental attitude will depend. Indeed, monotonous work allows mental leisure which is unknown to the artisan who is entirely concentrated on his work. On the other hand, mechanical work contains the germ of a moral conscience for the worker which makes him happy or unhappy, according to the conditions of his existence, as to whether they are satisfactory or not. In the latter case, he will react by a mental attitude which, if not corrected by mental hygiene, will degenerate into a psychoneurosis and all kinds of psychic disorders, as trying to the worker himself as to those around him.

The causes mentioned may act in a collective manner, and lead to group manifestations which may disturb the moral equilibrium of the personnel and industrial peace. The presence of an element of discontent among workers is often sufficient to influence other workers by mental contagion. This danger is all the greater in the case of a psychopathic agitator, always a grumbler, who protests against everything and ceaselessly formulates his claims.

It is interesting to mention that strikes have been regarded as the result of such influences, for the conclusion has been drawn that, in these manifestations of collective life, the anti-social reactions of individuals, whose mental activity is often brilliant, although unbalanced, are found to be the start of the movement (Ball). Thus the strike has been regarded on the whole as a defensive reaction of those who cannot adapt themselves (Stewart-Paton), or of individuals whose resistance with regard to the demands of the work is found to be impaired (Pound). Anxieties in domestic life, irritation caused by those who supervise or the effect of an exaggerated responsibility arising out of work may, in a large number of workers, lead to the most varied forms of psychopathological reactions. There should be mentioned in the first place the syndrome known under the name of “neurasthenia”, which, according to Durig, may be almost considered as an occupational disease for some classes of workers: workers doing delicate work which requires an extremely rapid rate of rhythm, and also carries responsibility with it (Freund), as, for example, those employed on post office work, including telegraphists and telephone operators, chain assemblers and printers. According to an enquiry made by Leubuscher and Bibrowitz, which dealt with 150,400 workers affected with nervous conditions, this group contained 15.75 per cent. of printers (compositors), 9.43 of carpenters, and 3.9 of mechanics. Account must here
Mental Hygiene in Industry

also be taken, in the case of the printers, of the fact that their number represents only 1 per cent. of the insured workers examined; hence the conclusion may be drawn that in this occupation the number of neurasthenics is particularly high. The enquiry was also able to establish that the hereditary factor was only of secondary importance, for in three-fourths of the cases studied the diseased state was due exclusively to occupation.

The defects of mental adaptation, and the psychic disorders which follow, manifest themselves in a psycho-neurotic form. Contentions which have been nipped in the bud, complete repression of contrary instincts, and strangled emotion, such are the origins of manifestations called psychoasthenic, the most characteristic traits of which are the phobias and obsessions. They are the special idea-affective complexes corresponding to the conflicts, repressed instincts and sentiments, which tend to reappear in the conscience of the workers in the disguised form of fixed ideas, phobias, dreams, or of such symbolic actions as psychogenic tics.

The mind of the worker in some cases is haunted by a sense of defects in character or in psychic traits. In all these cases when no salutary influence is introduced by suppressing the causes, or setting the mind right by an adequate course of mental hygiene, psychic disorders may arise, repercussion from which may show itself in the occupational life of the worker; by a diminution in the capacity for work and a feeling of malaise which may be converted into a spirit of revolt.

A large number of psychic disorders become converted into bodily conditions, so originating such occupational nervous as telegraphists' and telephone operators' cramp, and miners' nystagmus, or certain respiratory disorders, or circulatory, digestive and somatic reactions associated with hysteria.

Very often the doctor who is not on his guard, and, still more often, the laity, are inclined to regard most of these affections as pretences, and to mistrust, as a disease-reality — taking refuge in sickness — a reaction which is only based on a failure in defence. The mental mechanism which psychological analysis has revealed should automatically enable an observer to find a solution for a given situation and not to seek an escape from it. The doctor should, by seeking the cause, help the patient to recover his psychic integrity.

Statistics

It has just been seen that the simplest signs of mental disturbance consist in a feeling of discontent caused by work. It is not the work in itself which plays a depressing part; it is the conditions under which the workers are called on to perform it.

According to statistics collected by Lewenstein in 1912, the majority of workers are not satisfied with the kind of work they do. The following are the results of his enquiry:

An investigation undertaken by Stevens, on the incidence during six months of functional nervous diseases among 4,000 workers of the Jordan Marsh Company has shown clearly that 405 (about 10 per cent.) suffered from an incapacity for work due to psychogenic nervous syndromes which had been the cause, as regards 123 individuals, of a loss of 1,546 working days which represented 3.2 per cent. of the total time lost on account of sickness by the whole of the workers of the firm. Further, among the diseases treated at the workers' dispensary, functional nervous affections occupied the fourth place.

Elkinds has made use of the medical reports on the personnel of an important public utility business, the reports being supplied by the Statistical Department of the Harvard School of Public Health. According to this work, which deals with a period of five years, functional nervous diseases appear with a percentage of 16 for the group of stenographers (chiefly women): 10 for the group of clerks; 10 for that of auditors of accounts; 7 for that of firemen; 4 for telephone operators (women). For the total of all occupations the percentage was 6.

The total number of lost working days was 6,882, giving an average of 9.4 per worker-year. The cost to the company for the treatment of sickness during five years reached $139,872.40, of which $19,383.50 was for functional nervous disorders, amounting for each of these patients to $27.20 dollars, an unprecedented figure when it is known that for other diseases the average cost was 92 cents.

Collis has made an interesting comparison between the prevalence of mortality among coal miners and the mental unrest which leads them to strike. Although his deductions were based on somewhat unrelated figures, yet the coincidence
cannot be denied (see article "Miners' Diseases").

**Prophylaxis**

Measures for preventing, as far as possible, influences which may prejudice the health of the worker's mind should be taken (a) before engagement and (b) after engagement.

(a) **Before engagement.** — Special attention should be given to the personality of a candidate at the time he is under consideration or selecting his occupation, by first and foremost ruthlessly eliminating the abnormal and weakly, for whom work should be found which is suited to their psychic conformation, or to their mental level. If left to their own devices, these persons are quite unable to enter into competition with normal beings, and would represent a wastage of 65 per cent. of cases; they ought to be aided by public assistance schemes.

This same attention should be given to the mental state at the time of the re-engagement of workers who have been victims of industrial accidents, or of nervous shocks, or have acquired mental defects at work. It is interesting to note that weak-minded workers do not find any difficulty in doing certain kinds of work. There are even some industries in which automatic machinery predominates, where only a minimum of mental effort is required; they are actually to be preferred for this type of work (Pratt).

The importance of selection must not be underestimated, from the point of view of the danger to which individuals whose mind shows defective reactions are exposed. For example, in an American factory which had at great cost put in a system of automatic protection against accidents, the frequency of accidents at the end of some months had only diminished by half of what had been hoped for. An enquiry showed that the cause was a small group of weak-minded workers and persons whose emotional instability and irresponsibility reached such a degree as to make them unemployable.

When examining such persons it is necessary to mistrust the value of so-called tests of intelligence. Very often disconcerting replies in this kind of examination do not exclude a satisfactory aptitude for a definite process (Elkind). In spite of lack of intelligence revealed by the tests, their value should only be considered as very relative. In other words, capacity for work does not depend only on intellectual functioning, but on the character and whole personality of the individual.

The doctor should be ever on the look-out to detect cases of insufficiency or mental defect, which may escape superficial observation and can only be discovered, and then with difficulty, at a moment when mental contagion clouds the mind.

(b) **After engagement.** — Periodical examination by the factory surgeon enables him to diagnose in good time psychic disturbances or cases of mental disease.

The importance of this medico-psychiatric care is shown by numerous practical experiments. Pactet found some general paralytics employed on a railway in important posts of considerable responsibility; Collin found an epileptic, a discharged soldier, who was only recognised as such owing to his violent behaviour towards a station master, following upon an epileptic seizure. Fortunately the number of workers suffering from mental diseases, properly so called, is low. On the contrary, workers showing psycho-neurotic disorders, either constitutional or accidental, are more numerous. The doctor should study the suitability of workers for their occupation and their environment, detect the causes of discontent, and advise measures suitable for creating conditions of general well-being. He should revive those that falter, clear up awkward situations, and intervene when reactions or feelings capable of causing collective nervous instability may appear to endanger industrial peace.

The doctor should also follow up the cases marked at the time of engagement as requiring medical attention. A workman diagnosed as mentally defective on engagement was employed as a labourer in a timber yard. As he was considered a good worker, a well-intentioned foreman thought well to promote him and make him chauffeur of a lorry. As long as the new chauffeur was only employed on transport work about the timber yard all went well; but one day he was sent outside and told to be quick. On the return journey he had to cross a level crossing and a fatal accident occurred. On account of his defective judgment, with an excessively slow reaction time, he was unable to avoid a collision with a train, which proved fatal for him (Pratt).

In the case of discontent showing itself by definite permanent psycho-neurotic symptoms, the doctor should find out all about the situation, and find a remedy either by helping the patient to struggle boldly against his
weakness or offering him a possibility of a compromise or compensation.

In the latter case, it is a question of providing an occupation which during the hours of leisure enable the worker to satisfy his repressed tendencies; it may be by reading, music, or gardening, according to the case, or by some more or less important social activity. In all these cases, the leisure hours of the worker should be fully occupied, while the view is not to be lost sight of that every factory pays two kinds of output: the manufactured article and the personality of the worker (Campbell).

The causes of bodily diseases and mental disorders are interwoven, especially at the factory, in an inextricable way; and it is difficult to separate mental health from physical health. Hence in order to know the mental condition of each worker there is need for a close contact between the doctor and the workers. But, for this observation, auxiliary methods can be made use of, e.g. reports from foremen, information furnished by the attendance registers, and the wage-sheets. Thus, a wage-sheets, which, by its variations, contrasts with the previous regular curve, may deter the doctor to arrange an interview with the worker; this may enlighten him as to the cause, showing whether a physical disease is present, a latent state is present, or an emotional factor brought on by the conditions of work in the workshop or even by trouble at home, the repercussion of which is felt at the works. Campbell mentions the case of a working woman with an erratic wage-curve, whose bad output was due to pre-occupation quite unconnected with the work; she had left her two children in charge of a sister who had a perverted character, and she was uneasy about the moral state of her children, and was always thinking about it.

Resentment, anxiety, a feeling of injustice or of inferiority, of timidity or disappointment, discontent caused either by work or by the conditions of private life, may disturb the mental equilibrium of a worker. These troubles are generally indicated by irregular attendance at the works, waste of time, and fluctuations in the wage-curve. It is the duty of the doctor to recognise the cause of these symptoms and not to consider them as manifestations to be dealt with by disciplinary measures, reduction of wages or reprimand.

Clearly the practice of mental hygiene at a factory requires that the doctor should have, in addition to his general training, special psychological and psychiatric knowledge, which is indispensable for ensuring useful intervention at an early stage when a worker comes for consultation without showing symptoms distinctive of a definite stage. Only a skilled doctor will be able to detect the disturbance which has occurred in the mental stability of the person from symptoms of no apparent importance, and to recognise that every assistance should be given to help him to fight against the threatened condition.

As a matter of fact, the number of factory surgeons who have to the present time had psychiatric training is not large. Read states that modern schools of medicine train doctors who have had no psychological training and have never hitherto considered this disciplinary training. The factory surgeon who finds himself concerned with mental hygiene should not forget that this aspect is different from the older point of view of medicine, which was only concerned with definite clinical pictures. It is a question of a new mentality, the object of which is to prevent mental disorders by tracing their sources of origin and by using the means which psychological and psychopathological science have placed at the disposal of practitioners.

Mental hygiene does not encounter in industry simple problems which can be referred to one specific injurious agent. In order to practise mental hygiene in an efficient manner it is necessary to know how to sympathise with the worker, to study carefully his surroundings, his chances of recreation, his aspirations and disappointments. In a word the doctor who is to be successful in this work must be familiar with the organisation of social service. However perfect the condition of the factory may be, the health of the mind of the worker cannot be maintained if he goes back to a wretched and unhealthy home. With a view to encouraging the development of the practice of mental hygiene in the workshop, Genil-Perrin insists on the necessity for organising "psychiatric dispensaries", which have shown their value in America and have achieved a clearly defined place among the working classes and in manufacturing centres. Hence for this reason nurses attached to a factory should have some psychiatric training. Genil-Perrin sums up the principles of hygiene and mental prophylaxis in industrial areas in the following desiderata:
(1) The establishment of the best psychological conditions of industrial work with a view to making the best use of the mental effort of the worker, which increases in importance in proportion to his physical exertion.

(2) Psychophysiological selection of workers with a view to systematic direction of the worker's choice of work according to the special bodily and mental fitness of each individual.

(3) Systematic examinations of working communities, with the elimination of subjects predisposed to psychic disorders in order to withdraw them from tasks which are dangerous and full of difficulties and to submit them to special mental hygiene, each case receiving individual attention.

(4) A service of psychiatric registration organised by private initiative and public administrative bodies.

(5) Co-operation between the factory medical service with psychiatric dispensaries and laboratories of experimental psychology.

Mental hygiene at the factory clearly encounters great obstacles. The intervention of the doctor itself too often causes a feeling of distrust on the part of the worker, and whenever it is a case of examining or protecting his mental state, he is apt to feel placed in a state of inferiority. But, wherever mental hygiene has been practised, satisfactory results seem to show that it is worth while to deal with the moral and intellectual health of the workers. Dershimer has observed that the works doctor is now called on to replace the family doctor of former times. The latter used to know all the joys and anxieties of his patients, to whom he was the counselor and friend as much as doctor; he knew all the joys and anxieties of his mental state, is part of the worker, and whenever it

ten causes a feeling of distrust on the intervention of the doctor itself too often encounters great obstacles.

Mercury (Quicksilver)

French: Mercure. — German: Quecksilber. — Italian and Spanish: Mercurio.

CHEMISTRY

The only liquid metal. Symbol: Hg. Specific weight: 13.595 at 0° C. Boiling point: 357.3° C. Solidifies at approximately 92.4°. Heated in the air mercury oxidises, and this oxide, carried to incandescence, yields mercury and oxygen again.

Mercury undergoes fairly rapid change at ordinary temperatures and becomes coated with a fine layer of mercurous oxide (Hg,O). Treated with cold nitric acid, mercury becomes converted into mercurous nitrate (HgNO₃), which dissolves in excess of the acid. Mercury has no action in a cold state on sulphuric acid; on heating, it yields sulphurous anhydride and mercurous sulphate according to the temperature. It is not attacked by cold hydrochloric acid.

For the principal compounds of mercury see article "Mercury (Compounds of)".

With most metals it forms "amalgams" readily—not so easily with copper. It forms no amalgam with iron, nickel, aluminium, cobalt, and platinum.

Vapours. — Mercury gives off vapour at ordinary temperatures and even at the temperature of solidification; these vapours are very abundant at high temperatures.

21.1 —
Hertz has calculated the volatilisation of mercury per cubic metre of air as follows:

<table>
<thead>
<tr>
<th>Temperature °C</th>
<th>0°</th>
<th>10°</th>
<th>20°</th>
<th>30°</th>
<th>40°</th>
</tr>
</thead>
<tbody>
<tr>
<td>Mg. of mercury</td>
<td>2.2</td>
<td>5.7</td>
<td>14.3</td>
<td>31</td>
<td>78</td>
</tr>
</tbody>
</table>

Kunkel found, on the contrary, at the same temperatures:

| Mg. of mercury | 4.2| 6.8| 10.4 |

According to the experiments of Renk, the quantity of mercury in the air at a temperature of 10° C. over a surface of 0.5 sq. metre of mercury was per cubic metre of air:

- 1.86 mg. at 5 cm. above the surface.
- 1.29 .. at 50 cm. .. .. ..
- 0.85 .. at 1 cm.  .. .. ..

Mercury vapour is heavier than air, but it does not localise itself in the lower part of a closed space (the laws of gaseous mixtures differ from the laws of liquid mixtures). Vapour produced at a high temperature has a tendency to rise.

**Sources of Intoxication**

*In its preparation:* see article "Mercury (Mines of)".

*In its use:* mercury is employed in the metallic state (cold, or in the form of vapour disengaged by heat) or in the form of compounds. The processes which expose to intoxication, either by contact with the metal or by inhalation of vapour, are very numerous, and opportunities of intoxication in the industrial field are increasing. The principal processes are as follows:

- Filtering of mercury. Treatment of argentiferous or auriferous metals. Treatment by heating of amalgams of silver or gold for the recovery of precious metals. Treatment by heat of amalgams by dental mechanics and dentists. Alloys with tin and copper containing about 5 per cent. of mercury. Amalgamation of zinc in factories making accumulators and electrodes amalgamated with zinc. Preparation and use of lead mercury solder (much employed during the war). Manufacture of scientific instruments, such as barometers, manometers, thermometers, mercury switches, mercury vapour lamps, and freezing machines. Manufacture and use (becoming less common) of mercury pumps.1

---

1 At the South Meadow boiler works (United States) cases of mercury poisoning occurred, but it was possible to prevent entirely the occurrence of further cases.

In another boiler works at Dutch Point an experimental boiler became cracked, with consequent loss of 2 tons of the 20 tons of mercury constituting the initial charge. The 2 tons became vapourised and were withdrawn partly by way of the chimney without affecting the workers. On another occasion an accident occurred as the result of the rupture of a defective pipe, but since the temperature of the fumes in the chimney did not exceed 150° C. the mercury became condensed.

---

**Toxicity**

Ingested in the metallic form in large quantities mercury does not appear to have great toxicity, but if finely divided or remaining for a long time in the digestive tract it can have very serious effects. The toxicity of the compounds of mercury (see that article) is also notorious.

The toxic dose of the vapour of mercury cannot be stated. According to Göthlin, for example, 0.4 to 1 mg. of mercury inhaled daily in the form of vapour (0.02 mg. per 28 cub. cm. of air, according to J. A. Turner, U.S.A., 1924) would set up gradually chronic poisoning. Workers employed 8 hours in a room containing 0.1 to 1 mg. of mercury per 4,000 litres of air showed 0.4 to 1 mg. of mercury in the urine.

Absorption of the metal by the skin is possible, especially if this is cracked; it occurs with the skin intact if mercury is vigorously rubbed in with fatty substances (for example during cleaning operations which facilitate absorption by the skin). The real danger, however, is inhalation of the vapour, for the droplets suspended in the air when they enter the mouth or the nose volatilise as a result of the rupture of a defective pipe, but since the temperature of the fumes in the chimney did not exceed 150° C. the mercury became condensed.
data exist regarding the resistance of the race, individual, or hereditary resistance to mercury and its compounds, but women are, however, said to be particularly sensitive to these poisons. (See "Mercury (Mines of").

Elimination.—Takes place chiefly through the salivary glands, the mucosa of the great intestine and the kidneys (markedly hit in the course of the intoxication because of the direct irritation by the mercury eliminated), by the skin, the bile, the milk, and the sweat. Elimination by the saliva and urine is not constant and uniform, because it is possible to detect mercury in the faces and urine even several months (six to nine and more) after the cessation of contact with the poison.

Statistics

The first case of occupational poisoning was reported about 1557 by Fermel, who instances the case of a worker, a gilder, who became deaf and dumb after mercury poisoning. Forestius, in 1600, while investigating occupational mercurialism, tells of a gilder who became paralytic as a result of exposure to the fumes of the metal. Walter Pope, towards 1655, relates that on visiting the mines of Friuli he noted, amongst the workers engaged on extracting the metal, certain symptoms of poisoning, such as trembling, paralysis, and mercurial cachexia.

Austria.—Six cases of mercury poisoning were reported in 1913 among 30 workmen in a workroom using cyanide of mercury, and 2 severe cases were caused by sublimates among masons who had to work in a vat which contained a solution of sublimates.

France.—Cases of mercurial poisoning notified in accordance with the Act of 1919 numbered 6 in 1922, of which 7 occurred among hatters' furriers, and 1 was that of a worker engaged in handling mercury ointment (druggist). From 1923 to 1927, 29 cases of mercury poisoning were reported as having occurred in hatcutting and caroting departments (21 cases); in the manufacture of mercury thermometers (4); in the hat industry (1); in the making of electric batteries (zinc amalgam) (1); in making special iron-nickel batteries (1); in an industrial photographic studio.

Great Britain.—From 1899 up to December 1923 the Medical Inspectors' reports showed 229 reported cases of mercury poisoning, distributed as follows: 1899-1912, 133; 1913, 14; 1914, 10; 1915, 6; 1916, 18; 1917, 17; 1918, 9; 1919, 7; 1920, 5; 1921, —; 1922, 6 (with 1 death); 1923, 4.

In the 229 cases the industries were:

52: Manufacture of explosives with use of fulminate of mercury;
47: Manufacture of thermometers;
25: Hatters' and furriers' processes;
25: Manufacture of electrical meters;
23: " felt hats;
21: " chemicals;
19: Various;
8: Watergilding;
4: Manufacture of mercury lamps;
3: Bronzing;
2: Photogravures.

For the period 1924 to 1930 the total number of cases of poisoning was 64: 1918, 8; 1919, 10; 1920, 8; 1921, 7; 1922, 8; 1923, 11; 1924, 4 (1 fatal); 1927, 3 (2 fatal); 1928, 4; 1929, 0; 1930, 3.

Germany. — Several cases have been reported in the industry (see article "Pulminiae of Mercury"), and some also among women working in a foundry making a mercury alloy (1914-1918). Mercury poisoning has been noticed amongst workers in institutes of technological chemistry (professors and assistants), and Holtzmann has estimated at 80 per cent the incidence of positive symptoms in cases brought to his notice (1929). Four cases of acute mercury poisoning affected locksmiths engaged in repairing boilers used in factories in which mercury was utilised (Hopmann). In Bavaria, in 1913, of 13 workmen examined about one-half showed signs of chronic poisoning in a factory for the making of sublimate pastilles (psychical disturbance, changes in the teeth); 3 cases occurred amongst apprentices in a thermometer factory, and 3 were the children of a thermometer worker carrying on his business as a home industry, with 3 other cases among glass blowers who poured mercury into glass tubes. Between 1914 and 1918 several cases were reported among solderers using an alloy of lead and mercury, among workmen employed in the manufacture of acetone (using acetylene as the starting point), and a photographer's apprentice was also affected.

Netherlands. — Cases are reported among persons using sublimate in making the elements for the accumulators of pocket electric torches.

Switzerland. — The National Accident Insurance Fund received notice of 8 cases of poisoning in 1918, 10 in 1919, 10 in 1920, and 12 in 1921, distributed as follows: 1 among gunsmiths, 2 among laboratory assistants, 2 among fitters and various workmen, 3 among foremen, 4 among locksmiths, and 28 among other workers. In 1922 cases of poisoning amounted to 11; in 1923 to 4; in 1924 to 14; and in 1925 to 70.

For details see the articles "Mercury (Mines of)", "Mercury (Compounds of)", "Pulminiae of Mercury", "Hatters' Processes", etc.

United States. — Four cases of sub-acute or chronic poisoning were reported amongst workers occupied at electric furnaces (high frequency induction), in the neighbourhood of which analysis of the atmosphere showed the presence of 7 mg. of mercury vapour per cub. metre of air (Jordan and Barrows).

Symptoms

The industrial poisoning is generally markedly chronic from the first; but acute exacerbations in the advancing chronic cases also occur, characterised by attacks always more frequent with increase of the motor signs. Nowadays, however, slight cases predominate as compared with the severe type so frequent formerly.

The clinical picture under these conditions shows little that is characteristic, and in consequence calls for very close attention on the part of the medical man.

The earliest symptoms, little characteristic, affect primarily the digestive tract and nervous system; but in time the poison brings about other very serious changes in the body (chronic nephritis, cachexia, etc.).

Digestive system. — The first symptoms, although little characteristic, are a metallic taste, anorexia, vomiting, gastric catarrh, chronic diarrhoea from the first or in crises, but above all stomatitis, which is the thermometer of mercurialism. It is very often chronic from the start and it generally follows acute and successive functional troubles. Moreover, predisposition is caused by inflammation or dental or oral lesions (dental caries, gingivitis). There is foetid breath, spongy or ulcerated gums, salivation attended with some foetor of the breath) amounting to several litres daily. The teeth undergo changes, becoming blackened, fragile, blunt, and eroded. At a later stage they fall out — especially the lower teeth — a consequence of a process of expansive gingivitis, often accompanied by abscesses. The healing of the buccal lesions as soon as no more teeth remain, or at least around teeth that have fallen out, should be noted. The tongue has been found to have a silvery aspect with indented edges (Legge). There is rarely dental nervergia. Some authors have given prominence to the presence of an inflammatory line on the gums round the upper teeth (see article "Hatters' Processes"), accompanied frequently by tattoo plaques on the mucous membrane of the lips and cheeks; this line may, however, be absent.

Sometimes the stomatitis takes the form of a purulent gingivitis with foetid discharge (alveolar dental pyorrhoea). The tonsils and pharynx also are sometimes inflamed (mercurial pharyngitis of Kussmaul). As an ultimate, though rare, effect of the stomatitis, necrosis of the maxillary bones is said to occur. The stomatitis is accompanied by
objective (pains, headache) or functional symptoms (anorexia, fatigue, etc.).

**Blood.** — At the same time the affected person becomes emaciated with more or less anemia, generally moderate. Effect on the blood is not characteristic and on the whole not comparable with that observed in other industrial intoxications, notably lead poisoning. The colour index and hemoglobin are very little lowered; the resistance, shape, size, and chromatic characters of the red cells are normal. Any diminution is at any rate late; punctate basophilia is very rare even in severe cases. Similarly, white blood cells are quantitatively normal, and their diminution or increase exceptional. A mononucleosis (lymphocytosis), however, and even complete inversion of the leucocytic count has been described; also a slight degree of chronic intoxication, and in withdrawing the person from the action of mercury a rapid improvement takes place corresponding with the renal excretion of the poison.

**Neuro-muscular system.** — Later, or even at a fairly early stage — especially in the predisposed — the neuromuscular system becomes involved, a real condition of "petit mal" showing itself in pronounced mental hyperactivity (mercurial erethism), morbid nervousness from which few affected persons escape, sensibility almost amounting to a neurosis, sensation of anxiety, painful embarrassment; then torpor, somnolence, marked mental hebetude with (rarely) attacks of acute mania, profound mental failure, paralytic dementia, loss of memory, etc. Most notable of all — especially in men employed in

---

**Fig. 20.** — Mercurial Tremor. *The attempt of an illiterate patient to reproduce the arms on the right of the diagram.*

increase in the eosinophilic leucocytes. Donajewsky and Peissachowitsch (1930) found chiefly lymphocytosis and a mylogenous reaction manifested by eosinophilia and monocytosis. These authors, not having succeeded in establishing any connection between the occupation and the changes observed, considered that such alterations of the blood may not be regarded as specific. Workers recently engaged in handling mercury showed the most marked blood changes.

According to some writers, these symptoms show profound mercurial impregnation (rather than a latent intoxication) and indicate imminent severe nervous manifestations. They are said to be even proportional to the mercury mines — tremors, and tonic and clonic spasms are characteristic (the "calambras" of Spanish miners, the "stolzi" of Italian miners). Muscular strength is diminished, troubles of nutrition, usually mild, are not uncommon, as well as partial paralyses localised specially in the extensors (actual paralyses are rather rare), sensory effects (anaesthesia, arthralgia, hyposthenia), neuritis (rare), difficulty in walking, hysterical symptoms as an indirect consequence of the intoxication and related notably to individual predisposition.

Apart from the psychical manifestations described, all persons affected suffer from tremor and muscular incoordination, which is an early sign and
often the only one (especially after inhalation of vapour). Trembling was first described as a very special symptom of mercurial poisoning among metal gilders by Ramazzini, and later on by Martin de Guinard and Merat in 1818. In 1848 Th. Roussel expounded a very clear theory of this motor derangement and painful convulsive crises found among miners at Almaden. In 1861 Kussmaul published his classic work on mercurial poisoning. Mercurial tremor shows itself in slow and progressive manner, but occasionally appears suddenly with great intensity. It varies from the slightest tic to chronic incoordination of the intensest kind, and can hinder the upright position. Generally tremor takes the form of slight oscillations, slow ("vibratory tremor" of Charcot), more or less rapid or rhythmical and localised in the face (lips, tongue)—to the left in left-handed persons—and extending then to the head, trunk, and to all the limbs with attacks of clonic shaking. It has the appearance essentially of being intentional, the effect of emotion becomes increased if the sufferer is watched. Its nature is still much discussed, whether toxic or organic or even hysterical. The toxic cause of the tremor seems to be quite definite, particularly on account of the infrequent but definite trace of mercury in the cerebro-spinal fluid. The extension of the phenomena, their aggravation due to multiple external influences and their evolution, etc., are the outcome of the very conditions under which tremor appears and develops. When the tremor is in the tongue, the affected person has naturally difficulty in pronunciation and especially at the commencement speech is hesitating and uncertain.

Cardio Vascular system. — Reisel- man (1930) has reported cardio vascular symptoms in workers suffering from mercury poisoning. These consisted of lesions of the myocardium or of cardio neuropathy and the symptoms noted were cyanosis of the extremities brachymercury poisoning. These consisted of loss of vision due to multiple external influences and their aggravation due particularly on account of the infrequent tremor. It has the appearance essentially of being intentional, the effect of emotion becomes increased if the sufferer is watched. Its nature is still much discussed, whether toxic or organic or even hysterical. The toxic cause of the tremor seems to be quite definite, particularly on account of the infrequent but definite trace of mercury in the cerebro-spinal fluid. The extension of the phenomena, their aggravation due to multiple external influences and their evolution, etc., are the outcome of the very conditions under which tremor appears and develops. When the tremor is in the tongue, the affected person has naturally difficulty in pronunciation and especially at the commencement speech is hesitating and uncertain.

Kidneys. — Rarely has chronic mercurial nephritis any special features. The urine presents no chemical change which would differentiate it from that of an ordinary chronic nephritis. At the same time the well-known condition may occur.

Ocular lesions. — Ocular lesions are represented by an amblyopia due to a retrobulbar neuritis. This lesion, often unilateral, will extend to the other eye unless of course it is immediately withdrawn from the action of the poison. At first diminution of vision is observed with small paracentral colour scotomas; later visual interference rapidly increases.

Sexual functions. — Frequent cases of miscarriage among women workers engaged on work which exposes them to mercury poisoning are said to occur, and even among wives of poisoned workmen. (See article "Mercury (Mines of ").)

Skin. — The local action of mercury sets up frequently in the newly employed dermatitis, eczema, cracked skin, lesions of the fingers sometimes severe in work of the most varied kind (solderers, founders, chemists, accumulator workers, etc.). See articles "Mercury (Compounds of)", "Hatters Furriers' Processes", "Fulminate of Mercury", etc.

In addition to the usual factors which predispose to poisoning, the social condition of certain groups of workers (see article "Mercury (Mines of ") should be borne in mind, especially the influence of alcohol. Those who are affected by mercury are very susceptible to the action of alcohol, which not only makes the symptoms worse, but acts as a valuable stimulus in bringing out latent mercurial tremor.

DIAGNOSIS

Stomatitis, loss of teeth, anaemia, and especially tremor, brought out or increased by alcohol, are sufficiently characteristic of chronic cases. Examination of the blood does not help. Search should always be made for mercury in the urine, in the substances which may be suspected to contain mercury as, for instance, the air of the workroom (fumes, dust), and on the work-clothes. But it should be borne in mind that elimination of mercury by the urine is neither constant nor regular, and that mercury is often absent even in the most typical case of poisoning. The industrial causes are sometimes difficult to discover, especially when the compounds of mercury or of the metal itself are employed under another name or mixed with other toxic materials (as, for example, lead, etc.).

SEARCH FOR, AND DOSAGE OF, MERCURY

(a) In the urine it is not necessary to destroy beforehand the organic matter. With a strip of copper cause the deposition of mercury on a strip of platinum (Mer- get's method); determine the quantity of mercury deposited, by colorimetric comparison of the stains produced by compres-
sion of the platinum strip dried between filter paper sensitised by ammoniacal nitrate of silver. The reaction is sensitive to 0.25 mg. of mercury in 500 grm. of urine. There has also been proposed spectroscopic examination of the radiation emitted by a modified Geissler-Plucker tube in which has been inserted a copper wire previously dipped in a liquid to be analysed. This method is said to have a sensitivity of 1: 500,000,000 (Le Faso). The reaction with ammoniacal nitrate of mercury is applicable to all the compounds of mercury, but it is necessary to heat the compound with dry soda to liberate the vapour of mercury.

by means of chloride of lime through a glass tube 2.3 mm. diameter and 24 cm. long, into which some crystals of iodine are introduced. On heating, a reddish yellow deposit of mercuric iodide forms above the spot where the iodine lies and this is dissolved in potassium iodide. Filter rapidly to separate the iodide crystals which remain; absorb the excess of iodine by the addition of sodium hydrate until the colour disappears. Determine the mercury by electrolysis or colorimetry. In the latter case convert the iodide of mercury into the black sulphide by treatment with hydrogen sulphide and by comparing with alkaline solutions of mercuric chloride of known titration treated similarly with hydrogen sulphide.

(b) Blood. It is impossible to show the presence of mercury because the metal is present in infinitesimal quantity in the small quantity of blood which can be dealt with in practice.

(c) Feces. In analyses that have been made mercury was present in minimal amount.

(d) In the air of workrooms. (1) Kunkel's method: Pass the air slowly (1 litre at most in 8-10 minutes) filtered and dried by means of chloride of lime through a glass tube 2.3 mm. diameter and 24 cm. long, into which some crystals of iodine are introduced. On heating, a reddish yellow deposit of mercuric iodide forms above the spot where the iodine lies and this is dissolved in potassium iodide. Filter rapidly to separate the iodide crystals which remain; absorb the excess of iodine by the addition of sodium hydrate until the colour disappears. Determine the mercury by electrolysis or colorimetry. In the latter case convert the iodide of mercury into the black sulphide by treatment with hydrogen sulphide and by comparing with alkaline solutions of mercuric chloride of known titration treated similarly with hydrogen sulphide.

(2) Method of Heim and Herbert: Aspirate a known volume of air as in the preceding method over a certain quantity (10 cub. cm. for example) of a decinormal solution of iodine; destroy the excess of iodine which colours the solution strongly by the addition, drop by drop, of the quantity just necessary to do this, of a solution of hyposulphite of soda 25 per 1,000; bring the discoloured liquid up to

Fig. 30. — Mercurial Tremor. The patient's attempt to sign his name.
a total volume of 30 cub. cm. by adding distilled water, and add to it 2 cub. cm. of an aqueous saturated solution of hydrogen sulphide, freshly prepared, which causes the formation of a blackish reaction of colloidal sulphide of mercury. Compare the tint of the liquid with that of mercurial solutions treated in exactly the same way and of known content of mercury. The reaction shows 5 hundredths of a mg. of mercury.

A third method is based on the reaction between mercury vapour and selenium sulphide easily perceptible to the eye by change of colour. The reagent consists of a tissue paper covered with a light coating of yellow selenium sulphide which, on exposure to air containing mercury fumes, becomes blackened by the formation of mercury sulphide. The degree of blackening varies with the quantity of these fumes and with the length of exposure. The reaction permits of detection of mercury in the proportion of mercury of 1: 20,000,000 (General Electric Company, United States).

Many processes for determining mercury in the air and in organic liquids demand conditions which are rarely possible for medical men and properly belong to toxicologists.

**HYGIENE**

In industries and processes making use of mercury in the metallic state, the preventive measures prescribed for the metallurgy of mercury are required. (See article "Mercury (Mines of ").) Further, provision of the general regulations laid down for unhealthy industries is called for (see article "Industrial Hygiene (Workshops "): the metal should be kept in a place efficiently ventilated. It must be admitted that in certain processes when mercury is dealt with in small quantities (manufacture of scientific instruments, of thermometers, etc.), application of the measures outlined is attended with some difficulty. At the same time neutralisation of the effects of mercury vapour should be recommended by sprinkling on the floor every evening ammonia, or sulphate of ammonia, or very small quantities of hypochlorite of lime, or by hanging up sponges soaked with one or the other. Nitric acid fumes, produced by means of a special apparatus, are said by some authorities to give good results. Similarly, cleaning of the floor by means of special compositions of sulphur or tin which form amalgams readily with mercury has been suggested. All home work which involves contact with mercury or its compounds should be prohibited.

The cautionary notice which should be affixed in workrooms, e.g. in France (Order of 9 October 1913), is thus worded:

Mercury and its compounds are poisonous. They can enter the body with the air breathed, as dust and vapour; with food; through dirty hands, dirty benches; through the skin; through cracks, scratches and cuts.

If you have cracks, scratches or cuts, inform the foreman immediately.

Before partaking of food or drink carefully wash the hands with soap and the mouth with good drinking water.

Consult a doctor immediately if you notice excessive salivation, tremor, swelling of the legs, the hands, or under the eyes.

For personal hygiene see article "Mercury (Mines of ") and the following: "Mercury (Compounds of ")", "Fulminate of Mercury ", "Hatters Furriers' Process ", "Gold ", etc.

**LEGISLATION**

For the production of mercury, see article *Mercury (Mines of ")*.

Adult women, as well as young persons less than eighteen years of age, are excluded from all employment involving handling of mercury and its compounds in the Netherlands. Women and young persons below fifteen years of age are excluded from all work exposing them to dust and fumes of mercury and its compounds in Japan. Women and young persons under eighteen years of age are excluded from all work exposing them to mercury fumes in France and Switzerland. The handling of mercury and its compounds by young persons under sixteen years of age and women under eighteen is prohibited in Greece.

Exhaust ventilation locally applied for the removal of vapour and dust, washing accommodation, douche baths, dressing room, overalls or special clothing are provided for in the Netherlands.

**Medical examination on engagement:** expedient (see article "Mercury (Mines of ").) *Periodic examination:* also expedient. In Austria it is made obligatory once a year for all persons employed in industries using mercury. The intervals of examinations can be varied according to the danger.

**Notification of mercurial poisoning** (sometimes required for particular symptoms only). Obligatory in the following countries: Austria, Bavaria, United States (Connecticut, California, Maine, Maryland, Michigan, Missouri, New Jersey, New Hampshire, Wisconsin), France, Great Britain and the Dominions, Netherlands, Poland, Prussia, Saxony, Switzerland, Jugoslavia. Section 21 of the 1911 Act in the Netherlands requires notification of mercurial poisoning among workmen in the following industries: chemical factories and laboratories; explosives works; manufacture of pharmaceutical products and dressings; textile printing works; laboratories for mounting and repairing instruments; incandescent lamp factories; processes in
Mercurial poisoning is assimilated to accidents for purposes of compensation in those countries which have ratified the 1925 International Labour Convention concerning workers' compensation for occupational disease, and likewise in those possessing a Compensation Act: Alberta (Canada), Argentina, Austria, Belgium, Bolivia, Brazil, British Columbia, Bulgaria, Canada, Chile, Cuba, Finland, France, Germany, Great Britain, Hungary, India, Italy, Japan, Latvia, Luxembourg, Minnesota (Canada), Missouri, Netherlands, New York, New Brunswick, New Jersey, New Zealand, Norway, Nova Scotia, Ohio (U.S.A.), Ontario (Canada), Porto Rico, Portugal, Queensland (Australia), South Africa, South Australia, Sweden, Switzerland, Tasmania, U.S.S.R., Venezuela, Victoria, Western Australia and Yugoslavia. See also the articles cited above.

**Mercury (Compounds of)**

Mercury gives rise to two series of compounds: mercurous compounds (derivatives of mercurous oxide) and mercuric compounds (derivatives of mercuric oxide). The first group comprises mercurous oxide (Hg₂O), the chloride or calomel (Hg₂Cl₂), the bromide and mercurious iodide, the nitrate (HgNO₃); the second group comprises mercuric oxide (HgO), mercuric chloride or sublimate (HgCl₂) mercuric iodide, the cyanide, mercuric nitrate (Hg(NO₃)₂), the sulphate, the sulphide or cinnabar, etc.

Certain compounds are dealt with in special articles; thus, for example, the cyanide, the nitrate (see "Hatters Furriers' Processes", and "Fulminate of Mercury"; see also the other articles on "Mercury").

These compounds are generally prepared either by a dry or wet method. One of the solutions of mercury in acid is mixed with other substances which, under the action of heat or of the reagent, precipitate from the solution the product in an insoluble form. The product obtained is washed, filtered, dried, ground, and after being mixed with the necessary ingredients, packed. In the dry method the compound is obtained by sublimation in an enclosed apparatus.

Mercurous chloride or calomel is found, in very small quantities, in nature; artificially it is obtained by the wet method by precipitating a mercurous salt by a chloroide, or by the dry method by subliming a mixture of mercurous chloride and mercury, or of the sulphate of mercury and common salt (Japan). It is used sometimes in the decoration of porcelain and the making of fireworks.

The cyanide and perchloride are used in making dressings, and the former also in gilding (see that article) or in the preparation of cyanogen. In sublimate is used as a disinfectant, for making the pocket dry cell — a primary battery, for stuffing animals, etc. It easily destroys the stratum lucidum of the skin, giving rise to lesions, sometimes deep and painful, of the hands (fingers), especially among apprentices.

Nitrate of mercury is used not only in the curating of rabbit fur (see "Hatters Furriers' Processes"); but also in gilding, work, decoration of porcelain, bronzing of steel, and embossing, etc. It gives rise to skin lesions analogous to those set up by sublimate.

The sulphide or cinnabar is found in nature (see "Mercury (Mines of)"); is produced artificially by a dry method (sublimation of a mixture of sulphur and mercury, grinding under water, washing with hot and cold water, and with potash, drying), or by a wet method (vermilion: digestion of the white precipitate by the yellow ammonium sulphide, or by heating a mixture of mercury and sulphur with a solution of sodium hydrate). It is well here to call attention to the fact that, commercially, a pseudo-cinnabar is recognised which consists of minium (see that article) mixed with artificial red organic colours, and even a kind of lake which consists of barium sulphate and eosin, and afterwards treated by acetate of lead or alum (see also article "Antimony"). Cinnabar red is a colour much in demand. Although only slightly soluble it can set up mercurial poisoning.

Among the other compounds of mercury which deserve to be cited are: the mercuric iodide (which sets up general poisoning and a very marked cutaneous eruption), the bichromate (very irritating), the mercury-phenyl acetate (which is made by heating a mixture of mercury acetate and benzene at a temp. of 110° C., that is to say, acetate with a base C₂H₅HO, hydroxide of Hg-phenyl), the mercury-phenyl (Hg₂C₂H₅), (which is a metallic aromatic compound arising from the reaction of sodium amalgam on bromo benzene; in distillation it decomposes partly into mercury and partly into diphenyl), the mercury-methyl and mercury-ethyly (which have at times set up sub-acute and chronic poisoning), etc.

Salts of mercury are employed as catalysers in making certain substances (acetic aldehyde, synthetic alcohol, etc.), in which case they decompose more rapidly and the mercury is precipitated in metallic form at the bottom of the reaction vessel. In certain patent processes the mercuric salt...
is regenerated at the same rate as it is decomposed.

Among the statistical data it will suffice to recall those as to poisoning by sublimate reported from Bavaria, for instance (1913), among persons employed in two pastille factories, when one-half of those examined (13) showed symptoms of erethism, blackened teeth, stomatitis, and lesions on the fingers; in Austria (1913) among men employed in the manufacture of salts of mercury by the dry method; in the Netherlands (1915) among workers employed in the manufacture of sublimate pastilles and in preparing the elements of batteries for electric pocket lamps (the air of the workroom for assembling the elements contained 2.9 per cent. of sublimate).

**HYGIENE**

Work should be carried on in an enclosed apparatus with exhaust ventilation applied to the vapour and poisonous dust: in addition all the usual measures required in the manufacture and handling of poisonous substances should be adopted. (See articles "Mercury (Mines of)", etc.

**LEGISLATION**

In France exclusion of women from the manufacture of sulphate of mercury, of chloride, and of colours containing mercury (the Netherlands exclude them also from handling it when preparing it for delivery and use); in Italy, exclusion of female young persons under the age of sixteen years and boys under fifteen from the manufacture of alloys containing mercury; in Spain, exclusion of male young persons under the age of sixteen and female young persons under twenty-one years from the manufacture of sulphate of mercury; in Spain, exclusion of female young persons under the age of sixteen from the manufacture of sulphate of mercury, as well as from the manufacture of colours containing mercury. (See also article "Mercury".)

Compulsory notification of cases of cancer of the skin and of cancerous tumours affecting workers in workshops in which impregnation of wood by means of a sublimate solution is effected (Netherlands).

***

**Mercury (Mines of)**

The only ore of importance containing mercury is cinnabar or sulphide of mercury (HgS), of which the beds consist generally of clay, siliceous rocks or calcareous rocks bearing cinnabar, rarely pure cinnabar. Native mercury is rarer still; zones of schist are met with at Idria (Italy), impregnated with minute droplets of mercury or of small real layers of metallic mercury at Almaden (Spain) and at New Almaden (U.S.A.).

The richness of the minerals in mercury is very variable; from 0.5 per cent. on the average (Monte Amiata, Istria, Italy), to 1.0 per cent. (Nikitomba, Russia), 2.5 (Brewster, Texas, U.S.A.) and even more (Almaden, Spain). In the case of certain cinnabar-bearing minerals in Hungary which contain at the same time much copper (40 per cent.) and antimony (30 per cent.). The mineral can also contain lead and arsenic (Almaden); similarly, mercury can be found in other minerals (e.g. spelter ores — see article "Zinc").

**PRODUCTION**

Deposits.— Of the beds still being worked to-day, those of Kwei-Chan (China) have been known from time immemorial, and those of Almaden since the Roman period. The beds of Monte Amiata (Tuscany) were worked by the Etruscans, who used cinnabar as a colour. But anything in the nature of real production only began between 1200 and 1300, and on a modern industrial basis in 1398. The Californian mines (New Almaden), discovered in 1499, have been worked only since 1580, and those of Peru (Mines of Huancavelica) since 1571. The Russian cinnabar-bearing mineral (at Meiji) in Hokkaido, at Hizoshi in the prefecture of Shime, and at Ugashi in that of Aomori, or as metal (at Shamoni in Hokkaido).

Other deposits of some importance have been found and worked in Japan, either cinnabar-bearing mineral (at Meiji) in Hokkaido, at Hizoshi in the prefecture of Shime, and at Ugashi in that of Aomori, or as metal (at Shamoni in Hokkaido).

Mines of less importance exist in Texas (Brewster County), at Koniah (Asia Minor), in Hungary, in Czechoslovakia (near Horwitz), in Loibethal (St. Anna), at Dellach, Reichenau, Hotschna, etc., at Reichenstein am Erzberg, in Steiermark, near Belgrad (AvalaBerg), in Dalmatia (Spizza), also in Italy (Valalta, Upper Adige), in Bosnia (Zec Planina), etc., but most of these mines are abandoned to-day. Deposits apparently exist also in Colombia, South Africa, New South

---

1 The actual production of minerals in the year 1919 is said to have been, for Spain, 24,066 metric tons; for Algeria, the export of minerals reached 8,100 metric tons in 1919 and 900 in 1921. In the United States, the production for 1919 was 855 tons. For mercury, see article "Mercury"
Wales, but no recent or precise data exist about them.

Processes in the mine. — The work is carried on in galleries (at a depth varying from some dozens of metres to 600-800 metres) and is of the same kind as in other mines (see article "Miners' Diseases"). The rocky beds often require use of explosives. Among accessory work that of supporting the galleries, transport of the minerals, lighting, ventilation, lifts, pumps, etc., should be mentioned. A preliminary classification of the ore often takes place in the gallery.

Of first importance are the problems of ventilation, of lighting, of dust (if the ground is silicious) or of humidity (if the mine is very wet), of the removal of the water which filters through the soil, especially on account of the dejecta of the workmen in the galleries (danger of ankylostomiasis — see that article), although so far this infection has not been reported in the quicksilver mines. Danger is present also from noxious gases coming either from the ground itself (carbon dioxide and especially hydrogen sulphide, more rarely fire damp) or from the explosives used. Energetic mechanical ventilation may be called for at times to deal with these gases when in quantity (Monte Amiata).

Although the insolubility of cinnabar may not be — as some maintain — a sufficient reason for excluding a priori the possibility of mercurial poisoning from inhalation of cinnabar-bearing dust, yet mercurialism among cinnabar miners is very difficult to establish. This fact is due either to the temperature of the gallery which, as a rule, does not exceed a maximum of 28° C. and consequently does not cause decomposition of the sulphide of mercury and volatilisation of the metal, or to the humidity of the mineral which hinders formation of dust. At the same time, if the mine contains the metal then cases of poisoning can be found. Pulmonary lesions are also possible if the mine is dusty, rheumatism if humid; possible, too, is poisoning by arsenic, lead, or antimony.

Preparation of the mineral. — The ore is crushed (by hand or machine) and then dried by exposure to the action of the sun or the air or to air artificially heated in tunnel driers, or vertical driers, or on bricks under which hot air circulates in channels of masonry. At Monte Amiata these methods are now replaced by revolving airtight cylindrical driers. A current of heated air maintains a temperature of from 30 to 40° C. The moisture in the mineral is then reduced to about 4 or 5 per cent., which is necessary for good distillation. During drying, the temperature only reaching a maximum of 30-40° C., the cinnabar is not decomposed and the aqueous vapour given off does not contain mercury.

The dried mineral falls gradually into a receptacle from where, through sieves, it is loaded on to trucks and wheeled to the furnaces. Danger from mercury here could only be the result of accident (closeness to the furnace, presence of oxide of mercury in the ore, etc.), and, as a matter of fact, persons employed in drying in the mines of Monte Amiata show no signs of mercurialism. The sifting — not always done — only gives rise to argillaceous or calcareous dust.

The ore is next cleaned according to the size of the blocks.

Roasting. — The ore is roasted in the presence of air in furnaces with charcoal and even wood alone in the presence of air (to get rid of the sulphur) according to the following chemical reaction:

\[ \text{Hg}_2 \text{S} + 20 = \text{Hg} + \text{SO}_2 \]

Gas firing of the furnace is likely to replace the systems at present used for roasting the ore which cause a loss in bye-products valued at about 20 per cent. of the mercury present. The advantages would be a higher calorific effect, suppression of dust, more limited production of soot, regularity in heating, diminution of hand labour, etc.

The modern furnaces (Cermack-Spirek system, etc.) perfectly airtight, with a negative pressure inside and automatic fall, only deal with the crushed ore, while tower furnaces (Spirek system) deal with ore in lumps, and the revolving furnaces with very fine mineral. The hopper for charging the tower furnaces is provided with a hydraulic lute. In certain mines, however, old systems of furnaces are still employed (with subliming pots).

The mercury vapour given off in roasting under the negative pressure inside is drawn off directly from the furnaces themselves by Root's blowers, and carried at a temperature of 100-130° C. to condensers.

Condensation. — The condensers consist of shaped airtight pipes arranged in a vessel filled with water which allows of recovery of the mercury in a metallic state. As the mercury vapour has a tendency to escape from the condensers, these are linked up to a series of condensing chambers provided
with gutters (wood or masonry — at Monte Amiata, cement) which facilitate deposition of the metal. The vapours are thus chilled by water spray before reaching the storage vats.

Distillation in muffie furnaces with chalk or iron ore is very rarely done: the process with alkaline sulphide or by electrolysis is not yet industrially practicable.

**Danger.** — The slightly lowered pressure inside the Cermack-Spirek furnaces reduces escape of vapour to a minimum; but this type of furnace requires very close attention to secure regular and perfect working. Any obstacle in the proper working may give rise to serious accidents as well as unsatisfactory production.

A perfect technique, therefore, can almost completely suppress escape of fumes, but the workmen at the furnaces can inhale the vapour, especially when, through special openings at the furnace mouth, they have to stir up the ore by means of long iron rakes to assist its fall into the inside of the furnace. Failure in attention or inexperience of the workman may allow mercury vapour to escape in a larger or smaller amount.

The danger is greater at the moment of discharge if the residues are hot. At Idria the residues from roasting contain 0.00036-0.0014 per cent. of mercury, whilst at Monte Amiata none at all. Further, the residues from the furnace fall automatically into a gallery which is periodically cleaned by a strong spray of water.

The work of cleaning the pipes is very dangerous. The effect of sulphur dioxide (SO₂), of ammonia, and the radiant heat from the furnaces must also be taken into account.

**Purification.** — The distilled mercury is mixed with remarkable quantities of impurities, particles of unburnt coal, undecomposed hydro-carbons, mineral dust, cinders and water, and traces of oxide and sulphide of mercury.

Three-quarters of the upper portion of the contents of the depositing vats placed at the bottom of the condensers are made up of the “blacks” or “stupp”, whilst pure mercury occupies the floor of the chamber and is withdrawn by a tap placed below the reservoir.

The “stupp” treated with lime and submitted to extraction in Exeli furnaces yields 80 per cent. of mercury, and the residue is roasted again with the ore. The “soot” from the chimneys and the “stupp” from the pipes collected during cleaning operations are submitted to the same procedure and yield about 30 per cent. of mercury.

**CLEANING THE MERCURY**

**Filling the flasks.** — An automatic system to-day replaces the cleaning of the mercury which was formerly done by hand by means of a sponge (very dangerous work). On leaving the Exeli plant the mercury passes through a series of reservoirs connected below and of which the last is in communication with the reservoir in which the mercury is automatically weighed. It then passes to the receptacle. The process being automatic, practically all danger is removed.

**Danger.** — After condensation, besides mercury vapour, the air contains in suspension droplets of the metal in a very fine state of sub-division. Further, the workman comes into contact either with the mercury or with the “stupp”, which are important sources of poisoning. Treatment of the “stupp” or “soot” gives rise also to the liberation of ammoniacal vapour.

The most perfect technique ought to prevent as far as possible every escape of vapour, and thus ensure the highest output. Even with these precautions, however, danger is inevitable, and the factory finds itself in a chronic state of mercurialism.

The whole of the installation has generally to be cleaned once a year, and work is suspended for a month; the factory portion is cleaned once a month; the condensers, which empty into the first two receptacles as well as the rest of the apparatus, is cleaned about every two months. In the event of repairs or partial cleaning, every measure possible to prevent the escape of fumes must be taken. Before opening up the pipes and furnace good exhaust ventilation for the fumes and complete cooling of the installation should be insisted on. At Monte Amiata, for instance, the furnace is divided into two sections, and every opening should be arranged alternately in the two sections, and good ventilation for removal of the vapour which might escape at the moment of opening is maintained.

Dispersion of mercury vapour, it should be remembered, is a serious danger not only to the personnel of the factory but also for the neighbourhood, including cattle.

**Statistics**

Modern technique is in a position to reduce, and, in some measure, suppress the conditions which in times gone by
resulted in serious and fatal cases of mercurialism. The clinical picture described by Arevaca and Kussmaul is becoming more and more infrequent among those engaged in the metallurgy of mercury, but a state of slight mercurialism still exists which can affect the furnace worker in his highly skilled work so much as to oblige him to accept a lower post or even that of an ordinary labourer. There are no recent data (see also article "Mercury"), and comparison of pre-war figures with those since the war cannot be given.

In the mines of Idria, before 1886, Baaz gave 11 per cent. as the average number of workers affected with chronic mercury poisoning and states that he had seen about 500 cases in five years. Previous to that time, according to various authorities, the frequency of mercurialism was even greater. The principal Medical Officer of the Mines (Dr. Siverak) stated that in 1906, of 209 persons employed, a third only — and they the ones least exposed to the danger — could be considered as constituting a stable personnel, as the other two-thirds left the mine after two or three months' work. According to him the workmen were timorous, weak, frequently addicted to alcohol, and very often ill (morbidity: 95-104 per cent.). In 1906, of 741 cases of illness among the group of miners only 6 were cases of mercurial poisoning, whereas among 179 furnace workers there were 12.

The perfected technique, and especially alternation of employment adopted in 1896 (one month at the furnace and two months in the mines), have without doubt improved the sanitary situation. In effect, while in 1896 there were 122 cases of illness for every 100 workmen, with 2,814 days of absence, in 1908 there were only 5 cases with 145 days of absence.

In the course of an enquiry made by Teleky, severe cases of disablement from mercury were found to number only 9 (among 1,200 employed), and among 299 workmen only 19 showed slight symptoms of intoxication. At the same time the mortality of the miners was very high, especially from tuberculosis.

It is of interest to recall that cases of mercury poisoning have been reported among the members of the families of miners in Idria, especially when the children slept in the same bed as their father.

Diminution in the number of severe cases has taken place, also at Monte Amiata, where, however, it is still possible to find cases of slight hydrargyrism, which, were it not for close medical super-
vision, would disable the furnace worker for his highly skilled work and compel his transference to labouring work. Giglioli, in 1908, among 135 furnace workers examined found 20 with moderately severe symptoms; 45 had had, or still had, typical symptoms; 25 had shown distinct mercurial disorders. In 1925 Loriga and Biondi noted an improvement in the state of health of the miners at Monte Amiata. The American quicksilver mines are in the States of California, Texas, Nevada, and Oregon. Of these, 95 per cent. are cinnabar mines and the remainder selenite or tennantite, telluride, and iodide of mercury. The number of workers was very small (95 at New Idria, 35 at New Almaden). Cases of tremor, psychosis, etc., are recorded. According to Kober, the eleventh census of the United States gave 10.4 per cent. of the workers employed in the mines of New Almaden as being affected by mercury. No further information is to hand.
Special Pathology applied to the Metallurgy of Mercury

Under the best conditions of work, probably 1 or 2 cases of poisoning occur among every 100 workers; of every 3 both arduous and continuous and without doubt unpleasant, predisposes to heart affections, and the humid atmosphere to rheumatism. According to the enquiry by Giglioli, 50 per cent. of the men at the extracting works in the galleries (which may be iuraaces and bottling) showed signs of mercurialism. The furnace workers who might have been expected to show the malady in its purest form, that from inhalation of vapour
(tremor, etc.), on the contrary had a mixed intoxication with symptoms like those induced by compound of mercury. This fact is due, in part at least, to the condensation of the mercury in the buccal mucous membrane and its transference by the saliva to the digestive tract from which it is absorbed as an organic compound. Stomatitis is probably the expression (at times the only one) of this intoxication by a compound of mercury superimposed on that set up by the vapour.

Account ought to be taken also of the less typical cases of illness, which have their origin no doubt in mercury (slight mercurialism). Further, a dry rhinitis is reported among the metalurgical workers, due probably to the vapour of sulphur dioxide and accompanied by frequent epistaxis difficult to arrest.

Further, a large number of ailments are attributed to the occupation, either respiratory (bronchitis, tuberculosis) or nervous, of long duration. The number of invalids is very high as well as the death rate (from respiratory diseases: pneumonia, tuberculosis). The effect of mercury on the offspring of those suffering from poisoning and the predisposition to miscarriage should be recalled.

Zangger (1930) has noted symptoms connected with mercury, especially amongst workers engaged in distillation repairing and cleaning. He found very serious symptoms amongst workers who during several years seemed to have been immune.

**Hygiene**

The preventive measures to be adopted can be summed up as follows: Best construction of furnaces (airtightness, negative pressure in the interior, automatic feeding of the ore, etc.), constant supervision both of the action of the furnaces and the upkeep of the piping. Watch specially that no escape of vapour takes place from the upper part of the Spirek furnaces by increasing, if necessary, the thickness of the layer of ore; examine periodically the composition of the gas from the chimneys (which can besides effect a great increase in the output). If fumes do escape there would be advantage in adopting the electrostatic processes used, for example, in America for the separation of mercury from the smoke. As complete a condensation of the vapour as possible (by long U-tubes in sufficient number), followed by effective cooling, are factors of the greatest importance in preventing the escape of mercury into the atmosphere and ensuring the most complete recovery of mercury. Good exhaust fans to the Exel furnaces permit of all residues being used and condensed, and limit contact with mercury. It would, however, be useful to evolve a perfectly enclosed type of fan which could prevent escape of toxic vapour at the moment of the reaction between the lime and "stupp".

A mechanical system for the purification, cleaning, and bottling completes the series of measures of prevention on the technical and industrial side.

Seeing that the specific dangers are so great, the duration of the work of the shifts should be limited with alternation of employment for those most exposed to risk (e.g. one month for furnace work, and two months at outside work or) in the mines. There should be cloak rooms, separated from the work rooms; meal rooms, etc. The working suits should be provided by the employer and washed once a week.

Douche and vapour baths should be installed, the first for use every day and the latter once a week. At Monte Amiata the furnace workers have the advantage of using the hot baths in Sienna. For details regarding measures adopted at Monte Amiata see article by Palumbo, 1921. For personal hygiene, medical examination before taking up employment, and periodic medical examination see article "Mercury".

**Legislation**

The first statutory intervention known dates from 1665, when the hours of work in the quicksilver mines of Friuli were reduced to six per day in consequence of the effects on health.

Women under twenty-one years of age and young persons under fifteen are excluded, in Italy and in Rumania, from the work of smelting cinnabariferous ore.

Metal Grinding and Polishing

French: Métaux (Aiguisage et polissage).
— German: Metalle (Schleiferei, Polierei).
— Italian: Metalli (Lisciatura, pulitura).
— Spanish: Metales (Afilado y pulimentado).

**TECHNICAL DATA**

Grinding, that is, giving an edge to a tool or arms, is synonymous with sharpening, and is a term used especially in connection with tools ground on a wet stone. Whetting, that is, to give the finishing touch to grinding, is a process ordinarily done on a whetstone with oil.

Polishing or glazing is making the metal smooth and bright by mechanical friction.

These two processes are very similar to one another. Generally, grinding is first started by a file or on a grindstone, dry or wet, and is finished on softer stones with oil. Similarly, polishing or glazing includes habitually a series of processes like those described; there come successively in use strong files or hard grindstones; next, moderately soft files; and then finer and finer ones, or grindstones less and less rough; the process is finished on felt or cloth mops to which very fine and soft materials are added.

For very small objects lending themselves to the process, polishing is sometimes done in rotating receptacles (drums), in which the articles are polished by reciprocal rubbing, or by the aid of polished steel balls, or again of substances slightly abrasive often combined with soap.

Only very hard metal articles, nearly always of steel, are ground; on the other hand, most metals are polished. The term "polishing" is reserved for the polishing of side-arms.

It can readily be understood that in polishing, the methods, and especially the abrasives used, differ notably according to the nature of the metal worked.

**Polishing of hard metals** (cast-iron, steel). — Ordinarily, pieces of machinery of rather large dimensions are polished exclusively on finer and finer files. Cast-iron and steel articles lending themselves to it are polished on grindstones after the roughnesses have been removed.

The grindstones are of stone, quartz, corundum, emery, etc. The grindstones made up of these last ingredients are artificial stones of which the grains, more or less fine, are united by a stratum mainly consisting of cement, rubber or resin (see article "Abrasives").

When the object to be polished or glazed has been softened by the means indicated above, it is generally subjected to softer polishing wheels of strong leather, or, better still, of wheels entirely made up of leather discs in juxtaposition and bound closely against one another. These wheels, running at great speed, act very superificially and are often dusted over with very fine emery powder or abrasive substances of only slight hardness, such as pumice, Tripoli, polishing rouge, etc. Circular mechanical brushes made up of wire and sometimes of bristles are also used. Very often the finishing is effected by means of felt or cotton.

The wheels and finishing brushes sometimes assume a hemispherical shape at the extremity of a rotating axis. The advantages of such an arrangement are that it is the only one which allows of mechanical polishing in rather deep cavities.

Finally, the mechanical wheels and brushes differ in size, form, and position, according to the nature of the objects habitually dealt with. Large metal plates are sometimes polished by hand.

**Polishing of soft metals** (copper, brass, nickel, silver, gold, etc.). — In the polishing of soft metals, grindstones of very fine grain, and brushing wheels of rubber, basil, or felt, as well as abrasive substances of slight hardness, are used: brick dust, pumice, Tripoli, washed chalk, yellow oehre, Viennese chalk, polishing rouge (which is an oxide of iron), and, finally, powder, etc. In the case of precious or soft metals, after a dry smoothing, the articles are dealt with by means of a paste prepared with the substances just named, diluted in oil or surrounded by fatty substances. Exceptionally, in goldsmiths' work use is made of a paste containing potassium cyanide.

When the articles are ornamented in relief or hollowed out, especially in workrooms for galvanoplasty, nickelering, silvering and gilding, scratch-brushing is frequently done. By scratch-brushing is meant energetic hand friction of the object to be polished by means of a kind of brush composed of a bundle of brass threads. The process is always done wet.

Another very frequent operation carried out on objects made of precious metals, or subjected to silvering or gilding is burnishing. This work, quite often entrusted to women, consists in rubbing, by means of a hand tool called a burnisher, the parts intended to be very bright. The polishing and acting extremity of this tool is made of bone, agate or, more rarely, steel.
The principal risk in polishing metals is due to dust. That can at any rate be said, and to a still greater extent of grinding. In the dust of the latter operation hard particles are met with, often siliceous which have come off the grindstones. The metal particles are here of little importance; the fineness of the particles removed favours their transformation into oxide owing to the high temperature due to the friction. In the polishing workrooms, even when done wet, the dust is often abundant and almost always injurious, whether derived from very hard abrasives like emery or carborundum or from very resistant metals.

When the polishing is done wet, or even with oil, the dust is thrown off by the grindstones and brushes: these projections dry on the ground and on the tables and the dust so created eventually gets into the atmosphere.

The "dressing" of the old grindstones and brushes and their necessary recutting from time to time is a particularly injurious occupation owing to the considerable quantity of the dust created.

Occasionally, in addition to the irritating action on the respiratory tract a toxic action is added; this is notably the case when the metals polished or the abrasive substances contain lead.

Contact with irritating substances gives rise to dermatitis, which is also caused by the fatty bodies entering into the composition of the polishing pastes, or by the solvents serving for the final scouring (benzol, methyl alcohol, benzine, turpentine, etc.).

While the figures are as a matter of fact the figures are as the result, especially is fairly frequently the cause of ulcers on the fingers and hands of polishers. These ulcers, always benign, very often take on a character recalling the "chronic holes" of tanners or ulcers of men working with bichromates.

Polishing by hand large surfaces of metal is a tiring job.

The abnormal stooping position of the polishers, and more especially of the grinders when they lie on their stomachs as is the practice in certain regions is a potent factor in the unhealthiness of the trade. In the cutlery workrooms the grinders are seated very near the ground, and the necessity of their work obliges them to be very close to the stones as they generate the dust. In polishing the workman generally stands upright and, in order to do the working distinctly what he is doing, brings his face close to the object he is polishing. When large pieces are

The data concerning the frequency of certain diseases among polishers has reference especially to cases of saturnism and diseases of the skin. Both in Austria and Great Britain numerous cases of lead poisoning have been reported among polishers of metal capsules made of tin and lead (the dust from this metal, capsules contained from 1.4 to 25.6 per cent. of lead). Other cases have been described between 1914 to 1918 in Great Britain among the polishers of copper articles (containing 1.5 per cent. of lead); 19 cases in Birmingham, of which 7 were due to insufficient locally applied exhaust ventilation to remove the dust; in Prussia among the polishers of goldsmiths' work from the use of chrome red and yellow and a substance with a lead basis (white lithopone). In 1902 an examination was made in Great Britain of 210 polishers, of whom 16 showed signs of lead absorption (see Annual Report of the Chief Inspector of Factories for the year 1915, page 388).

During an enquiry dealing chiefly with Sheffield workshops, Macklin and Middleton examined 1,153 workers and found a considerable number of workers regarded as suspects, however, were classified as follows after diagnosis: 221 cases of bronchial-catarrh (19.16 per cent. of the total number of workers examined), which affected chiefly glazers and dressers exposed to inhalation of silica, as well as other dusts. The latter play a role in the production of the respiratory disease, which is in direct proportion to their concentration. 146 cases of bronchitis (12.6 per cent.) affected chiefly textile machinery grinders and dressers. 76 cases of pulmonary catarrh occurred, chiefly amongst wet sandstone grinders aged sixty to sixty-five. This lesion is regarded as a consequence of silicosis which affected the workers in the proportion of 73.97 per cent. Signs of fibrosis became apparent in the majority of cases during the first five years of work, increasing progressively to the end of the twentieth year, at which period almost 80 per cent. of the workers were affected.

The frequent incidence of cases of fibrosis amongst wet sandstone grinders is related to a very high concentration of dust particles in the air (2,000 to 12,000 (reckoned with Owen's konometer, averaging 3 to 6,000) per cub. cm.). For details see the report of these experts (published in London by H.M. Stationery Office, 1928).

In Germany, Teleky, Lochkemper, Bosenthal-Deussen and Derdack studied (1958) troubles due to dusts amongst metal grinders. According to the research engaged in by them, sandstone grinding is quite as dangerous as the dry method. The quantity of dust liberated is considerable, since it is reckoned that in the space of four weeks the grindstone is reduced in diameter by 50 per cent. on an average. Thus, despite humidification, large quantities of dust become dried and liberated. Clinical symptoms of the disease — and particularly radiographic examinations — showed serious pulmonary lesions due to quartz dust, lesions occurring among sandstone grinders after the first four or five years of work. Polishers using chalk showed hardly any pulmonary lesions, whilst with the use of pumice stone slight modifications occurred after a fairly long time; grinding on artificial corundum grindstones is less harmful than grinding on sandstones; pulmonary changes are only noted in this case after a lapse of twelve or thirteen years and are not particularly severe, even after thirty-two years. The artificial stone wears out much less rapidly, the dust liberated coming rather from the object in course of being sharpened than from the grindstone.

An enquiry made in Belgium by the Medical Inspector of Factories in 1912 in a factory where articles were made of an alloy of tin and lead showed that of 15 persons engaged in polishing 7 showed slight symptoms of lead poisoning.

In Switzerland, K. Amman (1923) studied 15 cases of pneumoconiosis among polishers and made four autopsies. In 9 workmen X-ray photographs showed chalico-siderosis; in the others the hilum shadow was well marked; 4 had died of tuberculosis and 2 were suffering from it. Amman considers that cases of pure chalico-siderosis are very rare, and that the majority of the cases of pneumoconiosis end in tuberculosis. Enquiry made by him in a factory in Zurich showed that, between 1907 and 1916, 29 deaths had occurred among the workers, of which 20 were the result of tuberculosis (the workers' ages varying from 20 to 64 years). Prognosis is very bad; twenty years' work incapacitates the workman. Between 1900 and 1922 the labour turnover in a factory employing 25 polishers reached the figure of 236, of whom 18 had died. In the last few years (1917-1920) every year one workman died, and (1921-1922) two polishers per annum who had worked respectively for ten, twenty, and forty years had died with symptoms recalling silicosis. Amman is of opinion that chalicosis should be treated as regards compensation in the same way as silicosis.

Skin diseases also have been frequently reported, especially in Germany (eczema, ulcers, etc.), from the use of denatured alcohol and turpentine substitutes, either among polishers of ordinary metals (copper, etc.) or of gold, silver, etc. In Bavaria and Prussia cases have also been reported of blepharitis and conjunctivitis induced by the vapour from the polishing solutions containing turpentine substitutes; in Austria (1913) cases of poisoning by carbon monoxide due to escape of gas from piping and soldering irons (in the polishing and mounting department in a cutlery factory).

Skin diseases are sometimes caused by the benzine or benzene used by workers to remove the last traces of grease.
Among some of them alteration of the blood, characteristic of the action of benzene (lymphocytosis, diminution in the number of red blood cells), has been described (Teleky).

An enquiry by Agasse-Lafont, Domoulines and Heim (1915-1922) gives interesting information on pneumoconiosis among metal polishers. It related to a group of polishers of steel, iron and copper, aged 33 to 59 years of age, with a duration of employment of twenty to forty-five years, and to another group of tin polishers aged 20 to 44 years and duration of employment of nine to twenty-four years.

Clinical examination showed all to be subject to coughing with more or less abundant expectoration; in 30 per cent. these symptoms were moderate, and severe in the others. Physical signs were slight—localised especially at the apices; but definite pulmonary lesions were only made out in 20 per cent. of the subjects. There was no history of haemoptysis. Radiography, on the other hand, brought out very clearly a fibrosis of the tissues due to the dust which clinical examination alone quite failed to do.

The proportions of lungs affected numbered 69 per cent. and sometimes the apices, sometimes nodules situated in the upper lobe or along the bronchi (40 per cent. in the upper bronchi) were quite opaque. The mediastinum was relatively little affected, but in 15 per cent. of the cases showed an abnormal shadow similar to that of sclerotic lesions. The shadows from the pulmonary glands, bronchial and mediastinal, were rather like those of tuberculous lesions of fibrotic character, or in process of cicatisation.

The polishers of the lead tin alloy are not only exposed to fibrosis of the respiratory tract and parenchyma by the dust like other polishers, but are exposed also to the risk of lead poisoning. Radiological examination showed the same lesions as in the other polishers, the signs of lead absorption and lead poisoning were also very frequent (70 per cent. had a blue line, 40 per cent. colic, 30 per cent. tremor, 70 per cent. polychromatohil red blood cells, 50 per cent. basophil granulations).

Caffaratti has reported ocular lesions amongst grinders, which in Turin factories amounted to 83 per cent. of all ocular affections noted. In general the victims of these lesions had worked without protective glasses.

Hygiene

In addition to all the hygienic measures for workrooms and persons employed common to all industries, emphasis must be laid on processes for the capture and removal of the dust produced in the polishing processes. The reader is referred to the articles "Abrasives", "Iron. Pig Iron and Steel Industry", "Stone Industry", "Dust, Fumes and Smoke", "Glass Industry", "Timber Industry", etc., in which the best measures are described in detail for protecting the workmen against all dusts generated in the course of ordinary work; here questions concerning the polishing workrooms only are dealt with.

Every installation should comprise a fan (generally a suction fan), a dust collector and a hood for enveloping the tools in the best way possible.

In the case of emery wheels, when the work is good on the anterior face of the crown the covering hood adapts itself perfectly to the exhaust duct, and suction alone suffices as only a small part of the crown of the wheel remains uncovered. If work, however, has to be done on the upper part of the wheel, a hood should be used with movable sectors which can be adjusted to the necessary positions and the dust collected in a funnel-shaped receptacle placed at the back, but which can be turned towards the wheel at will. If the suction at the forward sides of the wheel is stopped, the draught at the back will be increased.

Although the rather special conditions of polishing shops, the variety of the work done, the smallness of the workrooms, the expense of installation, and the dislike of modifying the custom of the trade make conditions iminical to good systems of locally supplied exhaust ventilation for the capture and removal of dust, the advantages of ventilation are beginning to be appreciated by those interested, and marked progress has often been recorded by factory inspectors.

Experts advise that a fan of low power be not used, because if its speed will have to be increased, with the liability to cause an accident. The moving air leaving the fan can be used and blown again, for example, into the aspirating duct of the hood over the cleaning bath, or into the closets to help remove smells.

Besides the advantages to the workpeople from successful removal of dust, the installation of exhaust ventilation provides considerable material profit when it is a question of collecting metallic dusts of a definite value (copper, silver, gold, etc.). When this is the case, the dusty air from each tool is drawn away by piping connected up with a fan of large drawing power and low pressure with the introduction of a flannel filter between the machine and the fan.

Removal of the dust in burnishing should not be allowed to incommode the workpeople, who require great freedom of movement at every part of the wheel. Consequently, ordinary
hoods cannot be used if protection has to be limited to placing in front of the workman a sheet iron cupboard leaving the front quite free. The dust and fibres coming off the wheels or mops are stopped by a kind of movable sheet iron plate which the workman can bring almost right up to the wheel. Naturally, in the burnishing of very large pieces this cupboard would have such large dimensions that the draught would not be sufficient to take away the dust obstructing the piping, and it would then be necessary to connect up the back of the sheet iron cupboard to a fan of the appropriate strength.

Workers should be prohibited from greasing the wheels with oil or applying Vienna lime in powder form to the surface. The employer would be well advised to place at the disposal of the polishers cakes ready prepared of lime and grease thoroughly mixed, and it should be possible for the men to ride on the stone without dust being given off.

Authorities on the subject recommend also periodical medical examination, and regulation of working hours.

LEGISLATION

In France, the employment of young persons of less than 18 years and women in the polishing and grinding of metal is forbidden, as well as in the manufacture of grindstones and polishing wheels. In the Netherlands employment of women in the polishing of metals is also prohibited, and in South Africa that of young persons of less than 16 years (dry polishing). At the same time the technical experts point out that if all premises would put their house in order in the manner indicated by hygiene experts (removal of dangerous dust) the prohibition laid down by legislation could be withdrawn as the cause necessitating it would itself disappear.

In Great Britain regulations have been enacted: the Grinding of Metals (Miscellaneous Industries) Regulations, dated 2 September 1925, for the grinding and glazing of metals or the cleaning of casings (Statutory Rules and Orders, 1925, No. 904); the Grinding of Cutlery and Edged Tools Regulations, dated 26 October 1925, for grinding or glazing or processes incidental to grinding or incidental to the manufacture of cutlery, edged tools, swords, bayonets, files, saws, ploughs or other cutting or piercing implements of iron or steel (Statutory Rules and Orders, 1925, No. 1089). For details see the Legislative Series, 1925, G.B. 8 (published by the International Labour Office).

Compulsory notification of dermatitis (eczema, ulceration, etc.) occurring amongst metal polishers is also required in the Netherlands. Phthisis among grinders (aiguiseurs) is a disease for which compensation is paid in Canada (Ontario).

Special legislation is required for workshops in which metals are manipulated which might set up poisoning (lead).

Dr. L. Teleky
(Düsseldorf)

and Dr. Gilbert
(Brussels).

Metallisation by Pulverisation

The advantages of protecting metal surfaces against the action of atmosphere and of corrosive substances have for long been recognised. At first, application of a layer of paint or varnish to the metallic surface was practised; later use was made of a fine metallic layer which could not be attacked by the oxygen of the air or by acids. Thus arose the method of coating with lead, zinc (galvanising), tin, obtained by means of a bath of molten metal or by an electrolytic process.

Modern technique has introduced other methods, such as electroplating, see articles "Electroplating", "Copper", "Nickel", etc.; sherardisation (invented by Sherard Cooper) for the zinc-plating of objects, which are made to revolve in a cylindrical receptacle, hermetically sealed and brought to a temperature of 400° C., containing a mixture of zinc dust (zinc powder, a by-product in the zinc industry), fine sand and a small quantity of naphthalene (as a reducing agent); calorisation, with a deposit of aluminium, which is secured by means of a calorising mass composed of aluminium, alumina and ammonium chloride, this mixture being heated to 850-900° C. in a revolving furnace; and finally the Schoop process, modified and improved, consisting of the violent projection of finely pulverised metal on to the surface to be coated.

The "pistol", invented in 1910 by Schoop, of Zurich, consists essentially of a compressed-air blowpipe, into the central nozzle of which is inserted a metallic thread set in motion by a compressed-air turbine which can attain a speed of 30,000 revolutions per minute. The metal thread is melted as soon
as it reaches the flame; it is pulverised by the expansion of the air and projected with force onto the object to be metallised. The small turbine is set in action by the air, which serves to feed the blow-pipe. The Schoop Pistol can be used with various gases: oxygen and hydrogen, oxygen or compressed air and acetylene, or illuminating gas.

The fine metallic particles are chilled by the expansion to such an extent that it is possible to metallise objects made of cement, plaster, wood or cardboard. The air pressure can reach an average of 3.5 kg. or even 5 kg.

The metals most commonly used are zinc, aluminium, copper, lead, tin, nickel and many alloys, of which the melting point is about 700° C. For certain very volatile metals, the great loss from evaporation is lessened by lowering the pressure of gas. This pressure is, however, diminished by nearly 50 per cent. in the new models of the Schoop pistol.

For pulverising certain very refractory metals (tungsten, molybdenum), use is made of a pistol consisting of an electric arc playing between two metal threads which are pulverised. There is yet another model of the "enamelling pistol", fed by pulverulent metal; this is provided with three ducts for the gaseous mixture, compressed air and the metal. One part of the compressed air is directed towards the burner and the other towards an injector; aspiration of the metallic powder takes place into a reservoir and projection of this powder across the gas flame. The use of oxygen avoids the reduction of the lead compounds used. The enamel may contain colouring matter if necessary.

The Schoop process, although recent, is in general use. Many objects of various dimensions are metallised with zinc, aluminium, tin, etc., either by means of very complicated fixed machinery or portable apparatus, in order to protect them against oxidation or attack from liquids and vapours, or again as a method of decoration. Lead is used for apparatus intended for the chemical industry and for fabrics intended for protection against X-rays and radium rays. Bridges, roofs, boilers (zinc), and the hearths of locomotives (aluminium), brewing vats (aluminium), aeroplane wings, balloon envelopes, etc., are all metallised in the same way. Before metallisation takes place, the different metal objects require to be scoured; this is now effected by means of sand (see article "Metal Grinding and Polishing"). The workman conducting this operation stands in a compartment separated from the objects to be scoured by a partition of glass.

**Sources of Danger**

There is a risk of burns, not only for the workman, but also for persons passing by the apparatus. The burns, mostly due to incompletely airtight apparatus, are very deep and severe, as the molten metal is projected under great pressure. The lesions are situated especially on the face (eye), and on the upper and lower limbs.

On account of the heat given off from the apparatus, the workman is inclined to take off garments, thus rendering himself liable to injuries and burns on other parts of the body. The metal is even projected on to the walls and the floor of the workroom, so that dust may arise.

Oxidised dusts arising from the condensation of the metallic vapours are the more finely scattered the higher the temperature to which the metal has been raised and the more rapid the cooling. Their power of penetration and absorption is therefore considerable, giving rise to risk of poisoning in the presence of dangerous metallic dusts (especially lead). Thus cases of poisoning have been reported after only a few hours' work when lead has been projected by the pistol and adequate measures of protection have not been taken.

Eibel notes ear trouble due to the compressed air. In 1924 the Medical Inspector of Factories in Great Britain reported four cases of saturnism, even although the metallisation had taken place in a well-ventilated workshop and the operator had worn breathing apparatus. It would appear that the latter could not have been effective. In order to prevent poisoning, it is necessary that a positive pressure of air should be maintained inside the mask and this can only be secured by means of compressed air.

In a German factory (1923-1924) eight cases of saturnism were reported, and one case in a factory in Schleswig.

The Medical Inspector of Factories in Bavaria (1927) considers that health conditions depend on the properties of the metal employed. In the Schoop or Meunier processes the metallic mist formed may penetrate into the respiratory tract, especially when the workman takes up an awkward posi-
tion or when he is obliged to bring his face near the object to be coated. Hence the risk of saturnism when lead is used or poisoning from zinc when zinc is in question, etc. Medical literature has brought to light several cases of poisoning of this kind, but the medical inspector has not met with them, because of the relative infrequency of this work in Bavaria. At the same time, statistical data on the subject are few. Eibel insists on the risk of "metal fever", because the metal is projected into the surrounding air, either in a very finely powdered form or in the form of vapour at a high temperature (lead, zinc, etc.). Finally, the danger of scouring with sand ought not to be overlooked.

HYGIENE

Adequate preventive measures ought to render it easy to avoid the dangers presented by metallisation: cleanliness of workrooms, use of apparatus perfect from the technical point of view, and provided, where necessary, with an adequately protective envelope; protection of the workers against the action of fumes and metallic droplets suspended in the air, by means of masks, goggles or screens. When large objects are handled, even if the operation takes place in the open air, the workman should be provided with a mask and with working clothes. Articles of moderate dimensions can be treated under efficiently ventilated hoods, and small pieces (bolts, rivets, etc.) should be metallised in completely closed revolving drums.

The worker should be protected during scouring by means of a mask supplied with a constant stream of fresh air. It would, however, be better, not only in the case of metallisation but also in that of cleansing, if such operations were undertaken either in special cabinets or in enclosed places provided with fans for collecting and directing into special receptacles the dusts given off.

No statutory regulations on metallisation exist.

BIBLIOGRAPHY

Methyl Acetate

Methyl acetate (formula C₃H₇O₂C₂H₅) is present in wood spirit (crude methyl alcohol) and in pyroligneous acid. It is prepared by distilling a mixture of methyl alcohol, acetate of potassium, and sulphuric acid. The distillate is dehydrated by means of calcium chloride and then again distilled.

Methyl acetate is a colourless liquid with an agreeable smell, boils at 57° to 58° C., and is soluble in water, alcohol and ether.

It is used as a solvent in collodion varnishes, etc., and with a view to this it is usually mixed with acetone. Pathology is similar to that for methyl alcohol (see that article).

Methyl Alcohol

(Wood Alcohol)

PROPERTIES

Methyl alcohol, when pure, is a colourless liquid, with a faint alcoholic odour, boiling at 66° C., burning with a non-luminous flame, solidifying at a very low temperature, and melting at —94° C. Its formula is CH₃OH. It dissolves in all proportions in water, alcohol, ether and chloroform. Its specific gravity is 0.7984 at 15° C. It is much used in industry, being a good solvent of fats, oils and resins. Heated with lime or oxidising substances it readily yields formic aldehyde and acetic acid.

INDUSTRIAL PROCESSES

Methyl alcohol is obtained from the dry distillation of wood and as a by-product in the manufacture of acetic acid.

The wood is distilled in steel or iron retorts placed in a brick furnace provided with a door which can be hermetically closed. The vapour of distillation is carried to a condenser, whilst the furnace gases are usually carried into the hearth to be burnt. The
liquid product of distillation generally contains plenty of water, acetic acid (6-8 per cent.), methyl alcohol (1-5 per cent.), acetone (0.1-0.4 per cent.), and a little tar. After separating the last named the liquid is saturated with lime, calcium acetate being obtained, which is then dried in the furnace beside the retorts in order to utilise the available heat.

The liquid is mixed with about 2 per cent. of methyl alcohol and distilled in a rectifying column apparatus. Crude methyl alcohol is obtained which turns reddish brown in the air and contains about 80 per cent. methyl alcohol, 10 to 14 per cent. of acetone and other slight impurities — acetic and formic aldehydes, furfuroil, pyridine, ammonia, etc.

They are purified by dilution with water, decanting, after lying some days, from the oily layer of tar which collects on the surface; treatment then takes place with lime and is followed by complete distillation. The distilled product is mixed with 0.1 to 0.2 of sulphuric acid and rectified by collecting separately the tailings (rich in wood oil and ketones). The portion which distils between 62 and 65° C. is used to denature ethyl alcohol and to make formic aldehyde. A third portion (about 25 per cent.) constitutes pure methyl alcohol, which is carefully distilled between 65° and 66° C. and serves for the preparation of synthetic organic products.

Purification is effected by distillation in presence of a little hypo-chlorite of calcium (elimination of acetone, formation of chloroform) or in converting methyl alcohol into a compound ether which is then saponified. Distillation and rectification follow.

Other processes of less importance need not be described except that of direct synthesis which is already applied industrially in Germany: methyl alcohol is obtained by passing a mixture of carbon monoxide and hydrogen at 500 atmospheres pressure over a catalyst (metallic oxides) heated to about 400° C. The gaseous mixture is obtained using steam as the starting point (see article "Gases and Fumes").

The alcohol so obtained also forms the basis for the preparation of dimethylaniline and other intermediate products used in the production of artificial dyestuffs and for the manufacture of formaldehyde.

USES

Among the numerous uses of methyl alcohol are the preparation of formic aldehyde and methyl derivatives (dimethylaniline, methyl chloride and bromide, etc.), the manufacture of aniline colours, etc.

As a solvent of resins and as an important ingredient, it is used in the preparation of lacquers, varnishes, dyes, starch paste, etc.: in the hat industry, making of artificial flowers; in the brewery industry (special varnishes for the vats); in polishing furniture and wood generally (pianos, pencils, canes, toys, etc.).

It is further used: as a solvent of acetate of cellulose, collodion (mixed with acetone or benzol or both together), etc.; in aniline colours, the drying of which it facilitates; to denature ethyl alcohol (mixed with pyridine, etc.); to clean machines (e.g. the letters of typewriting machines, etc.).

SOURCES OF DANGER

Danger arises both in the manufacture of the substance (when escape from the apparatus occurs) and during its use (from the evolution of fumes), but that from ingestion is very rare and accidental on the industrial side.

If in the course of manufacture the doors of the retorts are left with the slightest aperture owing to their being split, or do not close hermetically, the gases and vapours which escape constitute at the same time both a loss in output and a danger to the workers (from irritation of the mucous membranes especially).

The use of methyl alcohol as a solvent (of colours, resins, etc.) sets free vapours potent for serious harm to the workmen. Thus, in an American factory for making artificial flowers, at a distance of two metres from the point at which dipping and dripping was done, 2 volumes of alcohol per 10,000 volumes of air was found in the atmosphere.

TOXIC ACTION

Views vary as to the toxicity of methyl alcohol. Some authorities regard it as less toxic than ethyl alcohol, because, in their opinion, toxicity increases with the number of atoms of carbon (Rabuteau's Card), while others take the view that methyl alcohol is an exception to the law in question and is more harmful than ethyl alcohol. It is certain that in massive doses the latter is more toxic than the former, but in small and repeated doses it is considerably less so than methyl alcohol. This contradiction is explained by the fact that accidents due to methyl alcohol take much longer
to develop and elimination by the kidneys is much slower; as a result symptoms of poisoning are slower in appearing themselves and more severe in the long run than are those caused by ethyl alcohol. Further, account must be taken of the fact that in its industrial use methyl alcohol always contains impurities which certainly play a part in the production of the reported lesions. Thus, for example, the presence of pyridine bases and furfurol (used as a solvent in the manufacture of varnishes and protective coats) deserves careful study.

English methyl alcohol contains 2 per cent. of wood spirit, 1 per cent. of essence and 97 per cent. of alcohol. Special industrial spirit contains 3 per cent. of wood spirit and 97 per cent. of alcohol. Mineralised methyl alcohol contains 95 per cent. of alcohol, 4 per cent. of wood spirit and one-half per cent. of essence and is coloured by methyl violet (P. White).

In Germany, according to Koelsch, the wood spirit used for denaturing purposes contains, among other things, 50 per cent. of methyl alcohol, 25-30 per cent. of acetone, and 7 per cent. of amyl acetate and other impurities. Colombia spirit contains 95 per cent. of methyl alcohol and often takes the place of turpentine.

The toxic dose of methyl alcohol is difficult to fix. Loewy has found in the air of 8 workrooms from 0.005 to 0.06 per cent.; in 4 other workrooms a content of from 0.1 to 0.5, and among 4 others again 1 in which it varied from 0.1 to 0.622 per cent.

A content of 0.15 per cent. has not affected animals appreciably after twenty-four hours.

Brückner studied chronic poisoning experimentally in 1924, and he was even led to enquire whether the lesions described by authors before him were really to be attributed to methyl alcohol. The number of fatal cases of occupational origin is very small. Brückner considers there have not been more than 20 in the whole of Germany.

Methyl alcohol, according to this writer, is said to be an industrial poison which plays a rôle no greater than several other alcohols and other organic substances used as solvents in industry.

**Statistics**

Figures as to the frequency of poisoning and their sequelae by methyl alcohol cannot be given. Though acute poisoning is most frequently the result of ingestion (in 1904, for example, Buller and Wood collected 92 fatal cases and 156 cases of blindness culled from American literature), such poisoning occurs very rarely industrially (it may be met with among French polishers). Generally it arises from workpeople tasting denatured alcohol.

From the point of view of industrial hygiene, the cases of poisoning caused by alcoholic vapour are of greater interest. Nevertheless, apart from local signs of irritation of the skin and mucous membranes, it is often very difficult, it must be admitted, to attribute large quantities to health to alcohol itself rather than to the heat, benzine vapours, turpentine and other volatile substances present in the air, which would undoubtedly increase the injurious effects of the work done under the particular conditions.

Among the cases described in literature there may be mentioned one of Colburn's, in which methyl alcohol used for cleaning furniture had set up bilateral optic neuritis with marked diminution of vision; the very severe cases quoted by Koelsch among barrel cleaners and furniture polishers; two cases of Buller and Wood; cases of Schappringer, as well as those of Giftord, of transitory blindness from the use of methyl alcohol in dissolving colours; those of Schweinitz affecting a boat painter; of Herbert, a cooper; of Philipp, etc.

In America, Baskerville assembled details of 64 cases (in 1913) due generally to the inhalation of methyl alcohol. In 1914, Loewy made enquiry among persons employed in the manufacture of large quantities of methyl alcohol. From the replies of 40 works surgeons, he found that injury to health was quite of secondary importance. In fact, 34 doctors had seen no effects which they could attribute to methyl alcohol; only two cases of dermatis were known.

Koelsch has described (1921) cases of poisoning amongst doctors from fumes liberated in course of disinfection; a case of a woman in a boot factory, illness being contracted from a paste made up of cellulose or resins dissolved in methyl alcohol, acetone, amyl acetate, benzine, etc. After application the paste is allowed to evaporate leaving a protective layer against moisture, and giving certain elasticity to the boot.

According to Hamilton, methyl alcohol is said to be in a very special sense an "American poison", because the United States alone have more cases of poisoning than all other civilised countries put together. This is explained by the fact that nearly always pure methyl alcohol is used, whereas elsewhere it is denatured ethyl alcohol. Cases are most frequent in the painting industry and in the making of felt hats, artificial flowers, etc.

**Symptoms**

Very varying opinions are held as to occupational intoxication by methyl alcohol. Rambousek speaks of violent poisoning by the vapour with acute irritation of the mucous membranes, cough, etc.; in very severe cases, he
speaks of having detected bronchitis, headache, vertigo and tremors. Roth (1913) cites cases of intoxication with amblyopia, blindness and optic neuritis. Factory inspectors describe frequent headaches, vertigo, conjunctivitis, and visual affections as set up by methyl alcohol, especially during the war when it was used for preparing paints (Koelsch).

According to Koelsch, methyl alcohol is an important industrial poison having both a local and general action. Locally, it irritates the mucus membranes of the eyes, nose and respiratory passages, and may even set up fatal pneumonia. Absorbed internally, it sets up headache, vertigo, gastric trouble, nausea, and affections of sight which may even result in blindness. Ocular troubles begin with more or less serious diminution of vision followed by amblyopia, dilatation of the pupils (which no longer react to light), difficulty of ocular movements and blindness. Amblyopia may last 20 to 40 hours, but it is characteristic that, in severe cases, the lost sight becomes normal again before completely disappearing (Natanson). It is a question of oedema and degeneration of the ganglion cells: parenchymatous or interstitial neuritis of the optic nerve.

Irritation of the conjunctiva with follicular hypertrophy occurs among polishers set up by evaporation of the methyl alcohol from the varnishes used. The number of cases of conjunctivitis has certainly increased (statistics of Haselbery, Walker, Overweg, etc.). This danger presents itself also in silk dye works where methyl alcohol is used as a solvent for aniline colours.

The skin (forearms and fingers) is affected by lesions which may become eczematous, involving incapacity for work (for 9 to 30 days as reported in a walking-stick factory in Germany in 1919).

The symptoms in cases of very severe general intoxication with fatal issue are: rapid and marked drop in temperature; rapid breathing, followed by retardation until stoppage occurs; acceleration and slowing of the heart’s action (irregularity, intermittency); gastric congestion with haemorrhagic diarrhoea; convulsions, paralysis, loss of the reflexes and of sensation, nystagmus, mydriasis, and visual hallucinations. These fatal cases have occurred notably among workmen who had worked in vats in extremely confined spaces and had breathed vapours arising from the evaporation of large varnished surfaces (breweries, copper refineries, etc.). Very severe cases have even been reported amongst hat finishers and polishers of wood.

Hygiene

Among the hygiene measures to be adopted, only the following most important ones are mentioned:

(a) In the processes of manufacture, every leak in the doors of the retorts and every escape in the piping should be repaired. The workrooms should be well ventilated. Non-condensed gas should not be burnt under the retorts but under the furnace. All fire and hot cinders in the heaps of dust and refuse from the hearths should be extinguished (fire and explosion risk). A good draught for the furnace gases should be maintained by utilising a conoe or a cowl (controlled by a valve) coming from the main stack, and separate from all the other pipes connected with the retorts. Safety valves may also be used in each pipe passing from the retorts to the outside air. Such precautions will prevent all danger to the persons working in proximity to the retorts. During cleaning operations, valves should be closed to prevent entrance of gas from neighbouring retorts. Mention should be made of the fact that at the moment the doors of the condensers have been opened before the coal has completely cooled, very severe accidents have occurred (from spontaneous combustion of gases). But if the coal is kept for 24 hours in the cold and then left for 48 hours under covered sheds, ‘prior to transport, practically all risk of fire on trucks or boats is avoided.

The acetate of lime should be removed without exposing the workmen to high temperatures (in summer 30-100° C.); clogs should be supplied because the temperature of the floor on which they have to stand may be high. Passage ways or platforms should be arranged if possible. It is preferable to erect the dryer near to the hearths and to lead the heat and concentrate it under the floor of the furnace before it reaches the outer air.

In the distilling plant the condensers should not allow any uncondensed gases to escape. If there is likelihood of any being present they must be led to the outer air. Vats should be provided with covers or be guarded by railings to prevent any chance of a workman falling in. All risk of fire from sparks flying from electric motors must be avoided. When anhydrous vapour is to be feared, sparking cage motors should be used, instead of
those worked on the monophase system. Escape of excess of vapour into the distillation room must be avoided at all costs. This danger is especially great in winter when all windows are closed.

Only electric light should be used—neither torches nor lanterns should be allowed—and the electric lights should be of the safety kind.

Artificial light is always necessary for cleaning and repair operations. The breaking of an electric light has often been the occasion of an explosion—the filament igniting the gases present. Kerosene lamps also have caused fires.

The distilling apparatus is usually freed from accumulations of tar once every two months. At these times, the workmen are liable to suffer from amblyopia. They should wear effective box respirators. The tar is generally collected in receptacles placed in the ground and these are often left uncovered, thus favouring evaporation and giving rise to loss as well as constituting a danger. These receptacles should be covered, allowing, at the same time, for good ventilation inside them, or they should, at any rate, be situated at some little distance. Barrels or drums are often filled automatically by means of India-rubber piping, but the vapour given off when the alcohol enters the receptacle diffuses into the workroom and constitutes a danger for workmen in the vicinity. The fumes should, therefore, be led outside.

(b) During use. The workman should be protected against the vapours of methyl alcohol by a well-arranged system of localised exhaust ventilation (e.g. in the dyeing of flowers, work to be effected under a hood provided with local exhaust) or by placing the articles to be dried in a separate well-ventilated room. Certain substances which are mixed with methyl alcohol to make varnishes or protective coats should be replaced by others, e.g. in the making of pencils: for the final coating, pyridine (4 per cent.) should be used instead of benzine. This process has given good results in American factories and has eliminated at the same time all injury attributable to methyl alcohol. In a German walking-stick factory, eczematous ulceration was probably set up by traces of carhoic acid and formaldehyde contained in the alcohol. In the same way, acetic and benzol are often present in some solvents used in the doping of aeroplane wings, manufacture of motor cars (e.g. “titane spirit,” used as a solvent for acetate of cellulose in the aeroplane industry in the Netherlands (1916) contained methyl alcohol, acetone and 40 per cent. benzol).

An arrangement between the Health Office of New York and the brewers in that city resulted in the suppression of the use of methyl alcohol for coating the interiors of vats. Nevertheless, masks and goggles are placed at the disposal of the workers. Limitation placed on the use of methyl alcohol is said not to be necessary: preventive measures suffice, and these, according to the experience of the New York Health Office, should be applied when the denatured alcohol contains more than 5 per cent. of methyl alcohol.

These measures are summed up as follows:

1) Ventilation should be installed for the removal of vapour in all workrooms where one part (in volume) of methyl alcohol is found per 10,000 volumes of air.

2) All receptacles serving to hold alcohol should bear a label “Methyl Alcohol—Poison!”, with skull and cross bones.

3) When methyl alcohol is handled directly by the workman, impermeable gloves should be supplied which should be maintained in good condition.

4) When it becomes necessary to go inside one of the receptacles, vats or distilling apparatus containing alcoholic vapour, the workman should be provided with an effective breathing respirator or with other means of protection allowing pure air to enter through the mask. All vats, barrels or receptacles of whatever kind containing methyl alcohol should be provided with hermetically closing lids.

5) When methyl alcohol is used in any industrial process whatever, a printed cautionary placard should be posted up in all workrooms calling attention to the danger. (This notice is to be drawn up by the State Department of Factory Administration and should be distributed free.)

6) A ledge or platform should be erected round every furnace for drying acetate of lime, arranged in such a manner that the workman can from time to time remove the superheated matter.

LEGISLATION

Ill-effects set up by methyl alcohol are compulsorily notifiable in the United States, in the States of Massachusetts, New Hampshire and Pennsylvania, and in the Netherlands. They come under the-
Workmen's Compensation Act in Finland and in the United States (Minnesota, New Jersey, New York, and Ohio).

Methyl Bromide
(Methyl Bromic Ether; and Monobromo Methane)

CHEMISTRY

Formula: CH₃Br. A halogen substitution product of the aliphatic series, of which the specific gravity is 1.732 at 0° C. and the boiling point about 45° C. A gas at ordinary temperature, it liquefies easily at 0° C. and appears then as a mobile liquid, colourless with a pleasant ethereal smell but not very penetrating; the smell of the commercial product is more penetrating because of the presence of impurities such as oxide of methyl or alkaline bromides. It is extremely volatile; mixed with air it can give rise to explosions.

PRODUCTION

It is obtained by heating (at about 190° C.) bromide of sodium or potassium with methyl alcohol and sulphuric acid. The hydrobromic acid given off combines with the alcohol to form methyl bromide. It can also be obtained by heating the carboxylic com-

pound As (CH₃)₂(CHOH)₂ Br, or by mixing methylic alcohol with bromide of potassium and distilling some days later.

USES

Its use is rather limited; it is used in the chemical industry in the preparation of methylic compounds; in colour manufacture in making colours from methylated tar, blue colours derived from aniline red and the greens from aniline violet; in the pharmaceutical industry especially in the preparation of antipyrin.

CAUSES OF POISONING

Cases of poisoning have arisen almost exclusively in the manufacture of antipyrin. Those persons are most exposed to risk who prepare the methyl bromide and rather less so those who methylate the pyrazolone. The process is carried out either in a closed room — naturally more dangerous — or in the open.

In the regular course of production and use there is not now any evidence of the toxicity of methyl bromide. Use of the compound, however, and of its derivatives always presents a latent danger. Although the measures adopted universally in industries using this product have limited the risk of poisoning, it should be borne in mind that the frequency of poisoning is in direct relation to the extraordinary volatility of the product. Careless or accidental overflow in the processes can allow of the rapid formation of large quantities of vapour in the receptacles and pipes and give rise to explosion or escape. Further, as a result of this great volatility considerable quantities of the vapour can make their way into the workrooms even if the apparatus leaks only slightly. Lastly, and for the same reason, escape of the product can enrich the atmosphere so rapidly with the vapour that in the case of accidents the workpeople have already inhaled appreciable quantities before realising the danger and making good their escape. The risk is all the greater because the workmen can readily become acclimatised to the smell of this product which, although penetrating, is often masked by the other numerous odours present in the workroom.

TOXIC ACTION

The minimum toxic dose for man has not yet been fixed. It seems,
however, to be very small as poisoning has resulted in a certain number of cases without the persons affected, or present in the same room, noticing the peculiar smell of the product. The bromine element is generally considered responsible for the effects set up. At the same time certain authorities regard as possible a rapid fixation of the bromide on the lipoids which would facilitate diffusion of the poison in the nerve cells.

The product is a poison of the nervous system (especially of the central nervous system) showing itself in loss of consciousness, paralysing action on both sensation and motion — an effect which does not stop even on removal from the poisonous atmosphere, but, on the contrary, increases in intensity.

The great richness of the nervous tissues in lipoids may explain the special affinity of bromide of methyl for the nervous system and its special localization there.

In general, examination of the organs for the poison whether of human victims or experimentally in animals (even immediately after death) is negative. Examination, however, has been positive when intoxication has been massive and (experimentally) if the animal was rapidly killed. Predisposition is very variable and very important. Persons of lymphatic type show little resistance and nervous persons still less.

**CHANNELS OF ENTRY**

Respiratory tract and perhaps the mucous membranes. Irritation of the exposed mucous membranes occurs as a local effect.

**STATISTICS**

These are not numerous; cases, however, are said to be more numerous than the actual number reported would indicate. The first three cases — doubtful — were described in 1899 by Schueller (Switzerland) with 1 death; 2 in 1901 by Jaquet (although they occurred in 1898); 2 in 1910 by Bing (Switzerland); 1 by Zangger (attributed mostly to the impurities — methyl alcohol) (Switzerland); 1 case by Marmetschke, 1911; 1 in 1913 by Strassmann; 2 in 1915 by Floret; 1 in 1918 by Steiger; 9 in 1917-18 by Goldschmidt and Kuhn with 3 deaths; 1 by Röhrer in 1920 (fatal); and one other fatal by Löffler and Röttermann (also fatal), 1 case by Mazel and Jeanneret in 1921 (the reference is to a worker who had been slightly "gassed" four times); 2 fatal cases in 1917 in Switzerland; another case by Cade and Mazel, and 2 cases by the same authors in 1923 due to the inhalation of fumes (for some minutes) while bromide of methyl was being distilled — altogether a total of 27 reported cases in literature, of which 5 must be held to be doubtful.

In general, all the above cases are attributable to accidents in the work or explosions in the receptacles being fairly rare), or to the escape of gas due to leakage in the pipes or apparatus. The two cases which occurred in 1915 were caused by work with an ethereal solution of methyl bromide.

**PATHOLOGY**

The slight, moderate or severe forms all present generally characteristic nervous symptoms, almost always affecting the central nervous system, and more rarely the peripheral. The short incubation period, in the more or less serious and sometimes very slight accidents, between onset and development is said to be more apparent than real. This period, which is said by some writers to be unaccompanied by any effect on health and by others by a certain apathy and listlessness at work, lasts from one to two hours or even from 16 to 48 hours. This latent period is said to be longer the more severe the poisoning, and the period of onset and development is characterised by symptoms of moderate severity.

Slight attacks are much the more frequent; generally, workers in these cases are obliged to stand off for some days because of illness from time to time: vertigo, visual troubles, defects of movement, and general weakness.

Even among the persons most exposed to the injurious action of the gas, however, chronic poisoning has not been observed. Only repeated attacks of acute poisoning occur and usually they are not at all severe.

In very severe poisoning, after illness of short duration, the patient has epileptiform seizures, loss of consciousness, respiratory difficulty and death follows as a consequence of pulmonary oedema.

The intoxication has been summed up in its three stages thus:

(a) Prodromal or onset: after some hours (see above) sudden illness, visual affection, diplopia, dilated pupils, drunken gait, vertigo, more rarely syncope, excitement, headache, vomiting (rare), slow pulse, symptoms of progressive paralysis of the central nervous system. This stage may last from three to six days.

No bromine compounds have ever been discovered in the nervous system nor methemoglobin in the blood, though Steiger is reported to have found these. Bile pigments have some times been detected in the urine.
METHYL CHLORIDE — 240 —

(b) After a period of remission, which may often be absent, the second stage begins: pale skin, normal or subnormal temperature, movement and sensation affected, tremor, tonic and clonic spasms, somnolence, loss of consciousness, coma or delirium, or attacks of acute mania, epileptiform seizures, polyneuritis especially of the lower limbs, aphasia, diplopia, etc. This stage may last several weeks.

(c) Recovery: in the majority of cases may be prolonged for several weeks or even months before it is complete. For years afterwards there may be nervous affections (hypochoondria, neurasthenia, traumatic neurosis, insanity).

PROGNOSIS

Prognosis is favourable in most cases of a slight order. It is advisable to avoid prognosis except after the patient has been under observation for a few days.

PROPHYLAXIS

All necessary and effective measures must be taken to prevent explosion, breakage or leakage from the receptacles or pipes containing the product. These are in time corroded by the methyl bromide and frequently perforated. All precautions recommended in the case of volatile compounds should be taken: as, e.g., for petroleum essence, ether, etc. (See these articles.) Locally applied exhaust to remove the fumes and gas in all workplaces where they can escape from the receptacles; in the event of breakage or a leak the apparatus should immediately be closed and the distillation stopped; the workers exposed should put on box respirators which should always be at hand. The origin of the escape should then be carefully investigated and the needed repairs attended to. All the reported accidents have, in fact, been due to lack of attention or necessary precaution on the part of the workman. Oxygen should always be available.

LEGISLATION

Legislation is enacted only in so far as applies to hydrocarbons generally.

Compulsory notification: Netherlands, Switzerland. Notification might naturally be regarded as included in the wide formula adopted in certain states of the United States of America. Compensation is granted in Switzerland and in those countries which have scheduled, for purposes of compensation, injuries due to toxic gases and fumes or in which occupational diseases are compensated as such. (See "Occupational Diseases: Definition and Compensation").

Methyl Chloride
(Monochloromethane)

French: Chlorure de Méthyle, Monochlorométhane. — German: Chlormethyl, Methylchlorid. Italian: Cloruro di Metile. — Spanish: Cloruro de Metilo.

CHEMICAL PROPERTIES

Methyl chloride (CH, Cl) is a colourless gas having a faint odour of ether and burning with a green flame. Its specific gravity is 0.952 (at 0° C.). It boils at 23.7° C. and its melting point is 103.6° C. It is slightly soluble in water, more soluble in alcohol and acetic acid.

PRODUCTION AND USES

It is obtained by the reaction of sulphuric acid and methyl alcohol on sodium chloride, or by the action of hydrochloric acid fumes with zinc chloride on methyl alcohol in an autoclave at about 100° C., or by treating trimethylamine derived from the evaporation residue of beet sugar molasses with hydrochloric acid and by distilling the hydrochloride at 300° C. There is then obtained a regular liberation of methyl chloride and of trimethylamine.

Methyl alcohol and other methylated amines are also given off. This latter method is chiefly followed in France. The distillation product is heated with hydrochloric acid and the methyl
chloride obtained therefrom is then purified, dried and compressed or put on the market in steel and brass cylinders with a resistance of 20 atmospheres and a capacity of 1.25 litres per kilogram of liquid. Methyl chloride is used in the chemical industry amongst other purposes for the preparation of chloroform, of tar colours, and in medicine as an anaesthetic. It is now increasingly used as a substitute for ammonia and sulphur dioxide in freezing apparatus.

Sources of Risk

In the above-mentioned processes, especially in the case of the manufacture of freezing apparatus, workers are exposed to the action of methyl chloride. During preparation of the product, however, the workers engaged in preparing it are also exposed to the action of methyl alcohol fumes, of the acids used, and even of the by-products liberated during the operation: nitrous gas, arsineulatid hydrogen, etc.

Toxic Action and Symptoms

Kobert states that methyl chloride has a toxicity as compared with that of chloroform of about one-quarter. Rambousek designates it as irritating and only slightly narcotic. Gerbis reported in 1914 two cases of poisoning affecting workers engaged in cleaning apparatus which had contained methyl chloride. The symptoms were as follows: in the first case slight facial paresis and extreme somnolence; the patient slept for twenty-four hours with three interruptions for meals and therapy. The patient in the second case complained earlier of frontal headache and sleepiness, and developed acute poisoning. He became very excited, ran about the factory and did everything in a wrong manner. On arrival at home he tore his clothes off, went to sleep and wakened next morning talking wildly. He then fell asleep again and slept for twenty-four hours. He said that after similar work he often experienced a sensation akin to drunkenness and could only recognise people quite close to him. He recovered after fourteen days.

Floret reports cases of long-continued delirium followed by cachexy and mental derangement. Diminution of vision is another symptom reported. O. Roth in 1923 reported two slight cases due probably to methyl chloride.

In 1926 F. Schwarz, Zurich, studied a case of poisoning affecting a worker engaged on the construction of a freezing apparatus, and undertook experimental research in relation thereto.

The most important contribution to literature on this subject, however, is that of H. M. Baker (1927), who had occasion to study 21 cases of indisposition and poisoning due to methyl chloride in an American factory making freezing machinery.

A worker in the factory had suffered from somnolence for which he blamed methyl chloride. He had to be shaken in order to get him to answer a question, could not take his meals, and had great difficulty in getting up in the morning. The enquiry revealed several cases of average severity amongst the workers in the factory, especially in the department for inspecting the apparatus, where the coils were filled with methyl chloride and compressed. During this operation chloride fumes penetrated into the workroom, for there was no exhaust device for ventilation. The gas was given off at the level of the worker's face; further, the gas being fairly heavy easily reached workers working near the ground.

The cases were less frequent in summer because all the doors and windows were open, but in the cold season, with no such outlets, the quantity of toxic fumes which contaminated the air was very high.

In order of frequency, the symptoms presented by the 21 patients were as follows: attacks of vertigo, drunken gait, feeling of lightness (the sensation of treading on air with the result that the worker lifts his foot higher than is necessary), somnolence to the point of interfering with work and taking of food, ptosis of the pupils, anorexia. Half of the victims were affected with nausea, loss of weight (1.5-4.5 kg.). Amongst 16 persons there was eye trouble, amounting in certain cases to diplopia (4 cases) due to temporary paralysis of the ciliary muscles; no lesion of the retina was found; dysphagia (3 cases).

When the symptoms diminished persistent insomnia (15 cases) set in, with trembling of the extremities (5 cases). In 18 cases the urine was alkaline. Examination of the blood was negative, similarly that of the cephalo-rachidian liquid in 5 severe cases.

Examination of the urine revealed the presence of formiates, the quantity of which corresponded with the severity of the poisoning. It diminished in proportion to attenuation of the symptoms. The evolution of the poisoning is very slow; in 7 cases recovery only took place after the lapse of from fourteen to twenty-one days.
Hygiene

All precautions should be taken to prevent liberation of toxic fumes in the atmosphere. Attention should be paid to ventilation, exhaust devices, etc. It is also advisable that all contact of the product with the skin and the mucous membrane should be avoided in view of the irritant and caustic action of methyl chloride on the skin.

Legislation

No special measures. Injuries due to methyl chloride are compensated in Switzerland.

Bibliography

SCHWARZ and ZANGER, in Zentralbl. für Gewerbheilk., 1926, Nos. 8-9.

Methylenchloride

Methylenchloride, CH₂Cl₂, is got by action of chlorine or methane on chloride or iodide of methyl, or more frequently by reducing chloroform with zinc and hydrochloric acid. It is a colourless liquid smelling of chloroform and burning with a green flame; specific gravity 1.35, boiling point 40-41° C., slightly soluble in water, and easily soluble in alcohol, ether and other organic products. It changes on exposure to light and air, and in order to preserve it 0.5-1 per cent. of alcohol must be added. This product is highly poisonous.

Mica

French: Micas. — German: Glimmer. — Italian and Spanish: Mica.

The designation "mica" has been given by mineralogists to various double silicates of alumina and alkaline metals (potassium, soda) or other bases (magnesium, iron, lithia), characterised by a facility for scaling off into very thin, flexible flakes, more or less elastic and unbreakable. Amongst the numerous types of mica, only those which furnish large transparent sheets are used. Muscovite, or white potassic mica, is found in crystals which do not readily lend themselves to industrial uses; flogopite is a magnesium mica; lepidolite is a silicate of alumina, potassium, lithia and fluor; biotite is a black mica, etc.

The colourless grey, bluish, yellowish or brownish sheets may be divided into very fine leaves (of the thickness of fractions of a millimetre). Mica is not attacked by acids, remains long unaltered by the action of atmospheric conditions, is heat resistant, even at high temperatures, and is a bad conductor of electricity.

The most important deposits are situated in India, Canada and the United States. In Europe, the deposit already known and worked is that in the valley of Antrona (Domodossola) in Italy, situated at a height of about 1,400 metres.

Italian mica is found in the form of large sheets piled one upon another and occurring in a gangue constituted almost exclusively of quartz and white felspar. The work of extraction is trying, for the gangue is hard, and care must be taken to avoid damaging the sheets, the commercial value of which is in accordance with their size.

On the other hand, extraction is easier elsewhere, and there may even be used tools in the form of a knife. In Italy, the blocks are often detached by means of gunpowder, but the use of explosives is to be avoided, with a view to guarding the product from damage. The work of cutting, which is very slow, enables blocks of 1-1 cubic metre, weighing 1,300-1,500 kg., to be obtained. The first sorting leads to the selection of sheets fit for utilisation; the remainder is cut into small blocks of 10-50 kg. Extraction is effected by experts, who obtain the sheets (the thickness of which is only a few millimetres) by means of wooden hammers and small scalpels with a very large blade. After sorting the blocks and the sheets, these are reduced to thin, supple layers, polished and classified in accordance with their dimensions, their colour, transparency, etc. The remainder is ground mechanically in order to extract the smaller fragments, which are used in the preparation of mica dust.

Mica is used principally as a substitute for glass, in cases where the latter would not be heat-resistant: windows, lamp shades, lamp glass, windows and doors in stoves; in the electrical industry for insulating purposes, for various furnishings and
parts of dynamos, motors, and electric apparatus and storage batteries. The smaller pieces serve as ornaments in the ironmongery trade for making fancy goods, safety eye-glasses, etc. The debris and mica dust are used in the pottery industry to give a gloss to certain kinds of pottery, in the manufacture of certain decorative papers, imparting to these a flaked effect, in the manufacture of luminous signs and postcards. In the chemical industry mica forms an ingredient of certain varnishes, enamels, special lubricants, and certain explosives. It is further used in the manufacture of paper and cloth employed for insulating purposes, and as wrappings (mica paper, mica cloth), etc. Finally, mica is used in the preparation of micanite, which is a substitute for mica as regards colour and transparency, and which is a substance offering the greatest resistance to electric currents. It is used for the manufacture of insulating plates for storage batteries.

Micanite is obtained by submitting to very high pressure thin sheets of mica attached to each other by small quantities of insulating cement and varnish. There are on the market, moreover, other similar secondary products.

The risks presented by the manipulation of mica are connected with the dust produced, which exercises an irritant mechanical action on the skin, the eyes, and the respiratory passages. Prosser White refers to cases of eczematous and ulcerative lesions occurring among workers making micanite, due either to mica dust or to the use of denatured alcohol and solvents (turpentine), colophane, etc.

Bialokos, of the Institute for Occupational Diseases at Leningrad, has examined 26 workers (24 of whom were women) engaged in the manipulation of mica. Their ages ranged from twenty to thirty, and the average duration of work was 7.4 years.

In conformity with the system followed in the Institute in the case of examination of small groups of workers, Bialokos effected simultaneously an investigation into conditions amongst workers making cardboard, with a view to acquiring a basis of comparison, the latter group offering analogies in regard to age and certain working conditions with the mica workers. The examination has revealed a high percentage for loss of hair (16 out of 24), which in the case of the workers making cardboard was only noted as affecting 5 workers.

Affections of the upper respiratory passages only occurred in 6 cases, and 3 women workers were found to be suffering from asthma. The figures for the female workers in the cardboard industry were respectively 13 and 9.

A similar investigation was carried out by Kogan-Jasny amongst 52 male workers, and revealed the fact that 78 per cent. suffered from sub-cutaneous troubles, which Bialokos, despite the most careful examination, had not observed. These sub-cutaneous formations, resembling glands, took the form of a necklace and were revealed on anatomo-pathological examination to consist of a fatty substance. Hence arose the designation "Oleoma silicatum". In the urine 0.08 per litre of bi-oxyde of silicon was found.

Kogan-Jasny's enquiry covered women workers in an electric apparatus factory who used micanite containing 40 per cent. of dixoide of silicon for the manufacture of insulators. 52 women and 2 men had worked with the micanite for five years and complained of fatigue, headache and vertigo; 38 suffered from loss of hair; 31 from a sensation of dryness in the mouth; 36 from coughing and dyspnoea and 28 from necrosis of the alimentary organs. Dust in the workroom was very abundant and the workers were covered with it. Medical examination revealed in 26 cases sclerosis of the apex of the lungs (13 of a specific type) and in 19 cases heart disease. All suffered from anaemia, which was serious in 8 cases. Digestive derangements were reported in the case of 23 workers and nervous troubles in the case of 34.

Kogan-Jasny believes that micanite traverses the skin to the sub-cutaneous tissue, where it causes necrosis. It also enters the respiratory and digestive passages, which it impregnates, giving rise to the general disease form designated by the author "silicosis universalis".

The hygiene measures to be adopted are of a general order: an anti-dust campaign against the effects of the toxic products employed in the course of the processes, either by generalised or localised systems of ventilation.

BIBLIOGRAPHY

Miners' (Coal Miners') Diseases

The underground seams of coal are buried in rock and are reached by means of vertical shafts and horizontal galleries which start from the shafts and are carefully lined with brickwork or timber to resist the pressure. Passages protected in the same manner connect the galleries with the coal face, where the actual getting of coal is carried out.

Hewing by hand is carried out by means of picks (when the ground is loose), mattocks, pointed bars, and wedges. At the present time these tools are often replaced by machinery driven by compressed air or electricity.

Drilling and mine work by which large masses of coal and rock can be got at the seams are only possible in mines which are not affected with fire damp. This applies also to the extraction of hard coal in thin seams. The explosives used consist of mine powder, dynamite or other explosive; they are fired either by a fuse or electricity. Explosions produced by liquid air are also very often used at present. A first rough sorting of the coal from the useless material takes place in the mine itself. In narrow seams the coal is first carried by hand by means of baskets (hoppers), then mechanically in metal conveyers, from which it falls into barrows which a workman pushes as far as a haulage road, where it is loaded into tubs drawn on rails by ponies.

On certain British coalfields coal from thin seams is loaded at the face on to small sledges, known as hods or putts, which are dragged by youths to branch roads where the contents of the sledges are transferred to tubs. The tubs are worked by hand on rails into the haulage roads where ponies draw them to the pit shaft. In thick seams the galleries are sufficiently large for the tubs to be drawn either by locomotives or by electric traction, or by cables or chains worked by a fixed motor situated either in the mine itself or outside. Often also the full tubs descend by an inclined plane (dillies).

Part of the shaft or a special shaft is reserved for bringing up to the surface the tubs of coal. In another part, or in as a third, called the cage, the cage, hung on a steel rope, which lowers the workmen to the bottom of the shaft or brings them up to the surface again. In Great Britain the same cage is used at certain times for coal tubs, at another for men.

In certain countries (Germany, for example) each mine must have two separate and independent exits having access to all parts of the mine.

At the surface there is a fresh and more careful sorting of the coal from such useless material as rocks and slaty coal. This is carried out either by washing or by screening.

The getting of coal takes place at different depths. As the seams are generally superimposed, the upper seam is worked first to establish the ventilating gallery. It is there that big ventilating fans are placed which blow fresh air into the mine and draw out vitiated air. Air is brought into transverse galleries by long tin ducts and directed to the various points where men are working, whilst a special apparatus draws out vitiated air. This aeration serves to dilute the dangerous gases in the circulating air (see further on) and also to temper the heat which steadily increases as one descends.

In mines not affected with fire damp, lighting is effected by naked candles, oil or acetylene lamps with naked flames, but now the galleries are often lighted by electricity. In mines affected with fire damp, safety lamps are used; these are fed with oil or spirit; the side air inlet and outlet holes of these are made of gauze of fine metal wire which always remains cool and so prevents the combustion of dangerous gas mixtures. Further, this lamp has the advantage of showing the peculiar appearance of the flame. (See article "Mines (Hygiene in").

Dangers

Stassen summarises as follows the causes of injury to health encountered in mining: (1) lack of sunlight; (2) deficiency in oxygen as a consequence of inadequate ventilation; (3) close atmosphere; (4) toxic atmosphere; (5) repeated chills due to sudden passage from hot working posts to relatively cold galleries in the absence of all precautions; (6) inhalation of dust.

The gases which may vitiate the air of the workings are fairly numerous.

Carbon monoxide (CO) causes death, and often fatal poisoning, especially after an explosion of mine gas or of coal dust. These poisonings are characterised not only by general symptoms of poisoning, but also by burns due to explosion or fire. It is to be noted that carbon monoxide is very often inodorous. The Bureau of Mines of the United States Department of the Interior reports a case where 0.20 to 0.30 per cent, of carbon monoxide sufficed to kill a canary, whilst persons who were present did not show any symptoms. But a strength of 0.6 mg. per litre of air has injurious effects. High temperature and great humidity also favour the absorption of carbon monoxide.

Methane (CH₄) is the principal constituent of fire damp, or the gas found in mines. Mixed with air and carbon monoxide it forms a formidable explosive combination. It is known that methane is set free especially in places
where there is decomposition of thick coal either by slow accumulation or by sudden massive release from pockets. It is sufficient for there to be 5 to 15 per cent. of this mixture in the air to give rise to danger of explosion. Safety lamps show a strength of 2 per cent.

The effects of explosions caused by naked lamps or by the firing of explosives are rendered more serious because naked lamps or by the firing of explosives are rendered more serious because coal dust which is found throughout mines is raised in the air by the fire damp explosion; it is then ignited and explodes in its turn.

Ethane (C₂H₆) and ethylene (C₂H₄) may also, though this is rare in normal conditions, vitiate the air of mines. They are found more readily after explosions or fires. In certain mines of New South Wales, Atkinson (1923) reported the presence of a mixture of various gases (carbon dioxide, carbon monoxide, methane, nitrogen, and hydrogen) which he calls bottom gas; it settles in the form of a sheet upon the ground, like a liquid. This heavy gas is however rapidly dispersed by ventilation currents.

The gases from combustion of fire damp consist of carbon dioxide (4.7 per cent.), carbon monoxide (0.5 to 1.5 per cent.), nitrogen (80 to 85 per cent.), oxygen (12 to 17 per cent.). The quantity of carbon monoxide is higher after an explosion when there is not sufficient oxygen at the site of the accident for complete combustion of the gaseous mixture. Theoretically the combustion of methane and air should not give rise, according to Lewin, to carbon monoxide which appears — as of course one understands — when coal dust is involved in the explosion. Hence in explosions in mines this gas is always present (from 0.01 to 1.5 per cent.).

The forms of delirium and the psychic disturbances that are met with in cases due to above causes are generally of short duration; they may nevertheless be repeated at short intervals.

Carbon dioxide (CO₂) in sufficient quantity exerts a harmful physiological action upon the system. Its presence is due not only to the air expired by the living creatures (men, animals), who live in the mine, but also to chemical changes which take place in the materials found in the ground and in the galleries.

While Hill reported in 1920 that a strength of three parts of CO₂ in 100 parts of air increases pulmonary ventilation by 100 per cent., that a strength of 5 per cent. increases it by 300 per cent., and that a strength of 10 per cent. cannot be borne more than one minute because it causes headache, sweating, troubles of vision and tremors, the U.S. Bureau of Mines (1923) is of opinion that the same percentages of CO₂ in oxygen is better tolerated and that a percentage of 7.2 parts of CO₂ in oxygen gives only an increase of 200 per cent. of the pulmonary ventilation, and that a percentage of from 9 to 10 only caused the above-mentioned troubles after ten minutes' inhalation.

While an increase of carbon dioxide in the surrounding air causes the symptoms described above, a reduction in the amount of oxygen causes vertigo and tachycardia, etc., as well.

Occasionally some pockets of sulphur-etched hydrogen may vitiate the air in the galleries. The miners easily recognise the presence of this gas, which may also be set free by the firing of explosives, by its smell resembling rotten eggs. When sulphur-etched hydrogen is mixed with seven times its volume of air, it forms a violently explosive mixture.

Nitrous gas may also be found with carbon monoxide in the air of mines after the use of such explosives as dynamite or roburite. The clinical picture noted amongst workers in tunnels in Italy (Taramelli, 1931) has been attributed to this mixture of gases. It consists in loss of consciousness, cutaneous anaesthesia, abolition of superficial and deep reflexes, phenomena of vasodilatation followed by peripheral vasconstriction, headache, etc.

Among the infections which may attack miners the most important certainly is ankylostomiasis (see that article). The first case reported in the German mines from the district of Dortmund dates from 1885; the infection spread to the district of Bonn and developed to such an extent that in 1902 there were 1,555 cases. Medical examination of all the underground workers showed 17,161 carriers of worms. At the commencement of 1909 the frequency of cases of ankylostomiasis had diminished by 95 per cent., and recently by 99.3 per cent., due to the energetic measures of prophylaxis adopted, including microscopical examination of faeces, isolation of infected miners, exclusion of infected miners from underground work, sterilisation of faeces containing eggs, and rapid removal of the excreta buckets.

Prophylactic measures, on the one hand, and conditions of habitat unfavourable for the eggs, on the other, easily explain the good healthy condition of certain districts.
According to the Belgian press, an epidemic of ankylostomiasis and amoebic dysentery (which is, however, disputed) was introduced (1924) into certain mining districts by labourers from China, Annam, and North Africa. Thirty cases, 7 of which were fatal, have been recorded on the Nord coal-fields in France.

This infection has also been reported in certain mines of Arizona (U.S.A.), in the Belgian mines in 1920-1921 some cases of infection by 

The symptoms are those of acute inflammation of the skin and of subcutaneous tissue: heat, redness, swelling, and pain. At first the skin is unbroken, but pits easily. Generally suppuration occurs with or without involvement of the adjoining bursae or tendon sheaths. In the case of the knee and elbow, the course of the disease is usually benign and without sequelae; in six weeks, or even less, recovery of functions may be expected. In the case of the hand, on the contrary, the infection may involve the tendon sheaths and cause very serious maiming as a sequela. Some fatal cases have been reported, due generally to septicemia; one case of the knee and one of the elbow; no fatal case is known for the hand, but it is probable some have occurred.

These conditions are very important on account of the very heavy legal compensation imposed upon employers, and also on account of the suffering and incapacity for work which they cause.

With regard to frequency the lesion of the knee has for some years taken second place, coming next after miners’ nystagmus, in the list of compensated diseases, and that of the hand the third place. Lesions of the elbow and synovitis of the wrist are certainly less frequent than the foregoing, but still are as numerous as cases of lead poisoning and more so than industrial anthrax.

It is to be remarked that the conditions are not diminishing, which
shows that preventive measures have not been taken or are without result.

The total of all cases compensated under the British law were as follows:

From the point of view of compensation, it is also interesting to note the number of cases which are receiving compensation continued from the preceding year: in 1919 there were 144 cases; in 1920, 125 cases; in 1921, 135 cases; in 1922, 185 cases; in 1924, 294 cases; in 1925, 240; in 1926, 290; in 1927, 427; in 1928, 318; and in 1929, 357.

Comparison with nystagmus is here of interest; in 1921 there were 1,913 new cases and 4,054 continued cases. The much smaller proportion of continued cases of cellulitis indicates the much more rapid restoration of working capacity.

The new cases reported per thousand persons employed underground were as follows:

<table>

In Belgium, according to Stassen, among 30,000 workmen (of whom about 27,000 were employed underground) there were on an average 50 to 60 cases of cellulitis and bursitis of the knee, 40 cases of cellulitis and bursitis of the elbow, and 25 cases of cellulitis of the hand. The proportion per 1,000 persons employed is given as 2.04 for the knee, 0.92 for the hand, and 1.11 for the elbow, figures which are higher than those for Great Britain where for all mines the figures are: 1.19 for the knee, 0.87 for the hand, and 0.13 for the elbow.

The dusty work, assisted by humid heat and continuous friction causes an intertrigo upon the external part of the forearm and the internal part of the thigh. The scars are almost always of a blue-black colour, for the miners have a habit of touching all the lesions of the skin with their hands soiled with coal dust.

Upon any part of the body one may observe a form of eczema (water itch) which resembles smallpox and is situated on the hands, face, neck, limbs, and feet.

This condition is caused by dirty water which runs down from the roof and sides of the mine. In America there was in 1912 a real epidemic which Whishart attributed to sulphur dioxide and sulphuretted hydrogen dissolved in the water. The condition has often been confounded with true itch. Some eczematous conditions, often very serious, situated especially on the arms and limbs, are due to the larva of ankylostomiasis (see that article).

A dermatitis reported by Mackenzie (1898) was due to handling wood treated with creosote, which also caused quite serious conjunctivitis.

Amongst the miners of Morro-Velho, New Lima, Brazil, forms of dermatitis due to arsenical compounds contained in the ores worked have been noted, as well as attacks of urticaria from handling of certain woods for making pit props (Schinus terebinthifolius, Astronium commum, Bowdichia nitida, etc.).

The skin affections noticed by Cave-naille among the underground men at the colliery of North Fléni at Ghlin-Mons, are arranged as follows in order of frequency: boils, due to lack of cleanliness and profuse sweating, which among certain men appear after three to four weeks underground, whilst other miners remain immune for years and then show suddenly a crop of boils without apparent cause; sudamina; intertrigo, chiefly between the fingers; prurigo; and pimples, due to the peculiarly irritating action of the underground water or ground.

Massar (of Rocour) has also drawn attention to the blind boil of miners which is favoured by the general bad state of health of the individual, over-worked, badly nourished, and dirty. It is situated by preference on the anterior surface of the limb, below the
prepatellar bursa, but is found also on
the external border of the forearm, below the elbow, and sometimes at the
wrist, that is to say, always on parts
exposed to blows more or less violent.
The prognosis is as a rule good; the
blind boil healing in some days. It is
generally single and there is no infec-
tion of the surrounding part. The
treatment is very simple and of a sur-
gical nature.
Coal dust which settles upon the skin
blocks the sudoriferous glands and also
causes furunculosis. If the dust is
deposited in the auditory meatus it
causes eventually an eczematous
eruption.

Resulting from the had habit which
miners and workmen have of wiping
their hands with the back of the
hand, Fabry has reported among 255
miners, in a period of twenty years,
a form of cutaneous tuberculosis
situated on the back of the hands and
fingers. It had been caused by inocu-
lization from tuberculous expectoration
on the upper part of the skin; the thin
skin of the hands. However, recent
observations (1929) point to the conclu-
sion that such cases are becoming rarer.
The reduction is said to be attributed
to improved hygienic conditions and
the more expansive applications of
mechanical apparatus in the mines
(Fabry).
The prolonged stay in places where
daylight does not penetrate causes a
loss of colour from the skin and a
certain degree of anaemia which is
also favoured by vitiated, stagnant air,
excessive heat, a high degree of humi-
dity and perhaps by the poisonous
action of certain explosives (case of
Ebright, 1914).

Nevertheless the blood formula is, as
a rule, normal. The work of the miner
is especially injurious when it
is carried out in low galleries, at great
depth, where the temperature is high.
A miner employed in a very narrow
space must work with his pick, or
drill shot holes, in a crouched position,
or even lying down, as well as having
to shift, at the cost of great muscular
efforts, the extracted coal through
narrow passages over rough ground.

Freise (1930) has reported the occur-
rence amongst deep-level miners in
Brazil of troubles similar to those
affecting caisson workers: singing in
the ears, accelerated and then retarded
respiration, troubles which disappear
after one to two hours at work, but
which in a case of undernourished
individuals, leave sensations of pain in
the limbs. Where workers remain for
long (several weeks) at work under the
above conditions they become subject
to nutritional derangement, loss of
weight, anaemia, etc.

Mr. Moss calculated the energy used
by English miners by measuring the
consumption of oxygen and muscular
force.

According to his researches the air
inspired in one minute for loaders of
slack with hand shovels and rakes
is 36.2 litres; for hewers of solid coal
working with picks, 35.3 litres; whereas
at rest the consumption fell to 16.3 litres.

Average figures for muscular force
of the body, expressed in ft. lb./min.,
are given for loaders of slack as 4,000,
for hewers of coal in the floor, 2,500;
and for cutting and erecting timber,
3,000.

These figures show at once which
are the groups of workers most
exposed to fatigue and its consequences.

The effort thrown on the respiratory
apparatus necessitates breathing deeper
and more often and predisposes to the
loss of plasticity of the lung tissue.
The inhalation of coal and mineral
dust prepares the ground for and
favours the development of this lesion,
which develops at first at the lower
parts of the respiratory apparatus and
may next become general and attack
the upper parts, when the workman is
obliged to make forced expirations
after closing the glottis (especially
efforts in attacks of coughing). The
inhalation of vitiated air, the fatigue
occasioned by mounting ladders or
stairs to leave the mine, etc., are
factors which play a certain part in
the causation of emphysema and the
fatigue of the respiratory apparatus.

Nevertheless it may be said, even in
the absence of precise statistical facts,
that the frequency of pulmonary
emphysema has diminished among
miners, for their occupation, which is
becoming more and more mechanical,
calls much less for working in
awkward and painful positions.
Besides, advance in the technique of
ventilation and the suppression of dust
has contributed to diminish the fre-
quency of respiratory diseases.

The measures to be taken against
dust in mines during drilling operations
and hewing are dealt with in the
article "Mines (Hygiene in)".

The physical and chemical properties
of dust found in the air of the galleries
determine the pathological conditions
of the respiratory apparatus of miners.

But even with the best arrangements
it is clearly impossible for the worker
to avoid all exposure to dust. The
miner is certain to inhale during
work quite a large amount of dust;
hence anthracosis is still looked upon
as an industrial disease among miners. (See articles "Dusts, Fumes and Smoke" and "Tuberculosis — Silicosis").

In 1815 in England Pearson submitted a report to the Royal Society on the presence of coal in the lungs of miners. This matter was taken up later by Gregory and Christesin (1831). These three experts also drew attention to the frequency of tuberculosis among miners. Laennec attributed the expectoration. In part, however, they attain even the furthest ramifications of the respiratory tree.

If the miner is attacked, as is often the case, with acute or chronic catarrh of the respiratory passages, the mucous membrane comes no longer to possess the defence of the vibratile cilia, and the dust then is deposited in the tissue which becomes of a black colour. The abuse of alcoholic drinks weakens or arrests this defensive action of the cilia,

black colour of the lungs to the smoke of lamps; but Behier in 1837, and Billier in 1838, attributed the condition to particles of coal. Further, in 1827 Gobert of Hainault, and Kuborn, of Liège, recognised miners' asthma with its characteristic black expectoration.

Particles of coal which are inhaled are partly retained in the upper respiratory passages, and are evacuated either when blowing the nose or with which leaves the way open for dust. The miner is obliged, after many years of hard work in an atmosphere charged with dust, to breathe more and more deeply, strongly and rapidly. The dust, having reached as far as the furthest ramifications of the respiratory tree (alveoli), passes through the walls of the alveoli into the interstitial tissue where it is found in large quantity in the vicinity of the blood
vessels. Whilst a portion is confined to this area and causes cellular proliferation, leading to the formation of young connective tissue which contracts, another portion is carried into the lymphatic vessels and passes to be deposited all around the hilum of the lungs and penetrates into the peribronchial connective tissue and more especially into the multiple glands of the hilum and into the bronchial glands.

In anthracosis of old standing it is found that the lungs show on their exterior and on section a more or less blackish appearance in proportion to the quantity of coal dust in the tissues, and similarly have a consistence more or less hard.

A good description of anthracosis, or anthracotic pulmonary fibrosis, has been given by Courtois (1930), who refers to areas of sclerosis accompanied by compensatory areas of emphysema and to the following radiological symptoms: nodular opacities and by compensatory areas of emphysema refers to areas of sclerosis accompanied by marked emphysema or less hard.

...the more irritating the dust, that is to say, the more sharp particles it contains, resulting from hewing coal and crushing rocks, etc., the more numerous are the lesions of the pulmonary tissue. In the latter case the lungs are very black and have the appearance of leather; they contain little air and show in places points of calcification. These cicatricial modifications cause dilatations of the bronchial tubes. According to Patschkowski (1924), anthracosis among miners of the Rhine district and Westphalia allows only very guarded prognosis when it is associated with tuberculosis and chalicosis.

In slight cases of anthracosis where the objective and subjective symptoms are slow to appear, the capacity for work by the miner is not diminished.

This disease shows itself generally after a period of work of ten years, rarely before, more frequently among the hewers than among other underground workers. Workmen employed in drilling rocks which are found with the coal seams are more often affected than the coal hewers.

Boehme, who has studied (1925) pneumoconiosis in miners of the Ruhr district, insists particularly upon the difficulty of diagnosis—which may nevertheless be facilitated by radiological examination, even when the lesions of the respiratory apparatus have not caused subjective troubles in the miner. Out of 1,500 workmen examined, he found that the hewers and drillers were the most frequently affected. As among these 1,500 workmen young men were the most numerous, he was only able to find 81 cases of pulmonary fibrosis from inhalation of dust, of which half were incapable of work.

Radiological examination of 71 coal hewers who had worked more than ten years showed, in 23 cases (32 per cent.), a fibrosis of a slight degree and pneumoconiosis only in three cases (4 per cent.).

Among 49 stone cutters with more than ten years' work he found by radiological examination 33 cases (67 per cent.) of fibrosis, of which 29 (that is to say, 59 per cent.) were fairly serious.

It certainly is not possible to draw general conclusions, but it may be said that these two classes of miners are the most seriously affected by pneumoconiosis.

Post-mortem examination of 16 serious cases has shown in the lungs 27 per cent. of dry residue, 4.2 per cent. of ash, 5.4 of coal, and 2.3 of silica, whilst the normal lung contains an average 17 per cent. of dry residue, 0.7 of ash, and traces of smoke and silica. Pneumoconiosis existed when the lung tissue contained 2 per cent. of ash, 0.7 and upwards of silica, 1.6 and upwards of coal.

An autopsy on 240 miners from the Ruhr, who had been exposed to dust, enabled Hustedt (1931) to observe 177 cases of definite silicosis of nodular type and 35 cases without nodular formation. The majority of the deceased workers ranged in age from fifty to fifty-five years though 30 were over fifty-five. A very serious case was that of a worker aged thirty-seven. Of the 173 serious cases, 120 had at the same time active tuberculosis. Death occurred in 76 per cent. of the serious cases as a result of cardiac failure; in 9 of pulmonary tuberculosis, and in 14 of pneumonia. The duration of working experience had been from three to thirty-five years in cases of serious types of disease; very short (three to four years) for forms of silicosis and tuberculosis. On an average the working life of the miners was found to be between twenty-two and twenty-five years. An effort to determine how long a worker attacked by a serious
form of silicosis may live after appearance of grave symptoms (dysphoea cardiac insufficiency) gave the following results: of 170 cases, 9 died before reaching the delay requisite for compensation, 31 during the first year; only 35 were still living at the end of four years, and 3 at the end of six years.

Legislation in Western Australia provides for detection of cases of pulmonary tuberculosis, the granting of compensation to victims, and isolation of those affected. The first medical examination instituted (1925-1926) showed 3,257 out of 4,067 miners (80.1 per cent.) to be free from respiratory disease of occupational origin. Of those affected by this disease, 655 (16.1 per cent.) suffered simply from silicosis in an early or advanced stage; 143 (3.5 per cent.) from silicosis with tuberculosis, and 12 (0.3 per cent.) from tuberculosis without silicosis. The workers belonging to the last two groups were removed from the industry. Of the 3,912, 1,131 (28.7 per cent.) suffered from silicosis with tuberculosis and 3 (0.07 per cent.) pulmonary tuberculosis. Of 451 miners suffering from silicosis in 1926, 86 (17.5 per cent.) had now developed tuberculosis complications.

In Tasmania the medical examination covered 60 per cent. of the miners; amongst 455 engaged at the bottom of the mine 27 (5.9 per cent.) suffered from simple silicosis; 14 (3.1 per cent.) from silicosis with tuberculosis; and 5 (1.1 per cent.) tuberculosis. In another mine, amongst the workers who had worked from eleven to fifteen years, 22 (2 per cent.) suffered from silicosis.

Seltmann reported, in 1866, concerning inflammation of the lungs among miners—a disease fairly common in England and rare in Germany—the formation of cavities and necrotic changes of certain parts of the lungs, without any participation of the tubercle bacillus. The condition is found today very rarely among German miners, but is, on the other hand, now generally attributed to infections and chiefly to tuberculosis. A remarkable frequency of bronchitis and asthma, very probably connected with the amount of silica in the rocks which are found with the coal, has been noted especially in Great Britain (Lancashire). Fifty years ago asthma was very common among miners, but hygienic measures, chiefly improved ventilation, have ameliorated the conditions of work in the mines and reduced in a remarkable manner this special form of sickness.

Courtois has likewise drawn attention to cases of anthracotic fibrosis complicated with tuberculosis occurring specially amongst coalminers between forty and sixty years of age and following a typical clinical evolution: the tuberculosis usually of a serious type commencing generally with a form of caseous pneumonia.

The death rate from bronchitis and pneumonia is important; in Great Britain, for example, they exceed the average on certain coalfields, but not on all. Deaths from pneumonia are sometimes partly a sequel of carbon monoxide poisoning, and partly due to affections of the heart, the blood vessels, and the respiratory passages.

Pneumonia is also frequent among miners in the United States and in certain districts of South Africa, who are often exposed to the action of nitrous fumes with their capacity to set up pulmonary complications.

These serious cases and very serious pulmonary affections among miners are not as frequent as formerly, and this is due in part to good medical supervision of the working classes.

The sickness and death rate of miners from tuberculosis has always been lower than that of other trades. As a matter of fact, in the English statistics they are almost at the head of the list of occupations least affected by tuberculosis. According to statistics of deaths for 1890-1892, 1900-1902, and 1910-1912, for all forms of tuberculosis, miners come immediately after the agricultural class.

The death rate of miners from tuberculosis—according to Collis—was 1, whilst for all other males, aged 15 years and upwards, in England and Wales it was 2.1.

Certain English experts are of opinion that inhaled coal dust exercises an antiseptic action on the tubercle bacillus, and Haldane has even found that animals exposed to the inhalation of coal dust and then placed in the open air, did not show any particles of coal in the alveoli of the lungs. On the other hand, when these animals were exposed to silica dust, it was found that the particles became fixed upon the alveolar epithelium and are removed very slowly by the phagocytes. It will be interesting, therefore, to study what are the substances contained in coal which excite phagocytosis. It is to the variety of the rocks which accompany the seams of coal in the different English mining districts that must be attributed the various degrees
of reported sickness and death rates from tuberculosis. Statistics for 1910-1912 give the following comparative figures:

<table>

It is not necessary to insist on the influence of other factors which regulate the frequency of tuberculosis (see that article). But attention must be specifically directed to the factor of housing, for the conditions of life of the miners are very different from those of most other workers. The miners live in isolated villages or in valleys where it is usually difficult to build a good house. The son almost always follows the father at the colliery and hereditary influence certainly plays an important part in his life. The strenuous work, the cramped position while at work, the surrounding temperature, and the air currents are factors which must be taken into account.

Research effected by Allen (1929) in regard to reaction to tuberculosis amongst native workers occupied in a South African mine, showed rapid increase in positive reaction during the first six months at work. These reactions continued for a period somewhat beyond one year, but fell below the average at the end of a period of about ten years.

In Germany a recent enquiry into the frequency of diseases and especially of tuberculosis among miners in the district of the Ruhr has given the following very interesting results:

### DEATH RATE AMONG THE MEMBERS OF THE MINERS’ TRADE ASSOCIATION OF BOCHUM

This enquiry has brought out the fact that the death rate from tuberculosis among miners of the Ruhr district was lower than that of all other trades, and likewise of the dusty trades. According to Bochime tuberculosis among those affected with pneumoconiosis usually follows a very slow development, rapid development being very rare. Among 81 miners with fibrosis of the lungs he found only 15 (19 per cent.) with serious tuberculosis; and of these 13 were stone cutters and only two coal hewers.

The very small amount of tuberculosis among miners can perhaps be explained in the following ways: only robust men adopt the occupation of miner, for they know that the work is very strenuous. Further, a medical examination on commencing work, elimination of weak men, but slight danger of injury from exposure to infected dust or exhaled spray, early going on the sick list, and the comparatively small danger arising from coal dust explain fairly well the reported figures. The serious increase of the death rate during the war was only apparent, for most of the strong miners...
were no longer at the mines and the manual labour was done by men sent back from active military service and by foreigners, especially Russians. Since then the death rate from tuberculosis has been below that reported during the war, although it is not as low as the pre-war figures, because the men are still weak and the new organisation (seven-hour day) requires a large number of men who are not carefully selected.

It is necessary to be very careful before drawing conclusions from available statistics, for many different factors come into play. Thus, for example, the members of the insurance society of Bochum are chiefly drawn from an urban population, whilst those of Saarbruck and Tarnowitz are drawn from a rural population. Further, the conditions of work are different for the three districts in question, the work being harder in the west than in the east. The insurance societies of Bochum and Tarnowitz both include workmen in metalliferous mines, and the latter also includes workmen at metal furnaces. In the first case, only about 1.9 per cent. of members are not coal miners, in the second case 10.5 per cent. By way of contrast, in the insurance society of Saarbruck all the members are coal miners. Some women members appear in the three societies; their number was, in 1909, 0.9 per cent. in the Saar, 2.3 per cent. in Westphalia, and 9.5 per cent. in Upper Silesia. It is then impossible to obtain a uniform picture of the diseases of German coal miners. Similarly reservations must be made when comparing these figures with those of other trade groups.

According to statistics, the highest frequency of sickness is met in the Bochum district, where the scarcity of manual labourers is very considerable, so much so that it is necessary to employ workmen who are not trained, and that greatly increases the death rate. In Upper Silesia the number of notifications of diseases much increased since 1919, the year when compulsory hospital treatment was abolished.

Detailed statistics given by Heymann and Freundenberg (Essen, 1925) for the mining district of the Ruhr show that pneumonia is the disease which is the most frequent cause of death. This disease attacks especially workmen in the course of their first years of work. The death rate with them is higher than in the general population and its frequency increases with age more definitely than for the general population. Pleurisy is rarer and runs a more favourable course than pneumonia. The exact rates for bronchitis are not given, as its diagnosis is too often subjective. Fatal cases are, however, rare with adults. As regards influenza, the sickness rate is equal to that of the general population; it is particularly low for hewers.

In Great Britain a study by Collis of the mortality of miners aged from 25 to 64 years and covering the period 1910 to 1912 gives the following comparative figures:

<table>
<thead>
<tr>
<th>Class</th>
<th>All causes</th>
<th>Tuberculosis</th>
<th>Pneumonia</th>
<th>Bronchitis</th>
<th>Accidents</th>
</tr>
</thead>
<tbody>
<tr>
<td>All coalfields</td>
<td>514</td>

<td>66</td>
<td>38</td>
<td>47</td>
</tr>
</tbody>
</table>

There is a marked difference between the death rate of miners employed on the various coalfields, even when the conditions and environment of work, the hours of work, etc., are almost identical. The mortality is high on all fields for accidents, and on most for
pneumonia and bronchitis. The mortality for tuberculosis, although quite different on the different fields, is comparatively low on all. The average age for deaths from tuberculosis is 37-38 years for hewers, and 30-31 for other underground workers, and 31 for those working on the surface. The hewers suffer from tuberculosis chiefly when they have worked a long period and always in a higher proportion than the other classes of miners. The death rate from pneumonia shows high figures in certain districts particularly among hewers; it is associated with high rates for bronchitis, and comparatively high rates for tuberculosis. Accidents are very frequent on all the coalfields and especially on the fields where the death rates from disease is highest.

The following figures may be quoted:

(a) DEATHS AMONG MINERS, INCLUDING THOSE RETIRED, ARRANGED BY AGE GROUPS AND BY OCCUPATION (PERIOD 1910-1912), AND (b) MEAN ANNUAL DEATH RATE PER 1,000 LIVING

In collieries where the galleries have a height of from 8 to 10 metres and allow miners free movements, the transport of coal from the face is carried out by means of tubs. In these cases signs of exhaustion are seldom seen among the workers.

The conditions of work dealt with above and the fatigue of the respiratory apparatus both cause exhaustion of the circulatory system, and, in the first place, of its central organ, the heart. Thus is set up a state of unbalanced equilibrium between the capacity of the organ and the work to be done, which shows itself by dilatation and hypertrophy of the heart. If the exhaustion continues too long, and if other personal conditions are added, such, for example, as alcoholism, it is not uncommon to find myocardial degeneration.

Amongst miners in deep level mines in Brazil, Freise found (1930) cases of paroxysmic tachycardia amongst newly engaged workers during the first days at work, some minutes, or at times some hours, after the commencement of work. This tachycardia was followed by arrhythmia, stronger heart beats, and general weakness. Whilst these symptoms disappeared in a few hours amongst Negro and half-caste workers, white workers suffer from the attacks for a period of several months. There was likewise noticed acute cardiac weakness resulting from physical strain.

E. and A. Dickson, impressed by the very high incidence of arteriosclerosis amongst young miners, carried out in 1929 a systematic examination of 500 workers and found arteriosclerosis in 85 per cent. of the young miners aged twenty and under. The arteriosclerosis in question was of a special histological type, and was never accompanied by high blood pressure or by subjective symptoms. These authors attribute this occupational arteriosclerosis to the time spent in the mine galleries, as the proportion of cases increased with the number of years spent at the coal face. Others consider that it is connected with the use of alcohol and tobacco rather than with fatiguing work—a cause which takes a second place.

Marked thickening of the superficial and visible arteries, especially of the upper limbs, should not be confounded with arteriosclerosis, which, according to these experts, cannot be regarded as an industrial disease of miners.
The temperature rises as one descends in a mine. In certain cases it may reach 30° C. and more (for example, 38.8° C. on the Lancashire coalfields, Great Britain). Further, the activity of the men and animals, the machinery and lighting, all increase the temperature and vitiate the air, whilst the degree of humidity frequently reaches the limit of saturation corresponding to the temperature. Remaining in these conditions becomes intolerable. Sweat, which is profuse, cannot evaporate; the heat regulating function becomes defective and symptoms similar to those of heatstroke occur. (See article “Air: Hot and Humid Atmospheres”.)

The enquiry of the British Government Commission, 1922, upon the conditions of temperature in hot and deep mines, extending over a period of three years, showed that the daily quantity of sweat of a miner increased considerably with a temperature above 21° C. With an average temperature of 37° C. the average quantity of water consumed daily by miners at Pendleton was 12 pints. On the contrary, in the coal mines of South Wales, where a temperature of 12.7° C. prevails, the small quantity of water consumed amounted to an average of 2.7 pints each day for each miner. The average quantity of sodium chloride consumed increases equally with the temperature: Pendleton, 16.9 grm.; South Wales, 12.8 grm.

In the warm mines of Pendleton, where the thermometer marks 36.6° to 38° C. and the hygrometer 28.3° to 30.5° C., serious attacks of muscular cramp, followed by profound exhaustion, have been reported, especially among miners of poor physique.

These cramps occur in the muscles which are the most fatigued (arms, legs, etc.), and are attributed to the high temperature, to work which is too strenuous, to an excessive consumption of water, and, according to Haldane, to the considerable elimination of salt by the sweat.

As a matter of fact, the miner does not wait to be attacked by cramp, and more often stops work as soon as he feels giddiness or headache. The
administration of sodium chloride, or of a mixture of 60 per cent. of sodium chloride and 40 per cent. potassium chloride with a little tartar, is a preventive (about 2 grm. per litre for a dose).

Freise (1930), who studied the pathology of miners engaged in the deep level mines of Brazil (Morro-Velho, New Lima), does not indicate the proportion existing between the total number of cases of sickness and the total number of workers involved. He gives the following percentages for various disease forms: respiratory affections, 30 per cent.; heart affections, 20 per cent.; digestive derangements, 19 per cent.; skin diseases, 14 per cent.; rheumatism, 9 per cent.; eye diseases, 4 per cent.; various affections of the ear, nose and throat, etc., 2 per cent.; amongst the diseases of the respiratory apparatus he distinguishes: active pulmonary hyperaemia, 56 per cent.; acute alveolar dilatation, 27 per cent.; chronic alveolar dilatation, 10 per cent.; hyperaemia due to stasis, 3 per cent.; other pulmonary affections, 4 per cent.

Miners easily become accustomed to high temperatures, although under certain conditions they may be threatened with failure of the heat-regulating function. Refreshing ventilation in mines is therefore necessary.

In the German mines, which are much less warm, attacks of spasmodic cramp are not known, and they can be easily avoided by reducing the day's work to 6 hours as a maximum when at the coal face and in places reserved for machinery where a temperature of 29° C. and more prevails (Germany: Mines Act, 1905; Police Regulations of the Westphalian mines).

Loss of fluid due to profuse sweating gives rise to dryness of the mouth and pharynx, and compels the miner to drink great quantities of water to quench his intense thirst, which often causes catarrh of the stomach and intestines. Strict rules must be enforced for ensuring a system of watertight pipes to convey drinking water into the workings, furnished with numerous taps, and for protecting the principal reservoir against impurities and infectious germs. Legislatures have even laid down regulations requiring that the water used for baths and for damping to prevent coal dust should be free of any risk to the health of the miners. In order to prevent miners drinking slop water, as is still done, care must be taken only to use closed conduits. The contamination of the

---

FIG. 36. — The coal face of a mine in Upper Silesia.
whole of a mine by the germ of typhoid fever may, in certain circumstances, be due to cases among a single gang of men, or to the presence of germ carriers. Sudden cooling of the heated body by draughts, work in a cramped position, or lying on the cold ground, and the fact that the miner is drenched with sweat, often induce manifestations of muscular rheumatism. The miners then complain of local pains, twitchings and fatigue of the muscles. Cases of lumbago and sciatica are also very frequent. On the other hand, acute articular rheumatism is an infectious disease which has nothing to do with the miners' occupation. According to the statistics already quoted of Heymann and Freudenberg concerning the Ruhr, the death rate from circulatory diseases (including those of the urinary passages) is the same as that of the general population for the first years of work only; later it is lower. Diseases of the urinary passages cause death among miners in the age of twenty, with a frequency perhaps a little higher than among other groups of the population; but this frequency is lower among the older workmen.

Diseases of the digestive organs (7.3 per cent.) are no more numerous than those of the organs of respiration. They are due, at least in part, to the pressure and vibration which the compressed air tools exercise upon the stomach and liver, and to the ingestion of dust, etc. According to Lindemann, the same peculiarity is noticed as regards the death rate, that is, if infectious diseases are excluded. Cancer is not rare among miners; however, the English statistics of deaths according to occupation show for the miners' group, and for 100 years of life, a rate for any age which is certainly one of the lowest.

The digestive troubles may be explained by the climatic conditions of mining, especially when the men have not yet got accustomed to them. An explanation may also be sought in the psychological habit of declaring subjective troubles when medically examined (Heymann and Freudenberg). As to muscular rheumatism, the figures of different German insurance societies show great variations and suggest a suspicion of differences in diagnosis. The average figures available do not correspond with the true distribution of the disease.

The rates given by the local health insurance office of Leipzig are as follows: digestive system, 6 per cent.; respiratory system, 5.6 per cent.; rheumatism, 3.3 per cent. But all these figures should not be considered as exact, for 'internal diseases of occupational origin affecting miners are not yet well known.

The acute form of articular rheumatism is generally a more frequent cause of sickness than with other classes of the population. Heymann and Freudenberg are led to enquire why this cause is operative chiefly in the first years of work. In their view, it is explained by a greater incidence of diseases caused by cold and an insufficient acclimatisation to atmospheric and other conditions underground. In its turn, this frequency of rheumatism explains the very high mortality among the young men due to diseases of the heart and kidneys. (For lesions of the locomotor system, see article "Occupational Diseases: Locomotor System").

Generally, the experts, in noting an extremely slight mortality from chronic alcoholism, confess that this is an unexpected result. It should be borne in mind, however, that the alcoholic miner is not welcomed in a mine, for he is a cause of danger to his comrades.

The certified cases of alcoholism show the following rates in the Ruhr district:

<table>
<thead>
<tr>
<th>Year</th>
<th>Sick</th>
<th>Dead</th>
</tr>
</thead>
<tbody>
<tr>
<td>1919</td>
<td>4</td>
<td>1</td>

</tr>
<tr>
<td>1921</td>
<td>20</td>
<td>7</td>
</tr>
<tr>
<td>1922</td>
<td>30</td>
<td>7</td>
</tr>
</tbody>
</table>

The fact is that the miner never drinks during work. According to English statistics of 1910-1912, the comparative mortality rates for men aged 25 to 65 from alcoholism, distributed according to occupation are as follows:

<table>
<thead>
<tr>
<th>Occupation</th>
<th>Alcoholism</th>
<th>Alcoholism and disease of liver</th>
<th>All causes of death</th>
</tr>
</thead>

<td>33</td>
<td>780</td>
</tr>
</tbody>
</table>

The observations in which Collis compares industrial unrest with the death rates on certain English coalfields are also interesting. Figures, drawn from districts voting a strike (August 1920), class the districts in the same order as the mortality rates: Lancashire, with a percentage of 90.6 votes in favour; South Wales, 77.9; Derbyshire, 71.8; Durham, 69.9, and Nottingham and Yorkshire with the lowest figures, 55.1 and 51.1 res.
pectively. In 1924 the figures for miners who voted against the wages agreement were as follows for the above districts: 94.3; 89.8; 76.8; 75.9; 69.2 and 75.1.

Nervous diseases are not very common, with the exception of nystagmus (see article "Miners’ Nystagmus") as it occurs in Great Britain and, associated with accidents, of a state of anxiety caused in certain individuals by the fear of accident which haunts them every instant in the mine.

Underground work prepares the way for a state of neurasthenia and irritability, while the use of compressed air tools has also been regarded as a cause of nervous troubles among predisposed persons (see article "Pneumatic Tools").

As regards tumours, Heymann and Freudenberg estimate that work in coal mines does not increase the risks; it seems rather to diminish them. Out of 10,000 living, 5.3 active and retired miners died from malignant tumours in the years 1920-1922, compared with 11.4 for males generally (Prussian statistics).

According to the statistics of the German Mining Association, including active members, the death and sickness rate showed the following figures (average for the period 1912-1920):

<table>
<thead>
<tr>
<th>Active members</th>
<th>Number of sick per 100 members</th>
<th>Number of accidents per 100 members</th>
<th>Number of deaths per 100 sick</th>
<th>Number of accidents per 100 members</th>

* Gastric and intestinal catarrh only.

1 Cf. pp. 251-252.

In the United States, an investigation by Hayhurst (1918) deals with the bituminous coal of the States of Ohio and Illinois, the first including 59,000 miners and the latter 90,000. The average annual death rate of Illinois miners has increased from 10.03 (1913) to 11.85 (1918); and during 64 years (1912-1918) for the different causes of death, over a yearly average total of 77,051 miners, the rates were as follows:

- Typhoid fever: 2.8
- Tuberculosis: 19.4
- Nervous diseases: 5.3
- Diseases of the circulatory system: 5.7
- Pneumonia: 9.1
- Other respiratory diseases: 3.9
- External diseases: 36.8
- Cancer: 3.8

It is interesting to notice that deaths from tuberculosis were highest among miners from 25 to 34 years, whilst the deaths from pneumonia show the highest rate in the group from 45 to 54 years.

An enquiry dealing with the period 1916 to 1920, for an annual average personnel of 25,764 miners in the State of Indiana, has shown that, out of 100 deaths, accidents caused 26.20, respiratory diseases 9.15, pulmonary tuberculosis 6.45, diseases of the heart 8.75 (14.05 for the general population), nephritis 5.94, cirrhosis of liver 1.09, cancer 3.51, apoplexy 3.28, and various other causes 7.48 (the general population).

For various reasons one cannot always rely on the age at which invalidity occurs as an index of the strength and state of health of miners. Mille has calculated that in 1909 the age of invalidity was 50.6 years for the miners of Upper Silesia, 48 years for those of the Saar and 46 years for those of Bochum. The period of service was respectively 23.3, 28.3 and 22 years. For Upper Silesia the average age of invalidity was 48.8 years in 1910-1912 and 49.3 in 1916-1920; for the insurance society of Bochum in 1911-1913 43.1 (average duration of service, 19.4 years), and 43.9 years in 1919-1921.

In conclusion, work in the mines cannot be regarded as very injurious to health, except for accidents which
are fairly frequent and sometimes fatal, due to catastrophes.

In Germany the mining insurance association of Bochum reported in 1908 and 1910 that 82.5 per cent. of accidents occurred among underground workers, who constitute in Prussia about 75 per cent. of all the coal miners. The most serious accidents are due to fire damp and explosions of coal dust, falls of rock and coal, the premature or delayed action of explosives, the bursting in of masses of water, the breaking of cables, the sudden opening of cages, falls into disused shafts, etc.

The German coal-mining industry shows fewer dangers than occur in the occupations of transport, building, iron furnaces and iron works, and woodwork. It may be classed almost in the same category as foundries and rolling mills, underground construction work, and flour mills.

According to the calculations of Dr. Frey, the district of the Saar shows the greatest frequency of accidents, whilst formerly it was the mines of Westphalia which headed the list. It is clear that a general catastrophe, or the recruiting of strangers to the trade, may cause the figures to oscillate and produce temporary variations. The number of accidents is much higher in these two districts than in Upper Silesia, because the conditions of work are much more dangerous and difficult in the former.

According to Lindemann, 69 per cent. of the accidents are attributable to dangers peculiar to the mining industry. It is certain in any case that the number of fatal accidents has considerably diminished in German mines. For 1,000 miners the accidents were as follows:

<table>
<thead>
<tr>
<th>Mining district</th>
<th>1909</th>
<th>1910</th>
<th>1920</th>
<th>1921</th>
</tr>
</thead>
<tbody>

<td>—</td>
</tr>
</tbody>
</table>

The Local Health Office of Leipzig shows the figure of 0.25 per cent. for accidents (for male members).

A German statistical table for 1918 and 1919 gives the following rates:

<table>
<thead>
<tr>
<th>Year</th>
<th>Number of workers</th>
<th>Injured</th>
<th>Per 1,000 members</th>
<th>Deaths</th>
</tr>
</thead>
<tbody>
<tr>

<tr>
<td>1919</td>
<td>967,060</td>
<td>14,117</td>
<td>14.58</td>
<td>2,472</td>
</tr>
</tbody>
</table>

According to an enquiry by Heymann and Freudenberg, accidents occur to this class of worker with a frequency which follows very closely that given for transport workers and exceeds the frequency of all other industrial classes. Fatal accidents are in the same proportion. Accidents occur more frequently to the underground gangs than to those on the surface. Those most affected are the hewers, then the haulage men; other underground workers are less affected, but suffer more than the surface workers. Fatal accidents occur most frequently to the hewers and then to the haulage men. Generally, the accidents are more frequent among young workers, and their frequency diminishes with age; the death rate from accidents, on the other hand, increases with age.

For the period from 1894 to 1915 it has been possible to classify the accidents according to the days of the week, and the following is the table (for 100 accidents):

<table>
<thead>
<tr>
<th>Day</th>
<th>Monday</th>
<th>Tuesday</th>
<th>Wednesday</th>
<th>Thursday</th>
<th>Friday</th>
<th>Saturday</th>
<th>Sunday</th>
</tr>
</thead>
<tbody>
<tr>

<td>16.28</td>
<td>16.20</td>
<td>16.33</td>
<td>16.87</td>
<td>2.65</td>
</tr>
</tbody>
</table>

In the United States the collieries in 1922 employed 844,507 workers; and the number of fatal accidents was 1,979. In 1923 they employed 846,990 persons and the number of deaths was 2,452; whilst the loss of production by fatal accidents may be estimated at 241,006 tons in 1922, and in 1923 at 261,013 tons.

The accidents in the year 1922 were caused in a proportion of 1.81 (per million tons) by falls of rock, 0.71 by explosions due to gas in the mines or to coal dust, 0.19 by explosives. The accidents on the surface have only a figure of 0.24.

In Great Britain and in Ireland the number of fatal accidents was, during 1922, 0.95 for 1,000 persons employed, and in 1923 1.06.

Of 1,179 fatal cases reported among miners working underground 60 were caused by explosions of fire damp or of dust, 585 by slipping of coal-seams, 58 by accidents, 314 by means of transport, and 162 by various causes (1922-1923):

The following table gives the average of fatal accidents in the pits and at the pit-heads in the principal coal-producing countries:

PROPHYLAXIS

Generally all countries are anxious to ensure by law the best hygienic and safe conditions in their mines. (See article "Mines (Hygiene, in ")

Several of them have also published leaflets on the treatment of poisoning by fire damp, by after damp, and by coal dust, etc. Thus, for example, the leaflet published by the Health Office of the German Government shows the illnesses produced by these poisonous gases and gives necessary suggestions to doctors for proper treatment, for the use of oxygen, etc.

As regards tuberculosis, see articles "Gold Mines", "Stone Industry", etc.

With reference to the prevention of cellulitis and bursitis it must be borne in mind that the cause causans is always the same for the three forms: traumatism in direct connection with work. The knee is affected as a result of work carried on in thin seams or where the miner is compelled to work on his knees; the hand is affected by the use of picks with handles which are rough, or by getting hard coal.

These parts of the body must then be protected from repeated trauma, or its harmful effects must be diminished. Further, the entrance of infectious germs into the tissues of which the resistance is lowered should be avoided as much as possible. It is a question, it is true, of very common ordinary diseases varying from individual to individual: prophylaxis consists in avoiding all infection by keeping the skin clean and maintaining the system in a good state of health. In cases of infection it may be possible at an early stage to prevent development of trouble by early intervention, for example, by the application of tincture of iodine; later skilled surgical interference may be required especially if dealing with cellulitis of the hand. A good first-aid system should therefore be organised; workmen must be instructed; advice should be given against the wearing of garters worn below the knee; suitable knee pads should be used; rough pick handles should not be used. Douche baths should be installed. According to the report of Collis and Llewellyn (1924), there were in 1922 in the whole of Great Britain installations of douche baths only for 3,000 working miners, whilst the number of underground workers at this date comprised more than 950,000 persons.

An exhaustive investigation of the factors which cause pneumoconiosis in miners becomes more and more urgent. Some tens of thousands of hewers and drillers are exposed to a disease which reduces or arrests all capacity for work with the most serious consequences for the individual and the community. Every useful measure to remove dust or to lay it should be adopted without delay.

Certain recent British investigations have established that the group of men who work in mines on rocks containing free silica, particularly if they use percussive drills, are exposed to silica dust and contract silicosis just as are metalliferous miners.

The industrial diseases of miners which are compulsorily notifiable are as follows:

Netherlands: poisoning by arsenic, subcutaneous cellulitis of the synovial membrane of knee and elbow, dermatitis (eczema, etc.), nystagmus, inflammation of joints, skin and subcutaneous cellular tissue, ulceration of the cornea and conjunctiva.

| STATISTICS OF ACCIDENTS IN THE MINING DISTRICT OF THE RUHR |

**MINERS’ DISEASES**

**Norway:** infections and complications of ulcers of the skin.

**Western Australia:** pneumoconiosis, miners’ tuberculosis, nystagmus, ankylostomiasis, dermatitis.

The following diseases are compensated when they occur among miners:

**Bulgaria:** ankylostomiasis, nystagmus.

**Canada:**
- Alberta, Manitoba, New Brunswick, Ontario: ankylostomiasis;
- **Australian** Silicosis, Silicopneumoconiosis, Silicosis, pneumoconiosis.
- **United States of America:** Silicosis, pneumoconiosis, dermatitis.

**China:** infections and complications of silicosis, pneumoconiosis.

**Great Britain:** nystagmus, subcutaneous cellulitis of the hand and knee, synovitis of the elbow, ankylostomiasis.

**Italy:** ankylostomiasis.

**U.S.S.R.:** serious anaemia due to ankylostomiasis, nystagmus, cellulitis of the hand, knee and elbow, cancer of the skin, pneumoconiosis.

**Venezuela:** cellulitis of the hand and knee, synovitis of the wrist, nystagmus.

**Western Australia:** for diseases which are compulsorily notifiable (see above) and in addition inflammation of the synovial lining of the wrist joint and tendon sheaths, ankylostomiasis.

**Queensland:** inflammation of the synovial membrane of wrist and tendon sheaths, ankylostomiasis, nystagmus.

**South Australia:** ankylostomiasis.

For compensation on account of silicosis in South Africa, and the province of Alberta, see articles “Tuberculosis—Silicosis” and “Gold Mines”.

The cases of industrial disease, in all forms of mining, compensated in Great Britain during the period 1920-1931, other than nystagmus, forms of cellulitis and bursitis were as follows:

(Berlin).

Miners' Nystagmus

The visual apparatus of miners, and more particularly of coal hewers, is subjected to strain and repeated violent shocks from the time of going down (brisk changes in lighting, increase of pressure) and later to visual exertion (accommodation, fixation, etc.) demanded by work under bad conditions of lighting. (See the article "Occupational Diseases: Eyes").

The centripetal influences, visual, labyrinthine, static, etc. (light, sense of position), which daylight stimulates, to the normal release of the reflexes, which are centrally controlled undergo complete change and soon set up, in susceptible subjects, the phenomena of exaggerated fatigue showing itself in a nervous syndrome characterised by inco-ordination and exaggeration of the visual reflexes (Stassen).

The study of ocular fatigue and visual overstrain would be made much easier if the precise nature of these phenomena, generally morbid, were definitely settled. Unfortunately the biological problem of fatigue is far from being finally determined and at the present time the stage reached is purely hypothetical.

HISTORICAL

The first case of nystagmus was described in 1860. Rubberh, in 1872, described the phenomenon. According to Snell, however. Gillet, of Sheffield, is said to have diagnosed the disease in 1854. Thackrah, at any rate, wrote in 1855 of a disease of the eyes, particularly among miners, which, even obliged them to give up their work. In 1865-1867 cases of nystagmus were described by Popp-Muller, and in 1875 Bell Taylor made a study of nystagmus describing it as though it were a new industrial disease.

The pathogenesis of nystagmus has been successively referred to several causes, of which the most important are the following: the position which the miner has to take up during his work of hewing (Dransart, 1877); the upward direction of the eyes; defective lighting which, according to Romée (1878), was the principal cause of the trouble; poisoning by mine gases (carbon monoxide especially, insisted on by Pechdo, 1893) — a view repeated again recently by Robson and denied by Hal dane (1925); and "lighting" when combined with a faulty position of the miner during his work and with his eyes directed upwards (Nieden, 1894). All these theories have been later accepted or rejected by the different authorities who have been occupied with the problem of nystagmus. Thus, for example, in 1887 Jeafferson stresses position, and some time afterwards (1907-1919) Rutten took the view that nystagmus is a neurosis caused by the fatigue following on the dissociation of movements (flexion of the head, raising of the eyes). Nuel (1908) adheres to the view of Nieden; Court (1891) to that of Romée; and Butler (1914), Coulter (1914), Davies (1920), and others to that of poisoning by coal gas. Peters in 1907 and Trombetta in 1909 are of opinion, on the other hand, that nystagmus is of labyrinthine origin.

A series of enquiries carried out in Belgium and Great Britain have similarly resulted in progress in the study of this question. The Belgian official enquiry in 1907 on the hours of work in mines led
to the report presented by Nuel to the Academy of Medicine, in which he established the claim that nystagmus is an industrial disease of miners causing a real incapacity for work. Stassen's enquiry (Liège) dates from 1912 and that of Ohm (Westphalia) from 1912. The Congress of Ophthalmology, held in Oxford in 1912, was a triumph for the view that inefficient lighting in the mine led to the frequency of nystagmus: it is the view of Stassen, Elworthy, Llewellyn, and Ohm. In the same year Coppex attributed nystagmus to an incomplete tetanus and sees it in the result of fatigue, not only of the elevator muscles of the eyes, but also of convergence. While Dransart (1913) considers that deficient lighting in the mine is a secondary pathogenic cause, and while Wilson (1913) thinks the disease is due to imperfectness of the retinal images, and Shuttlebotham (1914) to defective lighting and refractive errors, Stassen finds a sufficient cause of the ocular troubles affecting miners in the prolonged work under bad conditions of light.

In 1916, Ohm presented his theory of labyrinthine disturbance; he considers that predisposing causes such as alcoholism, stature, light heterophores, etc., play an important rôle. Nystagmus, according to this author, is a disorder of tone, produced by the labyrinth in different muscles or groups of muscles. The cause of this disorder is said to be lack of light and other unfavourable conditions of work.

Several reports, English and Belgian, have been published since 1912; the report by Collis and Llewellyn appeared in 1923. At first nystagmus was regarded as a local myopathy (of the elevators of the eyeball) or as the result of fatigue of the ciliary muscle of accommodation; to-day this disease is ascribed rather to a general fatigue of the whole of the oculo-motor system or as a general neurosis with local manifestations of the said oculo-motor apparatus (Stassen, Llewellyn).

In other words in miners, especially among hewers working under unfavourable conditions of illumination, a fatigue of the visual apparatus exists which may remain localised to the light perceiving elements (hemeralopia, defective retinal adaptation), but which very often passes this stage and extends to the centres controlling the muscles of the eye (nystagmus) and the reflexes protecting the eyes (blepharospasm) (Stassen).

The resulting visual troubles go on increasing more and more and finally set up, in hewers principally, psychical disturbances through exhaustion of the central nervous system (amblyopia, tics, neuroses).

ETIOLOGY — PATHOGENESIS

Before even entering into details the different kinds of illumination in coal mines must be studied. Illumination is provided by candles, by safety lamps supplied either from oil or petrol, by acetylene or electric lamps.

The luminosity of a candle flame varies very much according to the quality of the tallow: it is not constant, the flame flickers, and the light is yellowish. The oil safety lamp gives a flame which diminishes rapidly and cannot be trimmed by the miner. It becomes choked easily and yields a light which gets feebler and feebler (from dust, smoke, etc.). The flame flickers and its colour is reddish. The petrol lamp gives a flame the luminosity of which is twice that of the oil; its intensity is pretty constant; if necessary, the miner can trim the wick and regulate the flame which unfortunately is not sufficiently steady as it is sensitive to air currents. Often its glare annoys the miner; also the glass of this type of lamp gets dirty easily (dust, etc.).

The electric light alone offers remarkable advantages, but at present it is not widely enough used.

The coal face absorbs a large part of the luminous rays: this is why illumination can be improved by dusting the walls of the roadways with lime, talc, etc.

The problem of the etiology of the visual defects of miners can be stated, according to Stassen's views, as follows:

Given exposure of a normal, or apparently normal, human being to the following conditions:

1. acute or chronic poisoning by mine gases;
2. abnormal positions of the body (work in low roadways) entailing a state of general fatigue;
3. abnormal and repeated irritation of the labyrinth;
4. fatigue of the eye muscles, especially of the elevator muscles;
5. defective lighting,

it is necessary to determine which of these conditions is capable of setting up the syndrome of visual overstrain among the miners.

By statistical and clinical study, aided by laboratory experiments, Stassen has tried to fix as exactly as possible the rôle which each one of the conditions of work described above plays in giving rise to the visual defects of the miners. After eliminating those cases in which one only of these conditions could be accounted the sole cause of the malady, he was able to convince himself that the neces-
Sary and sufficient cause of the visual troubles among miners is prolonged work under bad lighting conditions.

His conclusions are that:

(a) Nystagmus is met with in miners where the only etiological factor, to the exclusion of all else, is work under bad conditions of illumination (by means of candles, oil cressets (crassets à l'huile), and oil or petrol safety lamps).

This is the case with the prop carriers, those who lead the horses, and the couplers, among whom up to 10 per cent. are nystagmic.

However, the height of the roadways and trolley-runs is from 1.80 to 2 metres and more; the workers can stand upright and rarely have to elevate their eyes or turn them from side to side. Further, they breathe fresh air which is drawn in by the extraction fans and has not been vitiated by the mine gases. Nystagmus is found among the couplers working at a relatively slight depth (100, 150, 180 metres) where labyrinthine irritation set up by increase of atmospheric pressure can be held to be nil.

(b) Nystagmus is not found among miners who have to use their elevator muscles to a fatiguing extent, but, on the other hand, work under relatively satisfactory conditions of illumination (acetylene lamps with reflectors, fixed incandescent lamps).

Enquiry made in slate quarries where acetylene lamps have been in use for a dozen years yielded no case of nystagmus, not even among those cutting at the face or among the labourers who have to go up ladders carrying blocks of slate weighing sometimes 100 to 150 kg. These men, however, work most of their time with the line of sight below the horizontal plane. The same result obtained in iron and zinc mines where acetylene lamps with reflectors have been in use for many years, and nystagmus is reduced to its most simple expression and that even among the hewers and timber men.

Among the two last-named parties of workers, Stassen found no evidence of oscillation of the eyeballs in any who had used acetylene lamps throughout their professional life. On the other hand, among men over 40 years of age who in their youth had worked for a long time with candles he found some cases of nystagmus, but slighter the longer they had used acetylene lamps.

Hewers and timber men affected with definite nystagmus in coal mines find the condition improve or even disappear completely when they take up employment for several years as hewers and timber men in metalliferous mines or in phosphate mines where lighting is effected by means of acetylene lamps with reflectors, but where, on the other hand, their work remains unaltered as regards the life underground the elevator muscles of the eyeball are fatigued.

These facts are at variance with the theory of Dransart who considers that improved illumination could not cause the disappearance of nystagmus, which is mainly due to fatigue of the muscles of the eyeball.

(c) Finally, improvement in illumination exercises a favourable influence on the frequency and development of nystagmus. No case of nystagmus has been reported among the quarrymen and labourers in slate quarries, the hewers and timber men in zinc and iron stone mines using acetylene lamps with reflectors for about ten years, nor among the couplers, ostlers and machine hands in coal mines employed for at least three years in places illuminated by electric incandescent lamps of 32 and 64 candle power.

In conclusion, the necessary and sufficient cause of the visual troubles among miners, including nystagmus, according to Stassen, is prolonged work under defective conditions of lighting at the bottom of the mine. Improvement in lighting minimises and may even cause the entire disappearance of the troubles due to the ocular fatigue of miners.

These conclusions have been confirmed by the official enquiry in English and Scotch mines instigated by the British Government since the war.
The committee, among the members of which were Professor Pooley, of Sheffield, and Dr. Lister Llewellyn, of Newcastle, has given an admirable account of nystagmus and of the fatigue of the visual apparatus in miners.

From the etiological point of view the English committee was unanimous in recognising as the essential factor in the production of miners' nystagmus defective illumination (the other factors, such as the position assumed during work, accidents, alcohol, infection, heredity, predisposition, and errors of refraction, are only of secondary importance, and, on the other hand, the depth of the workings, the thickness of the seams, injurious gases, and mine ventilated air do not exert any direct influence on the disease), and that defective illumination is due to the feeble lighting power of the safety lamps in use in coal mines.

The importance of certain questions of interest, especially in relation to the physio-pathology of the eye and its connections in relation to too feeble lighting, has been given prominence recently (1925) by Haldane.

Taking the two enquiries together, the fact is abundantly made clear that to combat nystagmus and generally the pathological symptoms due to fatigue of the visual apparatus observed in miners, effort must be made more and more to increase the illuminating power of the safety lamps and to demand more light, always more light, at the bottom of the mine.

Thanks to the use of reflecting acetylene lamps, the disappearance of nystagmus is a fait accompli in metalliferous mines. Thus, for example, in the metalliferous mines of Sardinia, where for twenty years only acetylene lamps have been used and where the miner is not obliged to direct his eyes into an abnormal position, nystagmus is quite unknown (Biondi). Examinations must, therefore, be directed to ascertaining whether these lamps cannot be used in coal mines also, and the problem of the etiology of the visual troubles of the miners must be made the subject of more thorough investigation, and efforts made to determine, in regard to defective illumination in the deep workings, exactly the factor or factors capable of setting up these troubles.

This defective illumination in the deep workings may cause the condition by reason of:

1. A too feeble illuminating capacity of the lights used;
2. Defect in the steadiness of the lights;
3. The colour (predominance of certain luminous rays of the lights);
4. Insufficient protection of the miners' eyes against the lights.

The acetylene lamps used in the metalliferous mines have high luminous power (8 to 15, and even more, Hefner units). Naked, they burn with a clear and strong flame, producing an agreeable, quiet and steady light. Currents of air in the roadways and atmospheric humidity exert but little influence on the acetylene flame. Further, the eyes of the workers using acetylene lamps are protected against the glare by a reflector. Unfortunately, the use of cressets with uncovered flame cannot be entertained for use in coal mines. At the present, only one coal mine in Belgium is still allowed to use naked candles and oil lamps. All the other companies are compelled to illuminate their workings by means of so-called safety lamps.

Further, three other factors have to be taken into account: the medical man (diagnosis), the workman (auto-suggestion) and the surroundings.

Bartels and Knepper (1930), as a result of research into miners' nystagmus, have criticised, to begin with, existing statistics, which they affirm are confined to information about those patients who demand medical examination themselves at the pit-head. These authors have based their conclusions on English and German data and are convinced that the figures established in these countries have suffered the influence of economic circumstances to a considerable extent. Thus in the Ruhr mines (1922), out of 530,000 miners, there were only 31 reported to be suffering from nystagmus, whilst in 1928 out of a total of 380,000 miners the total cases of nystagmus amounted to 1,600. They found that in Germany the number of cases of nystagmus increased in proportion to the decrease in the number of workers occupied in the mine, whilst in Great Britain the two sets of figures are parallel.

In their study Bartels and Knepper report that in a well-lighted mine gallery where soft coal was mined they found 5.2 per cent. of cases of nystagmus, whilst in a mine where lean coal was worked, which was badly lit (lighting by benzine) and in which working conditions were difficult, the percentage was 10. Research carried out in the Ruhr showed 272 workers to be suffering from nystagmus, whilst of these only 3 presented themselves for
examination at the pit-head on account of the disease in question.

Workers engaged in repair and in hewing of coal showed the highest incidence for nystagmus. On the other hand, stone cutters were not affected, which points to the fact that the use of modern machinery cannot be considered as an important factor in regard to nystagmus.

The majority of underground miners affected by nystagmus were examined at the pit-head: in the case of a certain number the trouble disappeared on return to daylight. On the other hand, the majority of underground miners did not suffer from subjective troubles, and visual acuity appeared at least to be in no wise affected, for there is no certain method available providing an exact estimate of the effect of nystagmus on vision.

Nystagmus can be overcome in certain rare cases by the will of the patient; on the other hand, it can never be simulated; nevertheless, latent nystagmus can be caused to appear either by raising of the blood pressure (effort, etc.) or by modification of the pressure of the spinal fluid; such changes in pressure may occur in course of work.

STATISTICS

Belgium. — In Belgium Stassen's enquiry (1914-1919) has furnished the following data:

Among 20,000 men examined 5,000 were found suffering from nystagmus (25 per cent., of whom 8 per cent. were slightly affected, 12.5 per cent. suffered from transient fatigue, and 3 per cent. were severe; 1 per cent. only of the miners were affected by ocular overstrain and 0.2 per cent. with general exhaustion).

The frequency of nystagmus according to duration of employment was as follows: 2.5 per cent. for a period of 1 to 5 years, 4.5 per cent. from 6 to 10 years, 12 per cent. from 11 to 15 years, 24 per cent. from 16 to 25 years, 30 per cent. from 21 to 25 years, 40 per cent. from 26 to 30 years, 45 per cent. from 31 to 35 and 50 per cent. from 36 to 45 years.

Whilst nystagmus has been found in a proportion of 25.4 per cent. among miners working with oil lamps, and 20 per cent. in mines lighted by electricity, it has reached a percentage of 19.7 in mines lighted with naked lamps, of 8 in an iron stone mine and 5 in a zinc mine.

In state quarries lighted by acetylene lamps no case has been reported.

Nystagmus affected workmen on the day or night shift in accordance with their occupations in the following proportions:

<table>

Statistics of Dransart for France give for 1913 a proportion of from 12 to 20 cases of nystagmus per 100 workers underground.

Germany. — In Germany (Westphalia) cases of nystagmus numbered 788 in 1918, 322 in 1919, 135 in 1920, and 51 only in 1921. The mining district of Westphalia has a mining population of about 190,000. The smallness of the numbers may be explained by the use of electric lamps, acetylene lamps, etc. A Prussian committee to investigate nystagmus has quite recently resumed its activities, so that shortly exact information will be available. The walls of galleries which have to be utilised for a long time are whitened with lime (Frey).

In the mining district of the Ruhr the careful inquiry by Heymann and Freudenberg (1925) has furnished the following figures per 10,000 workers:

<table>

It affects especially men at the age group from 50 years and above.

Lindemann finds a percentage of 5 from nystagmus; Nieden, of Bochum, one of 5 to 7; and Ohm, of Bothrop, has reported from 1908 to 1925, 1,400 cases of nystagmus.

Great Britain. — According to Dransart (1877), A. Graefe is said to have seen only 3 cases of nystagmus; Ch. Bell, of Nottingham (1875), only found 3 cases. Recently (1925) Freeland Fergus stated that at the ophthalmological clinic of Glasgow when he was a medical student cases of nystagmus were rare and at that time there was no compensation.

Of 2,400 cases of nystagmus among English miners, 1,510 were coal hewers, 221 timbermen and repairers, 118 landers, etc. Of the 1,510 miners in question, 405 have worked a long time as hewers, 486 fairly long, 560 not long or not at all. About 50 per cent. thus fell in the "not long" or "not at all" class.

Of 1,613 colliers those who worked a very thin seam showed no case of nystagmus; 1 case among miners working a seam of less than 60 cm.; 66 in a seam of...
In slight cases of visual fatigue, Stassen says, these troubles of muscular equilibrium of the eyes ordinarily only occur on looking upwards, which is relatively the most difficult ocular movement to accomplish. But if, as a consequence of the necessities of the case, the miner overtaxes his eyes, the troubles increase in intensity. Using his eyes then on the slightest pretext (light reactions, static reactions, fixation reflexes, reflexes of convergence) the clonic spasms appear with each wider use of the field of vision; finally it becomes permanent in all positions of sight. Later, the clonic spasms are not limited to the ocular muscles, but sometimes reach the palpebral muscle (blepharospasm), the muscles of the forehead and of the face (tic) and reach even those of the nape, neck, trunk, etc.

In the effort to co-ordinate as much as possible their visual impressions in the midst of the nerve storms which affect their ocular centres (Nuel), the miners, when affected by severe forms of visual fatigue, require to make superhuman efforts of will power. Under such circumstances the trouble extends to a certain extent to the whole nervous system, etc., and after having exhausted all their stores of energy, these overstrained individuals succumb to amblyopia, and the neurosis which attends nystagmus.

According to the predominance of such and such symptoms as correspond with troubles of the centripetal impulses of the visual apparatus, with those of the neuro-muscular system of the eyes (centrifugal paths of the visual apparatus), or with those of the centres in the cerebral cortex, Stassen believes that he can distinguish the three following forms despite the clinical polymorphism which cloaks the nervous syndrome in miners working under conditions of defective illumination:

1. The retinal form: An early form or one which occurs when the malady is passing away, characterised notably by an affection of the light-perceiving elements of the visual apparatus. Principal symptoms: defective retinal adaptation (hemeralopia);

2. The clonic forms which affect the centrifugal paths of the visual apparatus (oscillation of the eyeballs, occupational nystagmus and blepharospasm);

3. The psychical forms characterised by affections of the cerebral system.
functions. Amblyopia and the neuroses of the coal miner are placed under this heading.

The malady may show itself in a slow form in which the miner is not sensible of subjective troubles, has no knowledge of oscillation of the eyeball, and is not incapacitated from work; and an acute form which can present three stages: slight, with very little incapacity for work; moderate, where underground work has to be abandoned (this is the ordinary form observed); and severe accompanied by total incapacity.

The first subjective symptom marking the onset of the malady is failure of sight, especially noticeable in the dark when delicate work has to be performed. This diminution, which continues on the surface, is worse at night, early in the morning and during twilight. It is a hindrance to the miner in his different movements, affects his sleep by violent headaches and nightmares; gradually, although at times with striking suddenness, vertigo and temporary loss of sight follow exertion and stooping.

This period is characterised by the following symptoms: diminution of sight, especially in the dark, occipital headaches, giddiness, after effort or after wounds, sometimes loss of sleep and photophobia. Nervous and even hysterical symptoms may appear, and if at this moment objective symptoms have almost disappeared, the subjective are always very marked.

The symptomatic triad is constituted by diminution of sight, headache and giddiness.

Diminution of sight is marked at night time so much so that the men working on the afternoon shift are often met on leaving the shaft by friends or parents to take them home. This loss of acuity would seem to be due to deficiency in adaptation to the dark. Among 1,330 cases examined by the British committee of enquiry, sight testing showed 57 per cent. with less than 3/12 vision at the acute stage of the disease (the test was only carried out when oscillation of the eyes was absent). Ohm found similar figures for 75 per cent. of the miners examined. The nystagmic has a feeling that surrounding objects are dancing and that the lamp dances. Although this feeling is pathogenic when it is present, subjects without a very marked rotatory oscillation of the eyes may not experience it.

The visual troubles bring in their train headaches generally situated at the occiput, but often temporal and sometimes ophthalmic. These headaches are made worse by effort, flexor movements of the trunk, or bright light. A characteristic of the malady is the persistence of inveterate and severe headaches, even after the miner has ceased work in the mine for some years. They seem to be the result of the development of a psycho-neurosis.

Giddiness soon adds itself to the first symptoms and develops along with them. They increase with efforts, bending or sharp turning movements. In severe cases the patient becomes ataxic and cannot move himself without assistance; photophobia, linked up very often with lid spasm, is associated with these symptoms. As the disease develops, mental symptoms appear showing themselves in marked mental hebetude with restlessness and insomnia at night, acute depression and fits of weeping ending in neurasthenia, neurosis with constant headaches, sleeplessness, anxiety, nightmares, marked mental depression, loss of memory, etc.

**Diagnosis**

Diagnosis is often made on noticing the special attitude of the patient from a distance. The walk of the nystagmic is often characteristic. The body stoops, the head is lowered, the eyes screened and the face is totally lacking in expression. Closer examination detects a slight tremor of the head (often resisting extension of the nape of the neck) and a rotatory oscillation of the eyeballs when the patient looks up. This oscillation, obvious in serious cases, can be elicited on asking the patient to look at a near object, to raise the eyes or to lower his head rapidly. These oscillations on the other hand are diminished or cease during repose, when the eyes are protected, or when the patient looks downwards. The movements are frequently associated with lid spasm (involuntary, persistent, synchronous), with photophobia, ascent of the eyeballs under the upper eyelid, with an intense convergent strabismus, lateral fixation and, in many cases, with slow half involuntary movements of the eyes. Oscillation of the eyeball is always present at one or another stage of the malady, but its demonstration is often difficult and requires at times repeated examinations after exercise or a stay in the dark. The rapidity of the movements is from 100 to 350 oscillations a minute — sometimes even more (Ohm: 150 to 400, 70 per cent. of the cases are between 250 and 350; Stassen: 90 to 360). The extent of the oscillations varies greatly; the amplitude is small when the rapid-
ity is high, and inversely. The gravity of the case can be gauged by the amount of elevation of the eyes in daylight required to induce oscillation. This test has a certain value despite the reservation to be attached to it. Differential diagnosis must be made with senile and alcoholic tremor.

**Course**

The clinical course of this fatigue depends on the state of general health and of the physiological personal resistances. Periods of exacerbation and remission occur. Thus symptoms are increased with intercurrent maladies (pneumonia, typhoid fever, etc.) which leave general debility behind them. Badly-nourished workers enfeebled by toil and privation, with large families, are a ready prey to severe forms of the disease. Relief of the general condition, rest, and good food exercise naturally a favourable influence on the course of the disease.

Miners’ nystagmus may be latent for years or gradually take on the acute form. Even when aware of his condition the miner may continue to work for years and a state of equilibrium be set up in which he is able to ignore the eye symptom. This fact is well known and it has even been suggested that he should educate himself after the onset of the first symptoms to accustom himself to them. While certain persons remain incapable of resuming work below, others can take up work in the roadways, but often as labourers only or as assistants’ repairers. Complete cure with resumption of work at the coal face is frequent, however, are frequent and each relapse makes the chance of resumption more remote.

In describing the course of the disease the British committee also distinguishes three principal types:

1. the atonic;
2. the spastic;
3. the psychic.

The first is characterised by loss of sight, headaches, giddiness and oscillation of the eyes. In the spastic form the patient has blepharospasm, photophobia, head tremor and severe headaches. The oscillation of the eyeballs is often difficult to elicit. The psychic form is characterised by the development of a neurosis or psychoneurosis with generalised tremors, nervous asthenia, functional heart troubles, headache, symptoms presenting the clinical picture of a traumatic neurosis or of “war-strain” (nervous exhaustion) shown by soldiers in the war.

The English report concludes that these three clinical types correspond generally to the retinal forms, clonic and psychic, which Stassen has described, of the fatigue of the visual apparatus in miners.

**Prophylaxis**

While improvement in lighting has been possible in the metalliferous mines, the difficulties of management, the presence of inflammable gas and especially of fire damp unfortunately make the use of lamps with a naked flame or of fixed electric lamps impossible.

It is however necessary to investigate whether there are no means, in the present state of lighting in coal mines with safety lamps, of improving the illumination and avoiding the visual troubles induced. It is, therefore, necessary to examine whether it is possible to increase the luminous intensity of the lamps, to give sufficient fixity and an agreeable colour to the sources of light, at the same time protecting the miner against glare and flickering.

In several ways electric lamps have made sensible progress, but their luminous intensity is still too feeble. Further, as compared with oil or petrol safety lamps, they have the great disadvantage of giving no warning to the miner of the presence of fire-damp and in many fiery coal mines, where electric lamps are used, it has been necessary to give the miners a second lamp of the safety kind to serve as an indicator of the presence of fire-damp, thus notably increasing the cost of lighting.

In Great Britain also interesting experiments have been made as to the lighting of roadways, and in order to increase the intensity of illumination the method of whitewashing the woodwork of the workings with milk of lime has been adopted. The miners’ eyes, too, ought to be protected from glare and flickering. With this object the British committee recommend the miners to fix their lamp above their cap.

The happy effect on the sight of the hewers and overmen of interposing a little screen of parchment between the fixing and the glass of the lamp has often been observed. This method of protecting the eyes could easily be extended because it would suffice if a
part of the glass of the lamp was made of matte.

To complete the history of progress in lighting there should be mentioned the experiments made in some Belgian and English mines, the object of which was to try and make the light pleasanter by using glass in the lamps of a yellow colour to cut off the blue and ultra-violet rays from the miners’ eyes.

Such protection of the eyes against glare, flickering, and injurious rays from the sources of light have not yet reached finality in coal mines, and it would be of great advantage to carry out further investigation in regard thereto.

Watch should be kept over the nystagminics because advice can be given to them as to certain precautions and practices which could prevent aggravation of their troubles.

As a precaution against hemeralopia, it would be worth while to recommend adoption of the practice of adapting a screen of parchment to the lamp; miners should wear dark goggles for some minutes both when going up and before descending in the cage in order to accustom their eyes to the changed lighting conditions and to avoid retinal shock provoked by the rapid passage from darkness to light and vice versa.

The ears should be carefully examined because lumps of wax are frequent and sometimes give rise to labyrinthine disturbance aggravating and complicating slight occupational nystagmus.

The general health should be attended to; tonics are here indicated.

In pronounced cases the worker would do well to take a less arduous task. Hewers and overmen of timbermen have seen their visual troubles notably improved by changing places; for example, some have asked to change their day shift for the night shift when the work is quieter and less intense.

Others have become couplers, conductors, or dillymen. They have been thus occupied in the wide workings in the trucking areas where circulation is easy and lighting sufficient — very much better than at the coal face, since almost throughout it is lit up by means of incandescent lamps of 22-64 candle power in much well-lighted places, after three or four years complete disappearance of nystagmus can be hoped for. Employment, therefore, of coal miners affected with pronounced nystagmus on surface work only is not absolutely necessary (Stassen).

On the other hand, some patients find work on the surface rather prejudicial to a cure because the miner likes his work below. The only work suitable for pronounced nystagminics who want to work at the surface is as lamp cleaners and caretakers, or some occupation not requiring excessive movement of the head or body. In severe forms of visual overstrain, complicated with amblyopia and neurosis, the patient must give up all work and rest several weeks — perhaps several months. Psychotherapeutic treatment (sometimes even as an in-patient in a hospital) is indicated.

The first duty of the medical man when confronted with this neurosis is, above all, to assure the miner that the infirmity is not final, but, on the other hand, that a cure is certain; they must be given confidence in themselves and anything that would tend to discourage this idea must be assiduously avoided.

Thus only can these victims of their occupation be given the power to resume work and become useful members of society (Stassen).

A study by Liewellyn suggests quite a series of measures to limit or prevent incapacity from work for nystagminics: Preliminary examination of the eyes on commencement of work; employment of semi-invalids on surface work; power to appeal periodically to expert medical referees; automatic and gradual lessening of the amount of compensation paid; payment of a lump sum in place of an annual sum; institution of medical services in schools for vocational guidance to select boys for work carried on underground.

### Legislation

Nystagmus is statutorily notifiable when affecting miners in Netherland's and in Western Australia (1924). It is scheduled under the Workmen’s Compensation Acts in Great Britain, Western Australia (mines and quarries), New South Wales, Queensland, the States of Minnesota and New York, and Russia. Nystagmus was added in 1907 to the list of scheduled diseases under the British Workmen’s Compensation Act, with the description “Nystagmus: Miners”. In 1913 this description was modified as follows: “The disease known as miners’ nystagmus, whether occurring in miners or others, and whether the symptom of oscillation of the eyeballs be present or not: Mining”. This definition may, however, be further modified (1926). Statistics show that the frequency of this disease has greatly increased since it was included under the Workmen’s Compensation Act, and especially after the extension given in 1913 to the description (Liewellyn). Economic post-war conditions have also played an important part in the increase of cases of nystagmus. The eco-
nomic loss caused by this malady in Great Britain is estimated at about a million pounds sterling yearly.

The number of cases of nystagmus which received compensation in Great Britain is as follows:

<table>
<thead>
<tr>
<th>Year</th>
<th>Cases compensated during the year</th>
</tr>
</thead>
<tbody>
<tr>
<td></td>
<td>Old cases</td>
</tr>
<tr>
<td>1910</td>
<td>693</td>

</table>

Further numerous cases receiving compensation continue from one year into another: 3,741 in 1917; 4,163 in 1920; 4,804 in 1921; 5,055 in 1922.

In New South Wales, 42 cases were compensated in 1920-1923 among 350 cases of occupational disease. They received £6,889 out of a total of £77,643.

Mines (Hygiene in)

GENERAL

Mines (this term comprises the working of deposits of alluvial iron ore, pyritic and aluminous earths and peat, etc.) may be worked in the open or in subterranean channels.

Once the ground covering the deposit has been removed, the open mine is worked by means of successive trenches or terraces. In the case of deposits which are not of great depth, inclined horizontal galleries, descending or ascending as the case may be, are utilised. The descending galleries reach the ore bed by means of vertical shafts which facilitate the working of various veins or layers at different depths (levels) by means of horizontal galleries. The workers attack the seam or vein or bed of the deposit at different points known as the "working face" or "headings".

Work at the bottom of the mine is not infrequently effected by three shifts: day shift engaged in hewing the ore or coal; night shift engaged in rock cutting, in making tunnels or galleries, in breaking the ground, and in coggine, etc.; the shift for repair work entrusted with repairs, woodwork, etc.

The galleries are provided with wooden supports in the form of a trapeze, whilst the principal galleries, stables, pump rooms, machine rooms, etc., are lined with masonry and vaulted. Hewing is effected by hand (with pick and shovel in soft ground, with pick, crowbar and wedges driven in by a small hammer, etc., in hard rock) by a worker who is in a standing, kneeling or lying position according to the thickness of the seam; by machines (drilling machines, hewing machines, etc., worked by air or electricity, etc.) and by aid of explosives.

The ore thus obtained is transported to the centre of the mine, that is, from the working face to the entrance of the extraction shaft.

Transport is effected by means of baskets dragged along the ground, by barrels or skips on rails, pushed or drawn by hand, often united by a framework, and drawn by cables or chains by means of a stationary motor. Traction may also be effected by animals (ponies), or again the extraction of one or more of the coal may be effected by means of winches which raise the buckets, or more frequently, by a cage with one or several compartments moving up and down the shaft along posts fixed to the sides and suspended by cable from the extraction machinery. The full skips are placed in the cage which also serves for the transport of workers.

In other mines special working conditions allow of the ore or the coal being shovelled into inclined chutes or into
automatic buckets which descend on an inclined plane (dillies), the weight of the descending bucket causing the empty bucket to rise in the opposite direction.

The introduction of mechanical methods in mining is acquiring more and more extensive application; automatic loading of skips which pour the ore or the coal automatically into reservoirs; sorting of coal on a travelling band; automatic washing or dry cleaning; electric traction; transport of workers in small cars, etc., down to coal getting by means of tools worked by electricity, or compressed air.

Special services are entrusted with the removal of water from the workings, airing, ventilation and lighting, etc.

The removal of water from the workings is effected by means of pumps at the surface and sump pumps at the bottom of the mine. The technical service sees to the maintenance and proper working of the water mains, reservoirs, etc.

The day shift includes the services in charge of the shafts and accessory services such as that of the power factory, that of the lamp department (maintenance and safety of lamps, etc.), the handling and preparation of coal (crushing in mechanical crushers, riddling, sorting, and separation of dust which is utilised in the briquette factory, washing in order to free the coal from soil, etc., the installation and maintenance of railways leading to the shafts; at times the working of coke furnaces, the manufacture of briquettes, etc.)

Waste matter is thrown on to a dump ("terril").

Ventilation

As regards ventilation, it is necessary to distinguish between metal mines and coal mines. The latter are more dangerous, the presence of fire damp, carbon monoxide, sulphured hydrogen, etc., demanding the provision of mechanical ventilation. Metal mines, on the contrary, only possess natural ventilation, artificial ventilation being exceptional.

Artificial ventilation has for its object to furnish the mine galleries with a large quantity of air to attenuate or suppress the toxic or harmful action of gases.

Formerly, technical efforts were limited to a flame lit in the upper part of a chimney, which thus acted as a means of ventilation similar to the system currently adopted in buildings. This method is, however, defective, costly and even dangerous, since it involves risk of explosion by backfiring. At the present time, technical efforts in the field of ventilation consist in the provision of powerful exhaust ventilators and compressors.

In certain mines other than coal mines the high temperature in excess of the outside temperature generally suffices in ensuring air currents. There are, however, metal mines in which the installation of artificial ventilation is indispensable; with a view to combating other causes of ill-health such as dust, toxic fumes liberated during explosions or by the oxidation of certain ores, e.g. pyrites.

Whether the ventilation is mechanical or not, the principle of air circulation always remains the same. There are, as a rule, two chimneys, one of which serves for the entry of fresh air and the other for the removal of vitiated air. This circulation is so arranged that no short circuit can occur, the air being made to follow a well-determined route. This objective is obtained by means of partitions or doors which send the air current in the required direction. A system of ventilation is sometimes shared by two neighbouring mines, the one serving for the entry and the other for the exit of the air.

Ventilation at the working face requires special consideration since it is directly connected with the method of work engaged in. In certain headings without issue which are veritable pockets, work with compressed air tools, on the one hand, and the difficulty of furnishing good ventilation on the other make it imperative that a good system of ventilation by the supply of compressed air should provide the worker with satisfactory working conditions.

Harrington has demonstrated the advantage of a system of ventilation in which the supply and distribution of fresh air is effected by means of flexible hose pipes which are less costly, lighter and easier of manipulation than rigid metallic pipes, though, however, less resistant to wear and to causes of deterioration.

Air in Mines

Poisonous Gases

The air furnished should be pure, invigorating and cool. The oxygen content should never fall below the normal (about 20 per cent.) since man is unable to work at an oxygen content inferior to this figure without certain respiratory constriction. If the oxygen rate descends to 14 per cent. men become dizzy, suffer from rapid heart action, buzzing in the ears and sometimes headaches. Very few men escape these symptoms when the percentage of oxygen falls to 10 or less.

In mining when workers are exposed to oxygen in excess of the normal con-
centrations (compressed air work, use of self-contained oxygen breathing apparatus) signs of irritation of the lungs are observed. Leonard Hill, however, showed that these effects only occur after 48 hours of continuous exposure to an atmosphere containing over 80 per cent. of oxygen. Leonard Hill likewise pointed out that mules exposed to an oxygen concentration of 60 per cent. for over a year in the Hudson tunnels remained in perfect health. Henry Briggs, after extensive investigation, states that men not physically fit find bodily work easier when they breathe oxygenated air than when they breathe normal air, but no such difference exists in the case of fit men. Dr. Briggs found, however, that when overworking even the fittest of men derived benefit from oxygen-enriched air. From observance of men and animals, investigators of the United States Bureau of Mines found no ill-effects from, or objections to, breathing of almost pure oxygen at normal pressures and are of opinion that there is a potential if not an actual benefit to be derived from breathing oxygen where physical exertion is excessive.

If the nitrogen of the air is increased, no effects ensue other than those due to the dilution of oxygen, the results of which have just been referred to.

"Fire damp" ("grisou") constitutes the principal risk in mines since it gives rise to explosions and catastrophes so extensive as to cause consternation throughout the entire world. Generally, the limits likely to give rise to explosion lie between 5 and 13 per cent. Being lighter than air, this gas accumulates in the lower part of the tunnels or galleries, in pockets and in workplaces without issue, and constitutes at times a danger by reduction of the oxygen content rather than by the percentage which it attains in the air. For the workers its presence is heralded by a sort of cap which appears above the flame of the lamp. This sign is positive with a content up to 1 per cent., but where the wick is turned downwards and where a hydrogen flame is used (Clowes' lamp) it is positive even at a content of 0.2 per cent.

Another apparatus for detecting fire damp is the self-acting gas trap of Desmond with inverted flasks. The flasks are placed in a basin of water where the water is run off by means of an orifice with a thin wall. These flasks have a double closing device consisting firstly of a ground glass stopper and secondly of an indiarubber flap valve introduced into the flask and which, when the latter is empty, constitutes a hydraulic joint isolating the air in the flask from the outside air. The slow emptying of the water basin causes the air to enter the flask by means of successive bubbling whilst the water leaves it at the same time drop by drop. The means of guaranteeing the airtightness of the apparatus are extremely good (see below, "Lighting"). Ignition of fire damp may also be caused by discharge of sparks. Possibility of ignition due to electricity depends on several factors: kind of metal which constitutes the terminals between which the sparking discharge occurs; rapidity of breaking of the circuit; surface of the contact at the moment of circuit breaking; induction of the unit; voltage induced; nature of the current, etc. (Wheeler).

Methane is also an important element of fire damp the presence of which may cause serious consequences either in coal mines or in metal mines. Though the gas has no physiological effect upon man, it may accumulate to such proportions as to constitute an explosive mixture with the oxygen of the air. Further, it may dilute the oxygen of the air to such an extent as to produce the effects of oxygen deficiency already referred to.

Sulphur dioxide usually comes from the decomposition of sulphide minerals or from the burning of explosives which contain sulphur. There is occasionally sufficient concentration in the mine atmosphere to constitute danger. It is easily recognised by its characteristic odour.

Hydrogen sulphide (stink damp) may be found in mine air but usually only in very small quantities. It has an extremely repulsive odour in very low concentration which may serve as a warning signal. It may be produced in mines of ore with a high sulphide content by some types of decomposition of such ores and also from the use of certain types of explosives. It has been found, though rarely, issuing from feeders or blowers in coal mines.

Carbon dioxide, traces of which, at least, are always present in the atmosphere, has long been used as a measure for the purity of air, though its importance in this connection has probably been over-emphasised. Nevertheless, in mines it sometimes occurs in sufficient quantities to cause symptoms in the men, or even unconsciousness and death. It forms an important constituent of "black damp" when all or part of the oxygen of the air is replaced by combustion or
oxidation of the iron pyrites present in the coal:

\[
4 \text{FeS}_2 + 15 \text{O}_2 + 8 \text{CaCO}_3 = 8 \text{CO}_2 + \text{CaS}_2 \text{O}_4 + 2 \text{Fe}_2 \text{O}_3
\]

Where the oxygen is displaced the “black damp” consists essentially of nitrogen with 5-15 per cent. of carbon dioxide. It is sometimes mixed with fire damp. Its presence constitutes a normal accident in coal mines, especially in old, badly ventilated mines.

“Black damp” is recognised by miners by a darkening of the flame of the lamp, without, however, the cap over the flame characteristic of fire damp. When the content of this gas is high the lamp may even be extinguished, and when it exceeds certain limits it causes asphyxia. The English Mines Act (1911) demands that ventilation should not cause darkening of the flame or laboured breathing. Analysis of the air should show an oxygen content not inferior to 19 per cent. and a carbon dioxide content of 14.

Carbon monoxide causes a great many deaths amongst miners. This gas without odour, colour or taste, the effects of which remain unnoticed by the victim until it is too late, is the principal element in the so-called “after damp” or “white damp”. It is present in the air of the galleries subsequent to explosions, being a result of spontaneous oxidation or combustion of coal. In the gold mines in South Africa the percentage of carbon monoxide in the air after the explosions have taken place may not exceed 1 per 10,000 and should this occur work has to be suspended. Hoover (1921) has proposed a portable apparatus capable of detecting up to 0.005 per cent. of carbon monoxide in mines. This apparatus consists of a special substance: “holamite”, sulphuric acid, pentoxide of iodine and pumice stone. The reaction is chromatic (see also article “Carbon Monoxide”).

Atkinson recalls the composition of gas known under the name of “bottom gas” (gas du fond), a mixture of carbon dioxide, methane, carbon monoxide, nitrogen and hydrogen, which has been well described by Robertson. This heavy gas is met with in certain mines in New South Wales, where it lies on the ground in layers like a liquid, but which can, however, be rapidly dispersed by air currents and ventilation.

Dust

The presence of dust in mines constitutes an important risk for the health of workers. It often happens that workers become the victims of serious poisoning when mining ores of lead, carbonate or oxide, whereas lead poisoning is rare among men mining only galena (lead sulphide). Another example is the mining and smelting of mercury, where the danger has long been recognised. When the ore contains free mercury or the more soluble salts and when the workings are underground and poorly ventilated, some cases of poisoning occur, but the number is far greater amongst employees in reduction plants.

Poisonous dusts are found seldom, if ever, in coal mines.

The enquiries effected at Broken Hill (1921-1922) have provided the following figures in relation to the composition of the ore mined: lead, 11.27 to 16.18 per cent.; zinc, 7.84 to 15.99; silica, 36.08 to 60.50. The latter constitutes about three-quarters of the total composition of the ores. The insoluble part of this fraction is composed of silica and manganese dioxide for over 80 per cent.

The chemical analysis of lungs made during autopsy indicates the presence of lead, zinc, manganese and silica after a period of work in the mines of about ten years.

The proportion of manganese (0.0038 to 0.00033) in the lungs analysed was 90 times greater than that in a healthy lung. The proportion of lead varied from 0.0007 to 0.0001. A single analysis did not reveal traces of lead. The case in question was that of a miner who for twelve years past had not worked underground. The percentage of zinc was 0.0011 to 0.00008 as against 0.00012 in the normal lung. The quantity of silica reached the figure of 0.296, or five times that agreed as the average for purposes of control.

While in general not much manganese is found in the lungs of workers having worked for a period under ten years, there does not always, however, exist any apparent quantitative relation between the period of work in the mines and the quantity of dust accumulated. Thus in one instance the pulmonary tissue of a man who had worked during forty years in mines contained more dust than that of an individual who had only worked for a period of ten years, while on the other hand the pulmonary tissue of workers, having worked thirty-six years or longer contained less dust than the lungs of a worker with a much shorter period of work.

The operations in which most dust is given off in mines are blasting, drilling, transport and crushing of the ore.
During blasting conditions are extremely bad, the unhealthiness of the surrounding atmosphere being at such times very much greater than under any other conditions.

Drilling is done by hand or with the aid of machines. The first method causes greater liberation of dust than in the case of mechanical drilling. Under certain circumstances (for instance where the hole is being bored downwards), the hole may be dammed as soon as the aperture bored is large enough to contain water. In this manner dust cannot accumulate to a dangerous degree. But even with great care it has been found that a quantity of dust reaching 200 to 300 million molecules per cubic metre is produced by mechanical and compressed air methods.

According to Harrington (1925) dry-drilling machines liberate more dust when the motive power is electricity than when they are worked by compressed air.

It is extremely difficult to determine a limit involving a risk to health, or, in other words, to fix the safety limit for dust in the air of mines. Thus, for instance, in the South African mines the maximum allowed is 5 mg. (3.99 million molecules of dust) per cubic metre, but the most recent analyses have only revealed 1.5 mg. No American mine shows such a low figure: in 1915 research effected by Higgins and Lanza led to the fixing of a minimum value of 10 mg. per cubic metre. In dry metal mines this figure reaches 29 mg. and extensively 50 mg. In the case of dry drilling there has been met with 7,000 mg. of siliceous dust with an average of 150 to 250 mg. per cubic foot at a temperature of about 16° C., whilst in wet drilling the dust rate was only 5 to 20 mg. per cubic metre. The average reported per cubic metre in the Transvaal mines were as follows: 4.9 mg. in 1921, 1.6 mg. in 1922, and 1.3 mg. in 1923. Experience, particularly in South Africa, justifies the conclusion that the problem must be regarded from a different angle than formerly. It is sufficient, for instance, that a molecule of dust of 100 microns in diameter may have the same weight as 250,000,000 molecules of 2 microns. Consequently, 200 to 300 million molecules of very fine dust (2 microns) are necessary to give a milligram of dust, and extremely delicate methods are required for estimation of these infinitesimal quantities of dust. In the article "Dusts, Fumes and Smoke" the best methods of attaining this object are described. It is sufficient to state here that accurate estimation can only be made by use of extremely minute analyses. In coal mines, for instance, the weight of dust is not so high as in the figures indicated above, yet the number of molecules is, on the other hand, much higher.

Collis has demonstrated in a very thorough study (see article "Tuberculosis and Silicosis") the injuries caused by siliceous dusts frequently met with amongst miners in Australia, New Zealand and South Africa, in the silver and lead mines of Australia, etc., where the presence of siliceous dust gives rise to a high morbidity rate from respiratory disease. Silicosis is likewise met with in Great Britain in the tin mines of Cornwall, and in various mining districts in the United States (Missouri, Oklahoma, Kansas, Nevada, Idaho, Arizona and California), as well as amongst the granite workers of Vermont.

Much of the dust breathed, especially the larger particles, is deposited in the upper air passages of the respiratory system. Some of the fine dust (10 microns and under) reaches the pulmonary alveoli. According to the most recent investigations made by Mavrogordato (1922-1926), penetration of dust into the lungs causes the formation of a large number of cells ("dust cells"), which take up the particles of dust. Many of these dust-laden cells escape into the air passages and are coughed up and expectorated. Those which remain in the lungs become fixed and may be dangerous. The life of "dust cells" is normally brief. They may be carried off by the lymphatics, or may die and be digested or dissolved by the body fluids, leaving the dust previously ingested on the adjacent tissues, such dust possessing also a further means of escape similar to that of the dust cells. According to Mavrogordato: "It is the dust which cannot escape from the tissues which is a source of danger, and as long as elimination follows fairly closely upon the heels of ingestion not much harm is done. Coal seems to set up a sort of asthmatic 'catarrh' in which there is a steady exodus of particles from the lungs." Dust from hard rock containing no free silica but entirely composed of fine spicular hard minerals (89 per cent. feldspar, pyroxene and other dense minerals) remains in the lungs after inhalation. The dust particles appear, according to Mavrogordato, to have exerted some protective influence over the cells containing them, thus preventing the death and autolysis of the cells. The Miners' Pneumonitis Medical Bureau of South Africa has detected no fibrosis of a silicotic type amongst workers in the quarry producing this stone.
Among the miners of Broken Hill (Australia), where the stone contains an average of 12.23 per cent. of free silica and 45.57 per cent. of silicates, the men develop a fibrosis, but of a different type from that due to free silica. The lung tissue of men suffering from this type of silicosis is not so dense as that of men suffering from silicosis due to free silica. Furthermore, the X-ray findings are somewhat different, and the appearance is described as soft. Mavrogordato found that it took six months for the changes described to take place in animals. Gye, in experiments carried out in a somewhat different manner, states that the changes can be demonstrated in about a year. Seven and a half years is the average time of exposure of men in the gold mines of South Africa before simple silicosis can be diagnosed, and the shortest period of exposure is reported to be two and a half years. From the above it may be concluded that the length of exposure to silica dust necessary to cause silicosis varies with the conditions of exposure from several months to several years (Sayer) (see also article "Gold Mines").

The Anti-Dust Campaign in Mines

The anti-dust campaign is based on the following measures:
1. Prevention of formation of dust by wet mining methods (wet drilling; wetting of the sides, roof and bottom of the heading; wetting of the ore; use of sprays and water blasts to alloy the dust after blasting);
2. Good ventilation by mechanical means to replace dusty air with clean air;
3. Physical examination of all miners prior to employment and periodically thereafter to prohibit tubercular men from working underground, thus protecting them from the ill-effects of silica dust and protecting the other miners from the possibility of contracting tuberculosis, since men suffering from silicosis are very susceptible to this disease.

The Broken Hill authorities recommend that blasting should not be engaged in until the end of each shift; that a water jet intended to alloy the dust should be applied after blasting as well as thorough ventilation; that each time after blasting is effected drilling should not be engaged in except after a lapse of thirty minutes (after an hour only where the water jet has not been brought into play but merely ventilated; after two hours only where neither a water jet nor adequate ventilation has been applied); that all drilling should be effected subject to the precautions above referred to.

Adequate ventilation has greatly reduced the occurrence of asthma, as well as that of phthisis amongst coal miners.

It is, finally, necessary to emphasize the fact that wet methods alone are not sufficient for eliminating the dust from the atmosphere of the galleries, ventilation being perhaps the most important factor in this connection. Further, ventilation by means of compressed air alone is not sufficient to eliminate dust from the air in the heading during use of the drilling machine.

Subsequent to repeated research effected by the management in the South African mines, the conclusion has been reached that damp working is an excellent means of combating dust except during blasting. It must, however, be remembered that the air in the galleries often contains a very fine dust which is not susceptible of being detected by ordinary methods. It has also been shown that as far as conditions in South Africa are concerned the dust which has been damped by water spray contains less silica than dust which has not been subjected to this treatment.

These experiments and research prove that water, when used judiciously, forms as a rule the most satisfactory means of combating the dust hazard. According to experiments engaged in by Macarthur and Johnston the quantity of mineral dust per cubic metre was as follows (in milligrams):

The methods of humidification being superior, the quantity of dust has now been reduced to 1.6 mg. per cubic metre (average of thirteen analyses) and even to 1.5.

The laying of dust by the use of special liquids containing colloids or by means of deliquescent or viscous substances has been considered, but it does not appear to have given better results than water. Belger, of Newcastle, has suggested a liquid called after him which contains calcium chloride and gum. Its use is, however, limited to ventilating chimneys where the air is below the point of saturation, the damp air having for its effect the liquefication and elimination of the mixture and the precipitate.

Haldane in 1930, however, reported that whilst methods of humidification had led to decreased risk from silicosis, they have
by no means eliminated that risk and, further, that they present a danger. Humidification favours the development of tuberculous infection and certainly that of ankylostomiasis, except where very strict methods of prevention, often difficult of realisation, are applied. The greatest obstacle to humidification resides in the fact that at great depths the bulb temperature becomes so high that efficiency is seriously interfered with. On this account Haldane has proposed the substitution for methods of humidification of the use of special dusts (shale, clay) projected into the atmosphere by special apparatus.

In the Rhine-Westphalia district, after having systematically applied during a quarter of a century the water-spray system for neutralising dust, there has been recently (1926) adopted a method known as aschiffisation, which assures greater safety, is more practical and less costly.

It is, however, advisable to wet the ore when it is attacked by the heavers and likewise the sides, the bottom and the hanging prior to blasting, as well as the ore prior to loading for transport.

Several types of masks have also been proposed as a protection against dust, but none of them corresponds to the requirements. When it is remembered that the most dangerous particles are between 1 and 2 microns, and that in order to accumulate dust for sampling purposes recourse must be had to sifted sugar, it is easy to understand how impossible it is to construct a mask which at the same time permits of respiration and filtration of dusty air. It has, since, been stated that the Technical Commission for Mines in the Don district (Russia) has adopted a type of mask invented by a worker as a protection against dust and which it is claimed has given very favourable results (1926).

**Dust Explosions**

The getting of coal and ore with a pick, drilling machines or explosives is always extremely dusty work. Further, the energetic ventilation required during this process constantly maintains in suspension a proportion of the dust which is raised by the going to and fro of the workers and of rolling stock.

It is now known that the production and violence of explosions is not to be attributed exclusively to fire damp, but that coal dust plays a very important role in regard thereto.

While a humidity rate of 30 and often of 15 per cent. renders coal dust inflammable (ignitees are usually without risk in this connection) variation in the content of volatile substances is of no practical importance. What is new to this is, that a coal under 11 per cent. is no longer dangerous, and dust explosions do not occur in anthracite mines. The concentration and state of subdivision of the dust have the same effect as the case of any other aerosol (see article "Dusts, Fumes and Smoke").

Explosion does not occur unless the oxygen content of the atmosphere is below 18 per cent. For this reason this limit must not be reduced where methane is present, even in feeble quantity. Ignition takes place at the moment when the explosive wave raises before it the amount of dust necessary for its propagation at a minimum rapidity of 27 km. per hour; when the aerosol contains explosive proportions or a detonating mixture of air-methane; or with the production of a high temperature requisite, for ignition.

The causes of ignition are due to imprudence on the part of the workers, defective lamps, electric sparks, dynamite fuses, etc.

The prevention of explosion and of its propagation involves precautions similar to those to be taken in a factory. For mines there have been proposed in addition: frequent cleaning of the galleries and the creation of dust-free zones to arrest the progress of the explosion (of slight effect); the reduction of the oxygen content of the air to 17 per cent., by application of flue gases (in the absence of methane only — which, however, has the disadvantage of rendering mining work less safe) and the creation of dust-free zones to arrest the propagation rather than to prevent the occurrence of explosions.

Dusting, which is superior to wet working, less costly, and has now withstood the test of long experience, deserves some mention.

Explosion can be prevented by injecting finely pulverised stone dust by means of a compressed-air machine at a rate of about one ton per hour and a rapidity of six metres per second. A cloud of dust hangs in the air for a long time (half an hour); its fine particles become intimately mixed with the coal dust, prevent any sudden rise in temperature and all explosion, and also favour precipitation of dust towards the ground.

This method is also useful after blasting, when the air is super-saturated with dust.

The use of dust in the galleries for the prevention of explosion has met with success in mines in the Dortmund district, but the miners have protested against the method since they see in it a health risk.

The experimental station of the U.S. Bureau of Mines at Pittsburg has studied the suitability of different kinds of dust for rock dusting in mines, and chemical and petrographical research has been engaged in, in relation to coal, quartz (the most dangerous dust from a health point of view), limestone, shale and kaolin dust. From these studies it has been concluded that limestone dust has no more
In eight Japanese mines the temperature varied between 25° and 31° C. and the relative humidity between 75° and 100° C. These unfavourable conditions were further aggravated by the presence of carbon-dioxide which was found to correspond to the following rates: 1 to 3 per cent.: 27 times; 5 to 10 per cent.: 5 times; 10 to 20 per cent., and over: 11 times.

Harrington and Sayers found on investigation of conditions in very deep metal mines in the United States stagnant air of 26° to 37.5° C. with the wet bulb thermometer. The slightest physical exercise caused the workers to suffer from increased blood pressure and fever (pulse 90 and over). Perspiration was very abundant, the miners complained of vertigo, weakness, incapacity for work, nausea and headache. These symptoms were less marked, but there was still increased blood pressure and fever when the thermometer registered 29.5°.

Without entering into details which have already received consideration in the article "Air: Heat and Humidity", it suffices to recall here that it has long been asserted that this vitiated air, especially in mines, reduces efficiency and constitutes a health hazard.

In order to determine adequate conditions of ventilation, air movement and humidity in the collieries, in other words conditions of comfort, it is the current practice at the present time to utilise the katathermometer, although certain authorities have raised objections to its use (see article "Air: Hot and Humid Atmospheres"). Haldane (1924) has studied the effect of humidity and high temperatures in certain metal mines in England. Neville Moss has carried out research both in the laboratory and in coal mines in England (1923), and Harrington and Sayers (1923) in the metal mines in the United States.

Cooling of the mine air by freezing apparatus has been considered by several mines and a plant has been installed by the St. John del Ray mine which cools 60,000 cubic feet of air from 76° F. and 80 per cent. relative humidity to 42° F. and 100 per cent. relative humidity.

A co-operative study of the effect of temperatures, humidities and air movement has been and is still being made under carefully controlled conditions by the Bureau of Mines, the American Society of Ventilating and Heating Engineers, and the United States Public Health Service, and has led to the following conclusions. The body is unable, even at rest, to compensate for saturated atmospheric conditions exceeding 90° F. when there is no air movement; remaining at rest in such an atmosphere in time causes an increase in the body temperature, an increase in the pulse rate and profuse sweating; the extent of discomfort is apparently determined by the pulse rate; subjects complain of being very uncomfortable when the pulse rate exceeds 135 pulsations per minute; symptoms become distressing when the pulse exceeds 160 per minute; symptoms experienced by exposure to higher temperature include restlessness, irritability, headache, itching of the skin and scalp, palpitation, weakness and subsequent fatigue (and over).

A given temperature and humidity rate may involve effects of exposure...
varying with the dry bulb and wet bulb readings and the air movement, varying in other words with the cooling power of the air. Air movement exercises a favourable effect on the body when the temperature is below 98.6° F.; in temperatures higher than that of the body, air movement increases discomfort. There is no advantage to be gained by imparting to the air movement a rapidity exceeding 500 linear feet per minute as far as the cooling effect on the body is concerned.

The zone of comfort is approximately between 62° and 69° F. In this zone the relative effects of the dry bulb and wet bulb temperatures seem to be approximately equal.

The effects of high temperatures may be lessened by: air movement (ventilation) when the temperature is below 98° F.; ventilation to replace warm air by cool air; cooling mine air by freezing apparatus.

The Central Hygiene Committee for Mines and the Coal Miners’ Committee in France have judged it expedient to fix at 6 metres the rapidity of air for ventilation purposes, which figure, except in very exceptional cases, is sufficient for assuring adequate ventilation provided that the air distribution is adequately assured and thoroughly controlled. When the temperature falls below 24° C. there should be a minimum ventilation of 1 metre per second.

The importance of good ventilation in mines from the point of view of efficiency has been brought to notice by the Committee appointed in 1920 to study working conditions in the Rand mines. Orenstein and Ireland, who published the report, have asserted that the working capacity of native miners commences to decrease as soon as the readings of the dry katathermometer fall below 6, and those of the wet katathermometer below 16. When the dry bulb registers 1.5 only and the wet bulb 5, working capacity is said to fall to 55 per cent. of its maximum. Such limits are, however, but rarely met with. Insufficient ventilation in mines is said to be the cause of a total loss of working capacity valued at 21 per cent. Heat and stagnation of the air which prevail in certain parts of the mine are also responsible for cases of pneumonia, which attain annually a rate of 2.65 per thousand for native miners and cause 23 per cent. of the deaths. In fact a miner bathed in perspiration has often to pass from a hot and humid atmosphere, where the dry bulb thermometer registers 2 or 3 and the wet bulb at least 9, to the outside where readings are 10 to 13 for the dry bulb thermometer and 27 to 30 for the wet bulb. Or again, he is obliged to pass through different parts of the mine where there are violent draughts (7 to 9 dry bulb). The miner under these conditions is naturally subject to shivering and exposed to grave risk from diseases caused by chill.

Transition of workers from the hot and damp mines to the outside air causes, according to different climates, lesions of the different organs, which are at times serious, and particularly of the respiratory system. Thus, for example, Murphy insists that the mortality from bronchitis amongst workers in English mining districts is higher than that for women in the same districts. In fact, for every thousand women who died of bronchitis in England and Wales there have been found, for the period 1920-1924, the following figures:

<table>

The influence of atmospheric conditions on the working capacity of miners has been studied in Great Britain by Vernon, Bedford and Warner (1927). They have estimated this capacity in relation to rest periods during work and to the time taken to fill skips of about 500 kilos, the enquiry covering 137 men observed during a period of 96 minutes each. When the wet bulb thermometer registered 19-14 a rest of 7 minutes per hour was enforced; when it marked 7-5 a rest period of 22 minutes. In the first case the filling of the skips demanded 8 minutes, in the second 9.6. It has been calculated that with the most disadvantageous atmospheric conditions efficiency was 41 per cent. lower than with the most favourable.

Atmospheric conditions similarly exert an effect on the incidence of accidents as well as on their severity. In fact in three mine galleries, where there has been reported a serious accident rate of 3.2 with a temperature of 13.7, the wet bulb, 4.8 with a temperature of 11.3 and 4.9 with a temperature of 10.2, Acci-
dent frequency was influenced in like manner. The authorities in question are of opinion that the worse the atmospheric conditions are the greater is the risk to the workers' health.

The authorities in question are of opinion that the worse the atmospheric conditions are the greater is the risk to the workers' health.

Lighting in mines is effected by means of candles, acetylene lamps, or safety lamps lit by oil or spirit, or finally by means of electric safety lamps (portable or otherwise).

**Candle light.** — The luminosity of candles used by miners varies considerably, according to the quality of the tallow of which they are made, the variation extending from 0.6 to 1.10 Heßner lux. The recognised average luminosity is 0.80 lux. The light provided by candles does not remain constant since the yellowish flame is affected by draughts in the mines and by damp atmosphere (in which its brightness is reduced), in short, it is given to flickering even in a stationary atmosphere.

From the point of view of avoidance of eye-strain, two cases may be considered:

(a) the worker carries a candle fixed in an earthenware candlestick placed above the peak of his leather cap;

(b) the worker places the candle opposite him on a wooden ledge, or against the wall or on the ground.

The latter case is obviously unsatisfactory since the glare from the flame is directed into the worker's eyes, whilst with the candle fixed in the cap, the peak of which forms a screen, the worker is provided with better protection.

**Acetylene lamps.** — These lamps fulfill very adequately the requirements of hygiene in mines where it is permissible to utilise a light source with an open flame. They must, however, be screened like the others to prevent their constituting a possible cause of injury to the eyes (see article "Miners' (Coal Miners') Nystagmus").

**Oil safety lamps.** — The original type of these lamps was invented in 1815 by Davy, and with successive improvements in form represented by the Cluny lamp, Boty lamp, Fumat lamp, and the foreman's lamp, the use of these lamps gradually became general in mines.

From the physiological point of view the oil safety lamp (Musseler type) presents the following characteristics: its average luminous capacity is 0.55 lux; at the entrance to the working post its luminous capacity may reach 0.66 lux, but the brilliance of the flame decreases rapidly and at the end of three or four hours its lighting capacity falls to half its original value, and even below that.

The miner has no means of regulating the flame, for it is impossible for him to open the lamp to trim the wick. Further, these lamps on account of the

---

1 According to the report of Dr. Stassen (Liège) on miners' nystagmus (see article "Miners' (Coal Miners') Nystagmus").
use of heavy oil tend to become choked with dirt which interferes with the flow of gas. It should be added further that these lamps smoke, the glass shade thus becoming covered with dust. As the day advances the lighting conditions become progressively worse for the miner, this state of matters being the more detrimental as it exerts its effect on visual organs which are already fatigued.

The flame of the oil lamps presents a further inconvenience due to flickering, this disadvantage being increased since the miner in order to see better is obliged to bring the lamp very near to his eyes. The light produced is reddish-yellow. Oil lamps used in certain mines (Belgium, for instance) are not provided with reflectors with the result that the workers' eyes receive no protection from the glare of the flame.

**Spirit safety lamps.** — The most currently used type of this kind is the Wolff lamp, fed from beneath. The average luminous capacity of these lamps is 1.20 lux, or about twice that of oil safety lamps. Further, they present the advantage of burning comparatively steadily, since with the use of spirit the wicks smoke but slightly and the supply is always regular as long as there remains an adequate amount of spirit in the reservoir.

At the end of an eight-hour working day the luminous capacity of the Wolff is still about 0.88 lux. With the spirit safety lamp the miner can regulate the flame thanks to a screw which turns the wick; he can thus increase the luminous capacity. The spirit lamp is in addition provided with an interior lighter.

The flame of these lamps is yellowish and is unfortunately not absolutely steady, since it also is liable to be affected by draughts in the mines galleries.

In the great majority of cases the lamps in question are not provided with reflectors. Consequently the workers' eyes are not protected against the glare of the flame. Finally, these lamps are not entirely free from the objections made against oil lamps, namely that the glass shade becomes dusty in the course of work involving a certain diminution of the luminous capacity of the lamp. On this account the miner, especially the hewer, is obliged in order to see better to ap-
Electric safety lamps (with storage batteries). — Portable electric lamps are practical for use at the bottom of a mine. They are already used in all coal mines.

From the physiological point of view, however, electric lamps possess considerable advantages over other types. Their luminous capacity is 1.60 to 2.20 lux, and it remains fairly constant during the whole shift.

Their light is steady and clear and when the glare of the incandescent filament falls on the workers' eyes the discomfort produced is not so marked as in the case of glare from oil or spirit lamps. The objection is, however, raised that electric lamps emit more blue rays and even ultra-violet rays than other safety lamps, which fact obviously constitutes a fairly serious disadvantage as regards eyesight. This objection could be met with by the use of opaque glass bulbs.

Reference has already been made in the article "Miners' (Coal Miners') Nystagmus" to the harmful effects of unduly weak lighting and the means proposed to prevent injury caused thereby. It has been noted that in certain countries (United States, for instance) nystagmus does not occur more often amongst miners than amongst the general population.

This is probably due to the fact that in the majority of mines acetylene lamps are used, or that the lamp used is fixed to the miner's cap directing the light on to the work and not causing any ocular discomfort.

This problem, which is of primary interest for other countries (Great Britain, for instance), has been the subject of enquiries and investigations dealt with at length in the article "Miners' (Coal Miners') Nystagmus". Recently (1926) the Industrial Fatigue Research Board has directed its attention to the means to be adopted for reducing the glare from unprotected light sources. It is evident that in dense obscurity a light source even with low luminosity and little glare may be the cause of ocular injury. It is urgent that miners should be convinced of the necessity for using lamps which are heavier than those at present in use but which will provide more abundant and diffuse light. It is to be hoped, moreover, that eventually technical improvements will make it possible to attain this object without increasing the weight of the lamps.

Finally, the management should pay strict attention to the maintenance and charging of the storage batteries, the choice of a good lamp and especially of a good bulb. It is also possible that the colour of light emitted by the lamp may play an important role.

In 1908 Snell drew attention to the importance of selection of workers to be entrusted with the work of detecting toxic gas in the mine collieries. It is notorious that this extremely delicate task is often entrusted to old miners, sometimes victims of nystagmus, and that detection of firedamp is effected by modification of the form of the flame of safety lamps, a form which is characteristic according to the quantity of firedamp present in the atmosphere. Snell, however, found no difficulty in asserting that the nystagmus lesion in a worker and the oscillating movement of the lamp constitute obstacles which hinder him from recognising the slightest modification of the flame, with the result that the alarm cannot be given even until it is too late, that is to say when the quantity of firedamp is already such that it is no longer possible to obviate the risk.

At present electric lamps are coming more and more into use and replacing oil lamps. It is therefore necessary that these new lamps should also replace the function of the former lamps as a danger signal. With this in view technical efforts made to construct simple electric lamps serving likewise for detection of firedamp have recently succeeded (1926) in the construction of a type of lamp containing a small receptacle for oil below the electric lamp. A switch enables the electric lamp to be extinguished and the oil lamp to be lit by means of a platinum wire, the oil lamp being so regulated that a percept of detection of the gas at a content varying between 1½ to 5 per cent.

Another type of lamp which detects the existence of firedamp by sound is constructed on the principle known as "chemical harmonica". It does not provide an absolute guarantee in its working unless the flame is produced in accordance with the principle of the Bunsen burner. The lamp commences to produce sound with a methane content of 2 per cent. As the content increases the sound becomes more piercing and at the same time the flame becomes brighter. It is extinguished when the methane reaches 5 to 6 per cent.

The introduction of electric lamps will lead to the suppression of another source of danger for workers entrusted with the maintenance of lamps, and
for those engaged in factories making paraffin strips treated with phosphorus paste for lighting miners' lamps. These strips consist of a band of metal 2 mm. broad and cut to a length of 45 cm. This band is covered at intervals by a layer of paste with a basis of white phosphorus, known as "Caps", having a width of about 3 mm. The space between two applications of this paste measures 5 mm. and each band holds 42 applications. It is introduced into the lamp by the head lamp man when the oil or spirit lamp is extinguished. The worker by means of an external device turns the paraffin strip with the result that the paste coming into friction with a pointed surface ignites the extinguished wick. It would appear to be technically impossible to replace white phosphorus by red phosphorus since the more violent friction necessitated might present a cause of danger (sparking discharge across the metal strip). Cases of phosphorus poisoning have been notified amongst workers engaged in making these strips, but cases amongst miners or workers in the lamp department of mines have not so far been reported.

English legislation contains certain provisions with regard to safety lamps (Order No. 1055 of 30 June 1926), whilst in France an Order issued in 1925 (9 October) deals with the types of electric lamps permitted for use in lighting mines.

**EXPLOSIVES — ODOURS**

The use of explosives in mines merits quite special attention, not only because they may give rise to accidents, but particularly because certain explosives are more apt than others to liberate toxic gases and fumes. *Liquid air* is also largely used (see article "Air, Liquid").

In the United States a study of explosives has been effected by the Bureau of Mines, which has designated as "permissible" certain types fulfilling the requirements of safety demanded for work in mine galleries.

In the composition of gases evolved during the outbreak of fire, the content in combustible gases (carbon monoxide, methane, hydrogen) is low. At the outbreak of fire, carbon monoxide, hydrogen and hydro-carbides are given off, later large quantities of carbon dioxide and a little oxygen, and finally, combustible gases and large quantities of carbon monoxide. Towards the outbreak of fire the gases formed are extremely rich in explosive gas (20 per cent.).

The use of explosives, the slow combustion of veins of coal, etc., liberate large quantities of carbon monoxide. Nitro-glycerine, in the form of dynamite produces a gaseous mixture containing up to 35.9 per cent. of carbon monoxide (Levin). Repeated explosions, especially in narrow and badly ventilated mine galleries or tunnels, and dust explosions constitute the most frequent cause of evolution of carbon monoxide.

During outbreaks of fire, extinguishers are often used. These should always comply with certain safety principles. In this connection the following recommendations have been drawn up: the use of extinguishers shall be prohibited in all places where there is close and vitiated air, and in paint shops (machines running on oil) and in galleries through which passes air that has already ventilated other galleries or where the atmosphere presents a high humidity rate. Their use may be permitted in well-ventilated galleries where the humidity rate is low, and where air is provided in sufficient quantity to dilute the gases given off. Extinguishers, however, shall not be employed except when there is every guarantee that the air vitiated by the gases given off will not penetrate to places where workers are engaged. These precautions are all the more necessary since extinguishers containing carbon tetrachloride (see that article) may give rise to highly toxic products of decomposition.

Finally there should be mentioned the use of certain odours as alarm signals. Thus, for instance, the introduction of non-toxic odours into compressed air has demonstrated that human life can be saved by the adoption of this method and many disasters avoided. The method in question may also be adopted with a view to detecting escapes in the gas mains, steam piping, etc.

The most adequate measures possible should be taken with a view to the dispersion of smoke and fumes in order to reduce as far as possible all inconvenience in the neighbourhood and possible harm to vegetation. Several countries have issued legislative provisions relative to the prevention of danger due to electric short circuits in mines.

**GAS FROM MINE DUMPS**

'Dumps heaped around mines, and especially around coal mines, often contain dangerous gas due to slow combustion fostered by humidity from rain, and to heat generated by the pressure
of the superimposed mass of material. Since the dump always contains combustible substances — and notably coal debris — mixed with all kinds of impurities, the gases given off comprise hydro-carbides, sulphur and carbon dioxide, carbon monoxide, etc., gases which on coming into contact with the atmosphere surrounding the dump may be productive of explosive mixtures.

When the prevailing wind facilitates penetration of air into the interstices of the material composing the dump, the oxygen thus introduced fosters combustion and likewise contributes to the liberation of toxic gases.

A distinction has been made between those dumps which have not been moved and which are considered dangerous and others which have been removed to another place and which in the course of this operation have been thus ventilated, subsequent to combustion. By reason of this fact the latter are considered less dangerous though they may have given rise to serious explosions in the course of removal to another site.

It is also considered that very old dumps represent less danger, since sufficient time has elapsed to allow of entire combustion taking place and of all the gas being liberated. Experience has, on the other hand, shown that such dumps are in reality excessively dangerous as, for instance, in the case of a dump at the Hörder coal mines in Schleswig, where during work an explosion occurred with eleven victims out of 40 workers engaged (Philipp).

The gases liberated from dumps may also set up poisoning.

Finally during the work of removing the dumps to another site workers are exposed to risk from falling material which may cause contusions, fractures, and sores, where there is ignition of gases, also burns. The importance of measures of individual protection is confirmed by the following fact. A case occurred in which a worker by reason of adequate protection in the matter of thick clothing and high boots, suffered only very slightly from burns on the exposed parts of his body during the work in question.

Amongst the measures recommended for the prevention of accidents due to explosion, poisoning, and burning, the following are particularly worthy of attention: strict supervision of work at dumps; wise and frequent instructions for the workers relative to the dangers involved in this work; prohibition of working in a dump or in a tunnel traversing it without provision of a safety rope. The latter should be fixed in such a manner as to permit of the worker detaching it if necessary; recourse should be had to the use of danger signals. Workers should be informed before commencing work of the situation of refuges where they can take shelter in case of an explosion or waves of gas. In indicating such places of refuge, account should be taken of the direction of the wind. Boots and heavy working clothing should be provided as protection against fire.

For “First Aid”, see that article.

**Personal Hygiene**

**Personal hygiene** in the mining industry is of capital importance. It is primarily necessary to furnish workers with working clothes, caps and where necessary suitable boots (in very damp mines, for instance).

It is also indispensable that workers are provided with drinking water complying with the conditions laid down by the public health authorities. Drinking water used in mines may be contaminated at its source, during distribution, and even in the course of its use. Where it is not possible to have a supply of pure drinking water, recourse must be had to sterilisation by boiling or by treating it chemically with calcium hydrochloride, etc. Small filters such as household filters are of little value. They retain the solids, but do not remove disease germs. The best method for distribution of drinking water in mines is by bringing it in water mains directly from the source to the place of distribution.

If containers such as barrels or kegs are used for taking water underground, they should be maintained in a thoroughly clean condition and be subject to constant supervision with a view to avoiding contamination. Any ice used to cool water should be made from distilled water or from water the source of which has been approved by the public health authorities, unless where the ice and the water to be cooled are not brought into contact.

The use of common drinking cups should be prohibited, and sanitary drinking fountains installed in the mines (see article “Personal Hygiene”). Each worker should be provided with a drinking cup.

A study has been made in regard to the best type of drink for satisfying thirst, which will at the same time compensate the considerable loss sustained by the body during arduous work. Good results have been found to ensue from the use of salted water (potassium chloride 120 grm., sodium chlor-
Cloakrooms with facilities for changing clothes, lavatories, and especially douche baths, are absolutely necessary in mines in the interests of good personal hygiene. Provision should also be made for drying clothes in order to protect the workers from a frequent cause of rheumatic affections.

The installation of pit-head baths is now compulsory in Germany, and in general use in France and Belgium. In Britain their use has been unanimously recommended by the miners' committees; nevertheless, mine owners have opposed the installation of these being made compulsory as long as the miners are under no compulsion to make use of them. The British Miners' Federation made a similar declaration, but it did not propose the support of members. The Act of 1911 makes the installation of bath rooms compulsory provided two-thirds of the workers vote therefor. It also compels the workers to provide the half of the cost, the maximum contribution being limited to 3d. per week per worker. This rate being absolutely insufficient to cover the half of the expense, the regulation in question has remained in general a dead letter.

A type of installation used in England answers the following description: 50 bathrooms opening on to a central cloakroom where the workers' clothes are attached to endless chains reaching from the ceiling to the floor and furnished with hooks; a numbered chain closed by means of a padlock, of which he is given the key, is furnished to each miner; all the bathrooms are heated with hot and cold water; radiators are placed at the level of the flooring to permit of drying or airing clothes; and there is a special room for drying very wet clothes. The workers furnish their own soap and towels, and pay a weekly subscription of 6d. for cost of maintenance. It is calculated that in the establishment in question 60 to 70 per cent. of the 2,900 miners make use of the baths. 70 douche baths provide bathing facilities for 420 men per hour, 7 minutes being allotted to each man.

At the end of the week each worker takes home his working clothes to have them washed, and the bathing accommodation receives a thorough cleaning. The establishment is managed by a mixed committee consisting of employers and workers' representatives. The Miners' Federation, which favours the establishment of pit-head baths, is, however, of the opinion that the cost of their installation and maintenance should be entirely borne by the industry. The workers are, however, opposed to the creation of an establishment of this kind near the mines, and it is considered that active propaganda would be required in the district to convince the miners and their wives of the advantages to be gained from its installation.

Whilst the problem of providing privies is comparatively easy of solution outside the mine, it presents certain complications as regards conditions in the underground workings. Installations of this kind should be available for the workers fairly near to their working posts and so disposed as to avoid the possibility of their becoming sources of contamination in the mine.

Latrines should be situated near the principal ventilating shafts, and the walls and roof of these should be whitewashed. Under no circumstances should they be allowed to get into a filthy state. Tin pails should be so constructed that there is no possibility of disease propagation by flies, rats, mice, or by water. Everyday experience has shown that inadequate or badly regulated devices of this kind facilitate the development of intestinal infections, particularly typhoid, dysentery, ankylostomiasis and other parasitic infections; that a sewage system is not practicable in most mines; and that in consequence it is essential to enforce the use of airtight receptacles, access to which is impossible for animals. It is advisable that a disinfectant should be placed in each receptacle: caustic soda (at 10 per cent. recommended by Chapman, Australia); cresol and other similar disinfectants are also good.

Tin pails or latrines should be situated at convenient points. They should be well lit, and their surroundings maintained in a thorough state of cleanliness.

Movable tin pails or latrines (trucks) have been used in many mines with satisfactory results (United States). Whatever the type used, adequate and constant supervision is always required with a view to good maintenance. A man should be entrusted with this supervision, and should undertake it at regular intervals.

All mines should have convenient latrines in sufficient number and hygienically installed, but it is certain that they cannot be maintained in accordance with the best principles of hygiene unless the miners have been trained in habits of cleanliness.
Care should be taken not to contaminate river water or subterranean water, and to this effect adequate means of filtering and purifying waste water from the establishment should be assured.

MEDICAL CARE AND SOCIAL WELFARE

Medical care in mines is one of the most important factors in assuring the health of the staff and securing the best possible efficiency. It has for its object not only to organise and provide first aid in case of catastrophes, accidents, or illness, but also to organise and carry out medical examination and thereafter periodical medical examination of the miners. The campaign against ankylostomiasis constitutes, for instance, one of the triumphs of preventive medicine.

The advantages of the collaboration of a trained doctor in the management of a mine have been often proved by practical experience. The participation of a doctor in the campaign against industrial accidents and their consequences, against illness and invalidity (more particularly against disease connected with the exercise of the miner’s occupation), in the organisation of measures of hygiene to be adopted with a view to securing for the mining population a maximum of comfort, has now been recognised by the industry, which, in several mining centres in Belgium, Germany, Great Britain, etc., can boast welfare schemes and medical organisations (dispensaries, etc.) of far-reaching importance.

The data provided relative to the activity during 1905 of the dispensary “Espérance” at Montégnée (Liège) are interesting. This dispensary comprises a service dealing with medical examination on entrance, supervising the employment of tubercular subjects and those predisposed to tuberculosis, providing treatment for them, as likewise for throat, nose and ear cases. It collaborates in the application of regulations concerning health supervision of young persons issued in virtue of certain laws. It keeps a register containing a file for each worker, and interests itself in their vocational guidance. Another important service is that for first aid in case of accident and rescue work. Not less important is the service concerned with sickness: classifying, examining and passing on to the competent technical service unfavourable reports concerning chronic and occupational disease, and respiratory disease. A fourth service is concerned with industrial hygiene, and effects work of immense importance. It might even be designated “hygiene and public health service”. This service, in fact, deals not only with questions affecting the staff, but also with all sorts of problems affecting their families: workers’ dwellings, infant care, hostels for foreign workers, medical treatment for women, propaganda, etc.

If proof were required of the value of a social service of this kind, sufficient evidence thereof is furnished by figures provided by Stassen: the mortality per annum and per 1,000 workers has fallen from 1.8 in 1906-1909 to 0.9 in 1910-1914 and to 0.3 in 1919-1925, whilst in the neighbouring collieries, which had no service of this kind, there was in 1919-1925 1 death per 1,000 workers and per annum.

The average number of days of unemployment per 10,000 days of work was 38, whilst in the other collieries of the Liège basin it amounted to 105. Costs per head per annum are represented by 45 Belgian francs and in the other collieries by 92 Belgian francs.

Whilst in 1907 370 working days per annum were lost by each working miner on account of accidents, in 1920-1925 this figure had been reduced to 1, or in other words 4 days per worker per annum had been gained, working out to a total gain of 40,000 working days per annum which exceeded 1½ million francs. (In reality the workers realised a gain of about 800,000 francs taking an average daily wage of 20 francs, the company about 320,000 francs by reason of the fact that there was no legal obligation to pay half-time rates, whilst the company stood to gain a further 200,000 francs by reason of the extra working days, at the rate of about 5,000 francs for 1,000 days.)

The competent technical service undertakes the maintenance of respiratory apparatus and masks and all such apparatus as compressed-air devices, haulage apparatus, transport facilities, etc.

It is well known that infection of external lesions is particularly frequent amongst miners and is often the cause of long illnesses or even death, which in many instances can be avoided by adequate first-aid treatment provided by a trained staff (nurses), or, where there is a very large staff, by a permanent ambulance service including a surgeon or qualified doctor. The ambulance rooms are situated near the pit-head in a well-selected spot. It is often possible to reserve a room for this purpose in the building which contains the cloakrooms.
Safety and Welfare

The above measures, to give effective results, should be supplemented by rescue and safety services, generally run in connection with the fire brigade for the mine. It is especially the training for instruction and equipment of rescue workers should be provided with all requisite safety devices against fire and accident, and should have a special training ground. Training should be carried out in galleries corresponding as nearly as possible to the actual conditions in mines, in an atmosphere charged with steam, a temperature reaching 50° C., toxic fumes, etc. In Germany, for instance, a special gallery has been constructed for the study of reactions between explosives, fire damp and coal dust. Special lectures should be given with a view to instructing skilled miners in accident prevention, etc.

Measures of social welfare for miners are similar to those for workers in general: see articles on Social Welfare. Cheap workers' dwellings, gardens, hostels for single men, recreations, provision of food-stuffs at a reasonable rate, classes in domestic science, etc., all represent activities which the industry, the State, or both together have in some cases already engaged in or ought to engage in more generally in mining districts.

Legislation

It is difficult to summarise even briefly all legislative provisions in regard to the health and social welfare of miners issued in the various countries. In general, it may be stated that the mining industry has in most countries been made the object of special legislation, the application of which is under the authority of a special inspection service (Mines Department). However, certain measures which are strictly medical come within the control of the medical inspector (in Belgium, for instance). The introduction of safety lamps; protection of women and children, and, ultimately their exclusion from work underground; control of plans for mines, ventilation, especially with a view to avoidance of explosions; measures of safety; the use of explosives, the danger from dust and firedamp explosions; the length of the working shift; the installation of lavatories and douche baths; the application of water in certain processes of coal-getting (drilling, etc.); the notification and later compensation of certain diseases to which miners are liable; the wearing of masks and breathing apparatus; the organisation of rescue work in the case of accidents; testing of eyesight for certain categories of workers (* firemen*, etc.) — these all represent the principal and successful stages in the progress of legislation in regard to work in mines.

Amongst the States which possess a Mining Code and often a series of regulations dealing with the different matters above referred to, the following may be quoted:

**Measures of social welfare for miners** are similar to those for workers in general: see articles on Social Welfare. Cheap workers' dwellings, gardens, hostels for single men, recreations, provision of food-stuffs at a reasonable rate, classes in domestic science, etc., all represent activities which the industry, the State, or both together have in some cases already engaged in or ought to engage in more generally in mining districts.
underground work the following limits have been established: Nova Scotia, Portugal, Venezuela, 12 years; Germany, Italy (when the coal-getting is mechanical), 13 years; Australia (Western Australia (coal mines), New South Wales, Queensland), Austria, Belgium, Bulgaria, Canada (Saskatchewan), Ceylon, Great Britain, Hungary, India, Ireland, Italy (when the coal-getting is not mechanical), Japan, Yugoslavia, New Zealand, Tasmania (coal mines), 14 years; Canada (British Columbia (coal mines), Quebec), France, Poland, Sweden, 15 years; Australia (Western Australia) (metal mines), Canada (Alberta), Holland, Luxemburg, Norway, South Africa, Spain, Tasmania (metal mines), 16 years; Australia (Victoria), China, 17 years; Argentina, Australia (South Australia), Canada (Ontario), Chile, Peru, and Rumania, 18 years.

In the United States legislation is very complicated since it is different for each State. It may be said in a general way and as an instance of this that 23 States have fixed the age of 16 years as the minimum age for admission to mines and quarries, whilst in others this limit is subject to certain exceptions. In four States only, young persons under 16 years of age are admitted to work in mines.

Belgium issued in 1924 (17 October) an Order regulating the use of explosives in mines, and Great Britain Welfare Orders No. 790, dated 20 August 1927, 1929, and 1930, with the same object; China on coal No. 308, dated 5 May 1923, dealing with accident prevention, and another, No. 349, dated 12 May 1923, on work in mines; in Western Australia the Miners' Phthisis Act was amended in 1925 (31 December) (Regulation of 16 March 1927); and in the Gold Coast an Order on native labour in mines was issued on 2 October 1925; in New South Wales the Act of 1 March 1927 deals with compensation for pneumoconiosis and tuberculosis and the Union of South Africa issued on 27 July 1925 an Act No. 35, codifying and amending the Acts relative to miners' phthisis and on 8 March 1926 a Govt. Notice, No. 401. Examination with a view to the exclusion of any workers suffering from tuberculosis or other contagious diseases was enforced by Western Australia in 1926.

For further data relative to legislation see articles "Miners' (Coal Miners') Diseases," and "Miners' (Coal Miners') Nystagmus.

1 In certain countries women are also allowed to work in the mines, but it should be noted that arrangements for their progressive withdrawal from this work have now been under consideration for some time. Thus, for example, the average number of adult women engaged in the coal mines of Bengal was, in 1926, about 8,000 underground and 5,000 (in 1925) at the surface. In the provinces of Bihar and Orissa the number was respectively about 19,000 and 12,800. In the mines of the Central Provinces of India the number only reached 1,472 underground and 897 at the surface. An Indian Act (1929) prohibits women working in mines. Japan is also in course (1929) of eliminating underground work (mines) for women and young persons (under 16 years of age).

Dr. R. Sayers

(Washington.)
Mirrors

The manufacture of mirrors consists of two phases: the preparation of the glass and the manufacture of the reflecting mirror.

So far as the preparation of the glass is concerned, it is necessary to begin with crude glass of special composition with an excess of silica. The glass must be perfectly transparent, without the presence of any colour, and as it is a little soft, it is necessary to give it a hardness of about 20° Reaumur, without passing through the formation of air bubbles, into the glass, which is well cleaned and dried, and is open to give a free passage to the air.

The glass is ready about twenty to thirty days later. It is then run into a drain running round the table. It is washed with distilled water, and the operation is repeated if it is desired to obtain a richer film. It is then slowly dried at a temperature of about 28° C.

The silver nitrate solution which is used is made alkaline by ammonia, which has the property of dissolving the silver oxide thus formed in an alkali medium. Use is made of the following as reducing agents: formaldehyde (Liebig), essence of cloves and thyme (Drayton), essence of camomile (Wagner), sugar of milk (Liebig), glucose, nitromannite, tartaric acid, etc.

In the process commonly used (that of Brossette) the deposit of silver is obtained by heating to 40° C. a solution of silver nitrate with tartaric acid and ammonia.

After drying, the layer of silver, the thickness of which is never more than 1/16,000 mm., is covered with a lacquer (gum lacquer, etc., dissolved in alcohol) and a layer of varnish (benzene, turpentine, linseed oil, resins, etc.).

To prevent blackening of the glass which is sometimes produced by the action of sulphuretted hydrogen, in spite of the protecting varnish, use is made of a glass slightly tinted rose or blue, or of a process (Lenoir process) whereby the film of silver is partly replaced by a layer of silver amalgam. The silvered glass is washed and sprinkled with a weak solution of double cyanide of mercury and potassium. The silver is partially dissolved in place of the mercury, which latter, becoming free, forms an amalgam with the silver which is white and adheres firmly to the glass. This reaction is activated by powdering with zinc dust.

Mirrors are also made with platinum (chloride of platinum) dissolved or suspended in lavender essence. The image is reflected directly by the platinum, without passing through glass. These mirrors are used for small objects in the ironmongery trade because of their coloured tint, for mir
use of small size and as electric lamp reflectors. Gilded mirrors are also made, known as Venetian or Nuremberg mirrors, etc.

Sources of Danger

Use of an amalgam in making mirrors exposes the workers to mercurial poisoning, either from direct contact or dust or inhalation of fumes. Old enquiries (Renk, 1889) are said to have shown that a workman in an eight-hour day inhaled 4.5 mg. of mercury in the form of fumes as well as dust, the mercury content of which over a period of eight hours per person might reach 2.5 mg. Intoxication is further favoured by particles of mercury adhering to the clothes, a danger to which not only the worker himself is exposed but also those persons in contact with him. The working clothes of a man using amalgam may contain more than 2.5 grm. of mercury and clothing which is smooth and close fixes the element more easily than others (Renk).

Risk exists during the handling of mercury (by carrying the troughs, during immersion, and recovery of the tin contained in the residue and heating the amalgam). Scrapping off the amalgam from old mirrors also exposes the workman to the risk of mercurial poisoning.

In the manufacture of mirrors by the use of silver nitrate and ammonia occupational risk is infinitely less than in the old method with mercury. Use of the cyanide solution to obtain a final coat of silver (Lenoir process) constitutes no risk if the workmen observe the elementary rules with care. On the other hand manipulation of the ammonical silver solutions may give rise to accidents. Thus an explosion occurred (in 1928) in a mirror factory where the silver solution was obtained by dissolving 40 grm. of silver nitrate in 100 grm. of water, adding 200 grm. of ammonia or a solution of 80 grm. of caustic potash in 200 grm. of water (solution 1). The reducing liquid (solution 2) took the form of an ordinary solution of sugar candy in dilute alcohol. Solutions 1 and 2 were cooled and filtered and then mixed and spread and diluted up to 10 litres. During work one summer a concentrated mixture had, accidentally been prepared beforehand, and on the introduction of caustic potash a precipitate was formed (fulminate of silver, silver amide, silver nitride) which had, dried, by evaporation. Organic dust coming into contact with this precipitate brought about an explosion, happily when no one was present (W. Meyer).

Silver nitrate causes pigmentation of the skin, nervous and digestive troubles, etc. Workpeople often use cyanide of sodium to remove the black pigmentation from the skin. In many American mirror factories, this preparation is placed at the disposal of the workers, who are unfortunately ignorant of the danger of the cyanides. The workman takes the product up in his fingers, rubs the discoloured areas on his skin and, if his hands are not then carefully washed with soap and hot water, a little of the cyanide remains on the skin or under the nails and so gets into the mouth (during eating or smoking, etc.). McMahon, of New York, in 1925, reported several severe cases of cyanide poisoning in mirror factories from this cause.

Statistics

In spite of the decreasing importance of the making of mirrors with a tin amalgam, it is interesting to cite by way of illustration some figures as to the ill effects the process had upon the workers. Between 1879 and 1883, 123 cases of mercurial poisoning in a working population of 170-180 were reported from Fürth (Bavaria). In 1885 out of an average number of 182 workpeople, mercurialism had caused 2,864 days of incapacity from work during the first five months and 1,210 days during the remaining seven months.

In general, the number of cases of mercurial poisoning increased in proportion to the number of years of employment. Thus, during the first and second years 21 per cent. of the workers fell ill, while from the second to the sixth year the percentage was sixty-one. After a certain length of time, however, the cases of poisoning appeared to diminish; they numbered 15 per cent. among workers with a duration of work varying between six and ten years and 3 per cent. among those employed for ten to seventeen years.

Cases were reported even within the first fifteen days of work, especially among women (80 per cent.), among whom there was a noticeable frequency of tuberculosis, miscarriages, combined with a high infantile mortality (65 per cent.). Finally, mercurial cachexia often appeared as early as the first year.

Hygiene

Adequate measures of hygiene have diminished the dangers notably. These have centred on re-arrangement of the workrooms and tables on which the process was carried on. Legislation requires at least 40 cubic metres of air per person, with locally applied exhaust ventilation for the removal of
the mercury vapour; duration of work limited to eight hours in the winter and six in the summer, and cessation of work whenever the temperature of the workroom exceeds 25° C.; medical examination every fortnight to detect the first symptoms of poisoning; installation of cloakrooms, washing accommodation and canteens; the wearing of overalls, etc.

In the various manipulations of mercury entailed, direct contact should be avoided as far as possible by using wads fixed to the end of rods such as were used already in the second half of the nineteenth century in the workrooms of St. Gobain, Cirey and Chauny. The mercury running off from the tables requires to be collected in closed receptacles, and the cleaning of all objects that have been in contact with the mercury (filtering cloth, purifying apparatus, etc.) should be effected by shaking them in an agitator in a closed machine.

In order to prevent risk of explosion in silvering, work should not be done with concentrated liquid nor with one that has been prepared some time beforehand. If the precipitate separates from the mixture, it should be redissolved by the addition of ammonia. The filters used with the silver solution should never be allowed to dry and all work should be done as far as possible in the absence of dust. In workrooms where varnish containing hydrocarbons is used, the floors should be impermeable and the ventilation adequate.

Openings on to a public road or neighbouring property should be kept closed. The varnish should never be applied in artificial light; it should be dried in a room separated from the silvering workrooms. If the varnish is made in the factory the work should be done in a special place constructed of non-inflammable materials. Materials necessary for the preparation of the varnishes should be kept in a special place to which access should only be allowed by daylight and where every possible precaution is taken against the risk of fire or explosion. The effluent from the factory should be neutralised before being allowed to pass into streams.

LEGISLATION

Women, children and young persons should be excluded from all processes in which dangerous materials are used (dangerous from mercurial poisoning, poisonous dusts, etc.). Compulsory notification of mercurial poisoning among glass polishers, and mirror-makers is enforced in the Netherlands. Compensation for mercurial poisoning is granted to workers in Italy, and in countries which have ratified the Geneva Convention (1925) and in those in which poisoning by mercury is scheduled under the Workmen’s Compensation Acts (see article *Mercury*).

***

**Molybdenum**

French: Molybdène. — German: Molybdän. — Italian and Spanish: Molibdeno.

Molybdenum (symbol MO) is a rare element found in wulfenite (PbMoO₄) and molybdenite (MoS₂). After preliminary crushing, the ore is ground, passed through washers, grading machines, and subjected to the floating process. The scum, containing 15 per cent. of molybdenite, is taken up by washing and grading machines. The concentrates obtained at 40 per cent. are thickened in a filter and the humidity reduced by steam heating. The concentrates are often despatched in jute sacks lined on the inside with strong paper, or, where it is a case of foreign export, in barrels. A mine worked in Colorado is situated at a height of about 3,400 metres.

The rocks used as ore in general contain hardly over 0.7 per cent. of Mo sulphide. They have therefore to be enriched by mechanical means. The enriched ore used for the extraction of Mo contains 80-97 per cent. of sulphide.

The ore is transformed by roasting into oxide (MoO₃), which, heated in a current of hydrogen or in an electric furnace with carbon, gives metallic molybdenum. The latter is a grey powder, giving, at a very high temperature, a molten mass with a silver aspect.

Oxide of molybdenum is used in the manufacture of filaments for incandescent lamps. Winkler noted on the hands of workers handling these filaments, bluish stains, which he considered to be due to molybdenum dust which had penetrated into the skin and become oxidised.

After preparation of metallic-molybdenum in a sufficiently active form, it is submitted to the action of carbon monoxide at a minimum pressure of 150 atm. and at a temperature of about 200° C. At a pressure of 200 to 250 atm., there is gradually formed a very feebly quantity of carbonyl crystals, the chemical properties of which are similar to those of the other carbonyls. The oxidising agents attack it rapidly.
with the liberation of carbon monoxide (Mond). In 1924 Karantassis and Pradier made experimental studies in regard to the toxicity of molybdenum in the state of molybdate of ammonium. By way of the gastric system, the molybdate causes anorexia, colic, uncontrolled movement, trembling and dyspnoea. The molybdate injected is eliminated in the faecal matter and urine. The molybdenum is found in the lungs, the blood, the liver, the kidneys, the stomach, intestines and bones, etc.

The salts of molybdenum act as slow poisons and cause death, with symptoms of asphyxia. Their toxicity is not great, but they may produce chronic poisoning by accumulation. Molybdenum is less toxic than tungsten, which fact is in accordance with their respective atomicity. The toxicity of tungsten and of molybdenum is higher than that of chrome compounds. As far as concerns industrial practice, molybdenum has relatively slight toxic action, and authorities on the subject even consider it harmless (Loewy, Lehmann, Fischer). Its power of injuring the nervous system and the liver is not considerable except when in combination with carbonyl.

No legislative measures exist in regard to the handling or manufacture of molybdenum.

***

Mother-of-Pearl

French: Nacre. — German: Perlmutter. — Italian and Spanish: Madreperla.

Mother-of-pearl or nacre is the name given to the inner part of the shells of the large marine bivalves — *Avicula (Meleagrina) margaritifera*, *A. macropetra* and *A. fucata* and others. They are chiefly found on the coasts of Ceylon, Manilla, Cuba, Panama, the Gulf of California, the South Sea Islands, and North-West Australia. They are obtained in the latter country by dredging rather than diving. The mother-of-pearl is more accurately the inner portion of the shell lining, formed of thin layers of superficial membrane and limestone secreted by the oyster and having a smooth iridescent surface. Gussenbauer investigated chemically and analytically the composition of the inner layer of the mussel shell and found it to consist chiefly of carbonate of lime and an organic substance known as "conchiolin".

The largest consumption of mother-of-pearl is in the button trade. It is used also for knife handles (fruit and dessert knives and forks), pocket knives, fans, lorgnettes, opera glasses, ornamental inlay and fancy goods in general.

The shells are first cut by means of a circular saw, usually in a damp state. The shells are thereafter plunged into hot hydrochloric acid and pumice stone is subsequently applied.

The next stage of the work differs according to the product. For opera glasses the shell is next ground with sand on a wet grindstone; thin plates of the material are then glued together and again ground on a corundum grindstone. All these operations are performed in a wet state and only polishing is done dry with emery paper on a cloth buffer. The head for the glasses is worked on a lathe and at this operation much dust is evolved.

For flat buttons mother-of-pearl is cut into rounds, then worked successively on a turning lathe and a boring machine. The buttons then pass to an earthenware drum containing water and are subsequently placed in pots containing peroxide of hydrogen and these pots are allowed to stand in water which is heated. The buttons are finally polished with sawdust and stearine.

The chief source of risk is constituted by the extremely fine dust liberated during all processes, whether wet or dry (Birge and Havens).

Pathology

As early as 1869 Englisch described an affection characterised by osteitis (found amongst young workers) which was later designated "Conchiolin osteomyelitis" or "Mother-of-pearl workers' osteomyelitis". Hirt (1875) regarded the trade as a highly dangerous one. Another authority states however that workers handling real mother-of-pearl are but little affected. Conditions were subsequently studied by Gussenbauer (1875), Weiss (1885), Fischer (1888) and others.

The etiology is still somewhat obscure, though the symptoms are commonly attributed to the constituents of the dust, which is believed by Gussenbauer to set up embolic processes in the bone. Gussenbauer speaks of this peculiar affection of the bones as due to "conchiolin", an organic substance present in the shells, or more exactly to the absorption of carbonate of lime from the shell particles inhaled. Levy blames the sludge from the grinding operations and its contents, viz. organic matter clinging to the outer surface of the shell. Poicaré remarks on the advisability, in seeking the cause of considering the influence of organic particles in a state of decay and also the composition of the mineral content, while Levy suggests that the disease may be due to pyogenic organisms.
contained in the water of the grinding trough. A number of cases of mother-of-pearl workers’ osteomyelitis described chiefly by French and German authors amounted to 32 in 1907: Englisch 6, Gussenbauer 6, Weiss 11, Fischer, 2, Levy 5, Tridon and Broca 1, and Teleky 1 (a single case amongst 150 mother-of-pearl workers examined in Vienna). Single cases have also been recorded from time to time in the annual reports of hospitals in Vienna, but such cases are now much rarer. The above-mentioned cases, with the exception of those cited by Levy, affected workers between fifteen and twenty years of age. In an enquiry conducted in Bavaria in 1909 Koelsch did not meet with a single case. Birge and Havens (1930) refer to the disease, but make no comment in regard thereto. Oliver found no confirmation of the existence of such a disease when examining the mother-of-pearl workers in the shops of Sheffield where grinding was done wet. Gerbium in 1927 carried out an investigation in a factory for the manufacture of mother-of-pearl goods without finding any case of osteitis. Also he was able to ascertain that no doctor in the district, in which the factory had existed for nearly a century, had met with any case of osteitis. In 1928 Bernstein reported a case of periostitis and infectious disease of the lower jaw and a case of inflammation of the metatarsus affecting a worker aged eighteen whose father, likewise a mother-of-pearl worker, had suffered from the same trouble in his youth.

According to Weiss, who had examined twelve workers suffering from the disease, osteomyelitis commences with violent rheumatic-like pains involving thickening of the bones after one or several weeks, accompanied by fever. The long bones are chiefly attacked, but bone plates may also be involved. The swelling usually commences at the end of the diaphysis and spreads towards the centre of the bone. Towards the epiphysis it ceases suddenly. The nearest joint is therefore only indirectly involved or not at all. The clinical picture is that of a subacute osteomyelitis accompanied by osteitis and periostitis of the ends of the diaphysis. The soft tissue covering of these is mostly unchanged or only slightly swollen. The scapula is often affected at the lower corner, and the ulna and radius mostly at the upper end. It is curious to note that the lesion never affects the first metacarpal and metatarsal bones while it commonly attacks the others.

Cases have also been reported in which the affection was localised in the jaw bones and bones of the lower limbs. The symptoms would appear to indicate the second stage of ossification, namely fusion of the diaphysis starting preferably at the point where ossification proceeds most rapidly. This is also borne out by the fact that the victims of the disease are in most instances very young. However in five cases described by Levy four were over twenty-five years of age and the oldest was thirty-one. After swelling and pain have lasted some time (several weeks) they gradually die down and disappear entirely, though in certain exceptional cases a permanent thickening of the bone remains. Opinion as regards development of necrosis of the bone appears to be doubtful.

Differential diagnosis is facilitated by the characteristic seat of the affection taken in conjunction with the patient’s occupation. Mother-of-pearl workers are also very much exposed to the risk of chronic diseases of the respiratory system — cold, catarrh, bronchitis, and especially to pulmonary tuberculosis.

Genkin reported in 1931 two cases of asthma affecting two workers which he had an opportunity of noting in Moscow, of whom one was a turner and the other engaged on sawing mother-of-pearl. Attacks characterised by fits of coughing, and air hunger obliged the victims to leave their work. But these symptoms disappeared on cessation of work only to resume as soon as the workers again became exposed to mother-of-pearl dust. From the pathogenic point of view, Genkin attributed great importance to the constitution of the workers in question, both of whom might be described as the neuropathic subjects of a vagotonic type.

As is revealed by enquiries effected by Teleky, Bann and Götzl (1907), Koelsch (1909), etc., the individuals in question were mostly weak, undernourished, pale and unfit for military service on account of their general health. The reason for the very high incidence of pulmonary tuberculosis amongst such workers may be sought in the working conditions (low wages, small badly ventilated workrooms without adequate dust exhaust systems), by defective posture causing frequent curvature (kyphosis) — this through standing on one foot and working the latex with the other — flat foot and varicos veins, etc. Of 390 deaths reported between 1895 and 1905 amongst button makers (mother-of-pearl workers were not given separately) who
were members of the Vienna Sickness Fund, 272 (69.7 per cent.) were due to tuberculosis, and amongst 150 mother-of-pearl workers examined in 1907, 93 only had healthy lungs (Teleky). Out of 127 cases studied by an insurance company, 48, or 37.8 per cent., died of pulmonary tuberculosis and 14, or 11 per cent., of other affections of the respiratory passages (Birge and Havens). Of the 20 mother-of-pearl workers examined by Koelsch, 8 showed infiltration of the apices of the lungs.

Out of 127 cases studied by an insurance company, 48, or 37.8 per cent., died of pulmonary tuberculosis and 14, or 11 per cent., of other affections (Birge and Havens). The incidence of tuberculosis among mother-of-pearl button makers in Iowa reached 2.6 per cent. in 1920, whilst for the general population it was only 1.2 per cent., and amongst those workers not manipulating mother-of-pearl, 1.02 per cent., 22 out of 33 workers engaged on cutting buttons, who were examined by Birge and Havens, showed symptoms of tuberculosis. The 22 cases in question comprised workers who had followed the occupation for at least five years. On the other hand, the percentage of 2.6 above referred to comprised workers in the button industry who had been engaged on the work for less than a year — too short a period to permit of the effects of the dust being felt. It must be added, however, that in large factories health conditions are very much superior to those met with in small workshops.

Mother-of-pearl workers are besides exposed to rheumatism, indigestion and ocular fatigue (Birge and Havens), to conjunctivitis as well as infections of the buccal cavity often developing suppuration. Koelsch has noted frequent inflammation of the throat, as well as callosities, rhagades and ulceration on the hands. The latter are said to be due to the caustic action of the lime (Jolly). Barres and Courtois-Suffit-record the appearance of a redness and swelling with vesication round the nails, said to be due to the dust produced in course of "pressing" the buttons (Herschheimer). Neisser records severe epistaxis, pricking of the eyes, inflammation, bronchial and even gastric irritation caused by the dust of shells from certain molluscs of a special kind (burghaus, burgadines), in a pearl factory in France.

**Hygiene**

Dust should be reduced to a minimum in all operations and especially during work in a dry state (cutting and polishing). All efforts should be made to avoid splashing since drops projected, during work in a wet state, carry with them fine particles which are later disseminated as dust after desiccation. All grinding mills and apparatus likely to produce dust should be placed under hoods provided with effective dust exhaust ducts.

In wet grinding the method by which the lower part of the blade is dipped in water is preferable to mere damping of the shell, for dust still escapes with this latter method and some authors hold that this dust would be more harmful even than dry dust. One method followed is to let water drop continuously on the revolving piece, but the dust removed thus is but slight in comparison to the total amount produced, and thorough damping of the material is to be preferred. A method proposed by best only damping of the surface. Levy insists on the importance of removing the grinding sludge and proposes with this intent improved construction of the casing of the grindstone.

There is urgent need for improvement of general conditions in the workshops and of better industrial organisation (reduction of the working hours especially for women and young persons, prohibition of domestic work or work in small workshops under unhealthy conditions). As far as possible manual work should be replaced by mechanical methods.

**Legislation**

In France young persons under eighteen are excluded from dry processes in the mother-of-pearl industry where dust is freely liberated in the work-room; in Spain young persons under sixteen and women under twenty-one are excluded from dry processes in the industry (cleaning and polishing). Osteitis is compensated in countries which provide compensation for occupational diseases of the bones.

Mouth and Teeth (Occupational Affections)

Occupational affections of the mouth and teeth and their adjoining parts form an interesting chapter in industrial pathology which affords scope for study, from the aetiological point of view, under two separate headings: one dealing with the bony parts—the teeth and jaws—and the other dealing with the soft parts of the mouth and its immediate neighbourhood.

**OCCUPATIONAL LESIONS OF THE BONY PARTS**

**Teeth**

Occupational lesions of teeth can be caused by mechanical means, acute or chronic, by certain kinds of dust, and by various poisonous substances. On the other hand, dental caries and occupations are closely connected. Finally, lesions of the teeth, particularly of the alveoli following injury, must not be forgotten. All these causes provoke lesions or deformities, colorations or affections of the dental substance, with looseness and falling out of the teeth.

**Wounds** (injuries) of the teeth may affect either the tooth alone or its connection with the dental alveolus, or the alveolar processes, or the bone of the jaw. The action varies according to the nature and intensity of the acting force, its direction and point of application. The front teeth are naturally more exposed to these accidents, all the more so as they are relatively not so well fixed to the jaw. (See article "Diamond Cutters"; under Splitting.)

**Fractures of teeth** may be of different degrees, from simple cracks or fissures to more or less extensive detachment of parts, causing pain and troubles of mastication and speech. If the pulp cavity is not opened, the dental pains rapidly disappear; if it is opened it may cause intense pain with inflammation, and quite a train of complications. The broken edge of the teeth may injure the lips or the tongue. A cure may be effected when the pulp is not exposed and is not infected, which is rare and usually only met with in young subjects. Treatment lies in the hands of the dentist.

Under the term **displacement** is included the loosening of a tooth in its socket, or its detachment or, more rarely its impaction into the jaw, which may be accompanied by a simultaneous fracture of the tooth. In these various cases pains more or less violent arise in the soft parts and the dental pulp. Infection can sometimes cause grave complications. Correct treatment lies in fixation of the tooth.

**Violent traumatism** can cause lesions of the jaw and the soft parts of the mouth: fractures and displacements of the upper and lower jaws with their ordinary sequelae, such as traumatic limitation of movement and secondary ankylosis.

Of other mechanical lesions, one which affects especially the incisors following on wear and tear or a local strain is characteristic of certain industries, constituting occupational **stigmata**. These deformities, due to wearing down of the incisors, have been noticed for a long time, for example, among soldiers who were accustomed to bite off the end of cartridges with their teeth; among the inhabitants of Arctic regions who complain that their teeth suffer from being obliged to soften by mastication leather used for sewing; among players on wind musical instruments and especially among cavalry trumpeters, who hold the trumpet against their teeth; among shoemakers and upholsterers who have a habit of putting nails in their mouth and pushing them out one by one between their teeth, which become worn down in the shape of a half moon or a groove; among designers and teachers, who have a habit of holding pencils between their teeth; among persons who have the habit of cutting with their teeth the material with which they work, for instance, dressmakers who bite through threads, cigar makers who bite the end of cigars, and brush makers who bite the bristles.

Among these trade deformities should also be mentioned those of glass blowers which are quite characteristic (see article "Glass"). Among smokers, who have the habit of constantly holding the pipe between the teeth, a "pipe hole" is situated sometimes on one side of the mouth, sometimes on both sides, and most often between the incisors and canines.

**Causes of Injury**

**Teeth.**—Among the dusts which originate numerous lesions of the teeth, metallic dusts must be mentioned; they cause deposits in the middle of the teeth and a brownish red coloration.
among iron-workers and a greenish grey and dark green among copper and brass workers. In the latter case gingivitis has been noticed as well. Work on mercury and its compounds, such as the sublimate, fulminate and nitrate, causes a special coloration of the teeth (see article "Mercury ").

Different colouring materials used in powder may similarly colour the teeth.

For a long time the injurious action of the dust of flour and sugar upon the teeth in certain industries has been recognised: e.g. millers, bakers, confectioners, makers of gingerbread, pastrycooks, and workers in sugar refineries and chocolate factories become affected with dental caries (see articles "Bakery Trade" and "Sugar Refining ").

The treatment of the caries does not present anything special, but prophylaxis should be established from the time of choosing the trade, and while carrying it on, by examination and appropriate dental care.

Premature falling out of the teeth among salt-workers (Franz) is disputed by Mayerhofer, who does not recognise dental caries as a disease specific to the industry. According to the investigations of this author, those employed in the salt industry who do not come in direct contact with this substance show the same percentage of dental caries.

Pathological changes in the teeth can similarly be found among workers who come into daily contact with acids, whether such mineral acids as hydrochloric, sulphuric or nitric acids, or such organic acids as acetic and citric acids. But a number of workers show the same lesions as workers in contact with acids, viz. those dealing with soda, nitration, cellulose, explosives, accumulators, engravers, metal workers, and others.

Voigt found the same characteristic lesions in 40 workers in an acid factory that Adloff did among 21.5 per cent. of 125 workers whom he examined. In German acid works, Koelsch (1923) found lesions due to acids as follows:

<table>
<thead>
<tr>
<th>Acid</th>
<th>No. of workers</th>
<th>Percentage</th>
</tr>
</thead>
<tbody>
<tr>
<td>Sulphuric</td>
<td>124</td>
<td>26</td>
</tr>
<tr>
<td>Hydrochloric</td>
<td>32</td>
<td>84, 30</td>
</tr>
<tr>
<td>Nitric</td>
<td>30</td>
<td>93, 32</td>
</tr>
</tbody>
</table>

That is, a total of 138 workers affected out of 397 employed in acid work or 34.7 per cent.

We are concerned here essentially with a molecular necrosis, a destruction of the organic substance and then of the mineral substance of the teeth, necrosis the beginning of which depends on personal predisposition, the nature of the work, and the measures taken for the protection of employees. The destruction of a tooth is complete in two or three years. The troubles may begin as quickly as a few weeks from the commencement of work; they are due to the action of acid vapours which with respired air pass over the most exposed teeth and condense in the mouth. The saliva made acid by these vapours decalciﬁes the dental substance, so that it is no longer able to resist mechanical action or the micro-organisms of putrefaction. The first sign consists in a blunting of the teeth, which lose their brilliancy and in time get rough, marbling with brown patches; they become sensitive to touch and to changes of temperature and to acids. The teeth become tender and brittle diminishing in length until they completely disappear. The incisors are cut with a bevelled edge at the expense of the thickness of their substance; the polished surfaces of the upper teeth form with those of the lower teeth an open angle in front, or rub directly ﬁat the one upon the other, which interferes with mastication. These troubles disappear fairly rapidly. The troubles indicated have nothing to do with ordinary dental caries, for they never result in the formation of cavities and loss of teeth.

Prophylaxis consists in washing the mouth with alkali solutions, such as 1 per cent. of borax and 3 to 5 per cent. of soda; in periodical examinations of workmen made by a doctor or dentist; and in the application of technical measures adequate for preventing the diffusion of acid vapours wherever they can be adopted. Materials used in respirators should be moistened by an alkali. Workers should be forbidden to adopt the bad habit of placing a wad of cotton wool or a piece of rag between the teeth with the object of protecting the respiratory passages. These articles as a matter of fact become impregnated with acid vapours and act in the contrary way.

A particular form of dental caries has been observed by Lazarus among makers of indiarubber dentures, which the author attributes to the rubber, whilst Breve attributes it to the subside of carbon, and other writers to cinnabar. It results in the roots getting into a state of suppuration: pressure causes a clear, yellow, foetid discharge to ooze from the dental alveoli. Signs of early necrosis of the
bone are noticed with swelling of the lymphatic glands of the region. Pre-existing dental caries favours the establishment of these lesions.

Numerous dental lesions accompany the production of many forms of industrial poisonings, as by lead, manganese and mercury (see those articles). In lead poisoning the teeth rarely show any typical lesions. The colour and greyish-brown deposits which are generally seen are not specific to lead poisoning. Lead dust, just like any other foreign material, may be deposited on the gums, more particularly at the level of the neck of the tooth. Hintze found among the workmen of an accumulator factory a deposit of from 0.35 to 0.48 per cent. of lead. Never-theless, as in all the other organs of the body, deposits of lead may occur in the teeth at the level of the dental stoma. (Carbon dust of an electric arc.) Hintze found 0.038 per cent. metallic lead in the crown and 0.033 per cent. in the roots.

Trophic troubles, which accompany carbon monoxide poisoning, similarly cause falling of teeth which appear unaffected, but may fall after a more or less long period after the poisoning. Those affected complain of slight rheumatic pains or of swellings of the corresponding parts of the gums and of the cheeks. The cure of the alveolar lesions which follow is long, sometimes accompanied by deep suppuration. Nothing unusual is seen on the roots of the teeth either before or after they fall out. Sometimes the teeth, which already rock in their sockets, can be made firm again when the general effect of the poisoning rapidly recedes. Falling out of the teeth also occurs following trophic troubles due to a lesion of the trigeminal nerve caused by the action of vapours of trichlor-ethylene.

Jaws.—Among the occupational diseases of the jaws, phosphorus necrosis occupies the first place (see articles "Matches" and "Phosphorus").

A similar lesion has been recently (1925, United States) reported among some workers in watch factories which is ascribed to the action of mesothorium (see that article).

Yet another lesion of the jaws has been noticed among the turners of mother-of-pearl, more particularly among the young workers at the commencement of puberty. In fact, in addition to progressive subacute osteomyelitis occurring as a sequela of the action of the fine dust of mother-of-pearl, which especially affects the long bones, lesions of the jaws (and more especially of the lower jaw) are reported. Accompanied by accentuated pains, even when the teeth are intact, a painful thickening of bony consistence spreads in fusiform shape along the lower jaw. Generally a concomitant ankylosis of the jaw is observed. Suppuration or bony necrosis is rare. For the most part the manifestations recede without any permanent injury; in other cases there remains a swelling of bony consistence indistinctly defined or a general thickening. There is a tendency to recurrence when the occupation is resumed.

The essential cause of this affection is not well understood; the osteomyelitis which is situated at the end of the diaphysis and of the epiphysis is attributed generally to troubles of ossification caused by the absorption of the fine pearl dust which reaches the bony tissues by absorption.

Diagnosis is easy and depends on knowledge of the trade and age of the worker, the seat of the lesion at the extremity of the lower jaw with a fusiform swelling in the middle, and freedom of the joint. Treatment is on the usual lines: local application of cold and ointments of mercury or iodine, with iodide of calcium internally.

The connection between dental caries and occupations is repeatedly emphasised in literature. But the different statistics published have not completely cleared up the situation. Up to the present there has been less dental caries in the rural than in town populations, but according to recent studies it seems that dental caries extends also to the country, due to the consumption of bread of beet flour, replacing black bread, and of sweetmeats to changes in food, and to alcoholism.

An investigation by Lührse on dental caries in the various trades shows that this disease occurs with the following frequency: agriculturists, 18.1 per cent. of teeth; clerks and employees, 21.8 per cent. of teeth; bakers and pastry cooks, 27.6 per cent.; tailors, 18.4 per cent.; café waiters and cooks, 19 per cent. A statistical table drawn up by Rose dealing with 353,377 teeth, possessed by 11,874 persons, shows that 26.4 per cent. of teeth were diseased and only 5.9 per cent. were free from caries. As regards the trades of the persons examined, the agriculturists showed 21.4 per cent. of diseased teeth and 9.5 per cent. without caries; masons, 25.9 per cent. of diseased teeth and 8.1 per cent. without caries; millers, 26.5 per cent.
of diseased and 4.2 per cent. without caries; waiters and cooks, 30.4 per cent. diseased and 4.2 per cent. without caries; clerks, 32.3 per cent. diseased and 2.4 per cent. without caries; bakers; 39.6 per cent. diseased and 2.1 per cent. without caries; pastry-cooks, 51.3 per cent. diseased and not a single tooth free of caries.

It can be said that generally the tendency to caries depends on the constitution of each individual, but particularly on the standard of cleanliness and care of the teeth. It follows that trade groups generally made up of healthy persons show very little dental caries especially when there is complete understanding as to the correct care to give to the mouth. The high percentage of dental caries in the “alcohol group” of trades, including waiters and barmen, reported by various writers, is explained by diminished constitutional resistance following the abuse of alcohol, which, according to Bunge, explains also the marked tendency to caries among the children of drinkers.

**Diseases of the Buccal Cavity and Adjoining Parts**

Like the teeth, the soft part of the mouth and the adjoining regions can be damaged by various trade conditions, such as injuries, temperature, dust, poisons, or infections.

**Injuries.** — Among the injuries should be noted the different haemorrhagic wounds which result from external blows, most usually accompanied by lesions of the teeth or the jaws. Generally they are accompanied by inflammation of the buccal mucous membrane and tongue, of varying intensity with redness, swelling, exaggerated salivation, and epithelial desquamation.

Among the chronic injuries must be classed inflammatory thickening of the lips of musicians who play wind instruments from pressure of the mouthpiece, or among glassblowers from pressure of the blowpipe. Sores and cracks on the lips, ulcerations of the tongue and buccal mucous membrane are found, for example, among upholsterers, shoemakers and glassblowers, and these, although slight, can form the portal of entry for infections of every kind.

**Fatigue, exertion.** — Glassblowers and musicians who play wind instruments frequently show a relaxation of the musculature of the cheek, so that it swells into a semi-sphere. Local irritation constantly repeated, due to this stretching of the cheek walls, causes thickening of the epithelium of the mucous membrane, of which the most superficial cellular layers become macerated in the saliva (the quantity of which is often increased) and then detached. The thickened and rough mucous membrane appears grey and whitish on the surface with patches of different sizes sprinkled over it. Subjective troubles are very slight or altogether lacking.

**Differential diagnosis,** guided by a knowledge of the occupation, must be made between syphilitic plaques, which are never isolated upon the mucous membrane of the cheek, but are found much more often upon the tongue or gums, are temporary, and ulcerate rapidly, and buccal leukoplakia, which is found most often on the tongue and the labial commissures, while with glassblowers these parts are not affected.

Exaggerated expiratory pressure sometimes causes among glassblowers a characteristic condition: pneumatocele of the parotid, due to the penetration into Sténon’s duct and from there into the parotid of air which the mouth has compressed before forcing it into the pipe (see article “Glass”).

The pneumatocele may occur during a violent effort while speaking or during mastication; further, debris of food can pass along the enlarged Sténon’s duct and cause a parotitis. According to Scheler, 6 to 10 per cent. of glass workers have this condition. Koelsch has seen it in a number of cases. Diagnosis does not present any difficulty. Treatment consists in the application of compressed ball-shaped pads made of feathers on the region of the maxillary articulation to prevent the accumulation of air. This treatment as a matter of fact is not very satisfactory. Serious cases are quite unable to continue blowing and a change of occupation is required. Abolition of this industrial disease depends on the introduction of a blowpipe worked by compressed air.

**Occupational neuroses,** following on excessive use of the motor or sensory apparatus, may occur in the region of the mouth, favoured by a general neuropathic condition. A neurosis of the mouth and the musculature of the tongue may be cited, for example, among such musicians as flautists and clarionette players—a neurosis which takes the form of painful muscular contractions as soon as they try to put the mouth in the position required for playing.
In this pathological group may be placed disturbances of the nerves of taste, due to overlong practice, among tasters of wine, spirits, spices and tobacco, disturbances which manifest themselves either by paresthesia, by metallic or bitter taste, or by anaesthesia (loss of power to taste). Complete or sufficiently long cessation of work is essential to treatment.

High and too low temperatures. — The action of abnormally high temperatures to which foundrymen, engine-drivers and stokers are exposed, causes, by direct thermic irritation of the trigeminal nerve, or by vaso-motor disturbances, neuralgias accompanied generally by a typical erythema of the skin and especially of the side of the face most exposed to the heat.

Localised burns of the mouth and the adjoining parts are met with occasionally among glassblowers; lesions of the buccal cavity, due to the action of steam or hot gas, are met with also among engine-drivers and stokers of steam engines. But these lesions are not generally associated with any serious injury, or only with hyperaemia or the formation of phlyctenules; at any rate they are not in any way specific.

Local action from cold also causes neuralgia on account of vaso-motor troubles, and rheumatic affections of the articulations of the jaws which are accompanied by pain, swelling and interference with movement, e.g. rheumatic limitation of the movement of the jaw. Necrosis of the articular cartilages, ankylosis or displacement of the articulation may occur as sequelae of chronic arthritis. Prophylaxis consists in the use of screens against heat, and of localised protection against intense cold.

Dust. — Manifestations of more or less acute irritation are found on the mucous membrane of the upper respiratory passages, the mouth and pharynx, according to the nature of the contamination due to dust.

Excoriation and deglutition favour rapid elimination of dust from the mouth. Stomatitis is rare; nevertheless dust of mother-of-pearl may cause inflammation with a cushion-shaped swelling of the front part of the gums.

Chronic catarrhs of the naso-pharynx are more common, often associated with polypi, swelling of the follicles, and catarrh of the Eustachian tube. Dust which is deposited in the nose often collects together into hard masses or rhinoliths.

Another sequel of dusty work among pigments, aniline colours, coal or metals, consists in discoloration of the teeth, lips, gums and buccal mucous membrane. Work on iron gives a reddish brown discoloration to the gums; silver a greyish colour, copper and bronze a reddish or brownish black, or greenish blue. These colorations of the gum are accompanied with irritation of the mucous membrane (gingivitis) or coloured incrustations in the layers of the tooth. A hundred and fifty iron-workers presented brown stains on the teeth, especially on the edge of the lower teeth. Nickel workers show, according to Miller, a coloured incrustation on the teeth due to a metallic deposit. Lewin did not find coloration among copper workers, but on the contrary he observed a red inflammation with non-painful swelling of the border of the gums. Dust's of zinc and cadmium leave sometimes blackish deposits and cause catarrhal stomatitis which, however, according to Koelsch is very rare. Seifert has sometimes found among smelters of zinc a dark line (see article "Zinc"). These different colorations of the teeth of metal workers have often been confused with the lead line, which is however too characteristic for a medical man to mistake. It must not however be forgotten that all metals contain lead as an impurity.

Koelsch has seen a very heavy line among brass-workers due to the dust containing 10 per cent. of lead.

Prophylaxis requires the employment of measures of protection appropriate to each kind of dust, with care of the mouth especially after work.

Poisons. — Certain industrial poisons act upon the mucous membrane of the mouth and pharynx either directly as a result of absorption in the form of dust, gas, or liquid, or indirectly during elimination by the saliva, or mucous glands, of poison absorbed into the system, which thus comes in contact with the mucous membrane of the buccal cavity, causing stomatitis of excretion. These two actions may occur simultaneously.

Irritant lesions occur in acute as well as in chronic poisoning, lesions aggravated to the highest degree by the presence of carious teeth or roots, or any other cause of irritation.

Prophylaxis can, speaking generally, be efficiently secured by the use of adequate respirators, the filters of which contain appropriate chemical substances, or by catching the harmful gases or dust at their point of origin, which enables the most serious troubles to be avoided. Other prophylactic measures must not be neglected, such
as instruction, cleanliness, and choice of workmen.

**Lesions in the Course of Poisonings**

1. The halogens (chlorine, bromine, iodine, and fluorine), especially if they are concentrated or if they act continuously over a long period, may cause symptoms of irritation of the mucous membrane of the nose, the mouth and pharynx, and of the gums, with salivation and a tendency to ulceration, giving rise to catarrhal and ulcerative stomatitis. Vapours of bromine and iodine cause besides a yellowish-brown discoloration of the gums.

2. The same lesions, i.e. catarrhal stomatitis with a tendency in serious cases to ulceration, are caused by sulphur anhydride, sulphuretted hydrogen, hydrocyanic acid, hydrogen telluride, and ammonia. Such cause, in very feeble concentration, violent irritation of the mucous membranes, a sensation of burning, constriction of the throat, and the formation of ulcers and later of scars. Treatment consists in the use of astringent washes, and touching or cauterising ulcers by ordinary means. Prophylaxis consists in washing out the mouth, in ordinary measures of protection against injurious gases, and finally in mechanical removal of the gas.

3. Aids, when strongly concentrated, occasionally cause cauterising of the face, the lips and the mouth, with the formation of ulcers and later of sores. Characteristic white sloughs are caused by hydrochloric acid; others reddish brown or black by sulphuric acid, and others yellow by nitric or chromic acids. Hydrochloric acid requires special mention for with average strengths it causes in certain cases, for example in the preparation of cleansing solution for soldering and in zinc plating, by the action of its fumes, serious irritation of the mouth and pharynx, while lesions of the trachea as far as the bifurcation have been occasionally observed, which lead to necrosis with the complete shedding of the mucous membrane and oedema of the glottis. The part played by a certain local predisposition is important.

4. Lesions of the mouth accompany phosphorus necrosis (see article "Phosphorus") and also acute or chronic poisoning by arsenic, antimony and bismuth (see those articles).

5. Alkalis and compounds of alkaline metals, more particularly soda and potash lyes, quicklime, chlorides of lime, calcium cyanamide, baryta, etc., rarely cause lesions of the buccal cavity. But small lesions in the form of ulcerations are frequently found around the corners of the mouth and the nostrils. Serious lesions from irritation of the buccal cavity, with formation of sloughs of a dirty greyish white colour, and deep ulcers only result from accidents and bad management.

6. More or less serious gingivitis with small ulcerations is met with among workers in chloride of lime. The dust of soda, lime and cement have a strongly irritating action on the nasal mucous membrane, an action which is characterised by catarrhal inflammation, polypoid excrescences, ulceration at the orifice of the nostrils, and, on the nasal septum, by perforation of cartilaginous septum.

Koelsch found among 600 cement-workers 26.6 per cent. of cases of hypertrophy and of polypi of the nasal mucous membrane, 2 per cent. of ulceration, 1.7 per cent. perforation of the septum of the nose.

7. Manipulation of alkaline chromates frequently causes irritation of the buccal cavity, and often small ulcers which have little tendency to heal, and generally are of a yellow colour (ulcerative stomatitis); they are situated generally upon the tonsils, the arch of the palate or the soft palate, and may even penetrate to the bone. Frequently small ulcers on the skin are found around the orifice of the nose and of the mouth, most often on the cartilaginous septum of the nose, sometimes even with perforation. In making a diagnosis the great resemblance of these lesions to syphilitic lesions of the palate must not be forgotten.

8. Various metals, such as iron, nickel, copper, and silver, cause incrustations upon the gums and are deposited there in the form of dust (see above). It is necessary to differentiate between these deposits and coloration of the gums, especially at their border, consequent on reabsorption of metal in the course of general poisoning.

In argyrism, or chronic poisoning by silver, greyish coloration of the mucous membrane of the mouth, borders of the gums, and parts of the cheeks touching the teeth is found (see article "Silver"). Chronic lead poisoning is accompanied by characteristic symptoms, such, for example as: a particular foetid smell of the breath, due probably to excretion of lead by the saliva and to lack of cleanliness of the mouth; stomatitis often accompanied by dental caries which Koelsch considers in certain cases at least to be a gingivitis or stomatitis originating from lead; the lead line; swelling of the salivary glands; and troubles of taste and smell (see article "Lead Poisoning").

Chronic poisoning by mercury also causes from the beginning lesions of acute stomatitis, purulent gingivitis, or inflammation of the pharynx aggravated by personal susceptibility and especially by the particular state of the buccal mucous membrane (see article "Mercury"). It is interesting to note that compounds of mercury do not cause typical lesions of the buccal cavity, and are not generally associated with stomatitis and hyper-salivation.

The dust of sublimate and fulminate of mercury, aided by the action of sweat, causes local irritations and ulcerations around the opening of the mouth and the
nostrils. This dust in powder or in concentrated solution may cause ulcers of a bluish grey colour.

Industrial poisoning by copper and its salts is rare; Koelsch has never found it. Nevertheless a case of excessively painful angina from the dust of verdigris and another case of chronic inflammation of the salivary glands from copper have been reported (Chauffard).

**Chloride of zinc** causes ulceration with white sloughs which are dry and tenacious upon the skin or rather upon the mucous membrane of the mouth. Convalescence is accompanied by lesions which are generally nutritional: skin eruptions of various kinds, swelling of the mucous membrane of the mouth and palate, fungoid gingivitis, pseudo-diphtheritic inflammation of the mucous membrane of the pharynx, and ulcerative tonsillitis.

(9) In acute poisoning by **carbon monoxide** among other general signs may be seen rose red spots on the face and mucous membranes. Convalescence is accompanied by lesions which are generally nutritional: skin eruptions of various kinds, swelling of the mucous membrane of the mouth and palate, fungoid gingivitis, pseudo-diphtheritic inflammation of the mucous membrane of the pharynx, and ulcerative tonsillitis.

(10) Among the **hydrocarbons** of chlorine which cause lesions of the mouth and the adjoining parts, the following should be kept in mind: tetrachloromethane (hydrogen tetrachloride) which decomposes with heat, for example, when used as a fire extinguisher, and sets free chlorine which, mixing with the moisture of the air, forms hydrochloric acid. The wrong use of extinguishers, as, for example, when they are placed in the direction of the wind, can cause irritation of the mucous membranes.

Ethylene, which causes irritation of the mucous membranes of the mouth and pharynx, especially when it contains certain impurities such as wood spirit, is one of the substances which cause lesions of the mouth and the pharynx.

(11) **Alcohol**, especially denatured alcohol, sometimes causes irritation of the conjunctiva of the mucous membrane of the mouth and pharynx with salivation, nausea, vomiting, and cough, which depend on the product of denaturing, such as wood spirit, oil of wood spirit, or pyridine. High temperatures favour evaporation and consequently increase the lesions.

(12) **Compounds of cyanogen cause**, among other conditions, congestion of the head, congestive hyperaemia of the mucous membrane of the mouth and pharynx, tickling and dryness, a sensation of constriction of the throat and oppression of the chest. This hyperaemia is noticed almost specifically when cyanamide and alcohol are simultaneously absorbed.

(13) **Tar and its derivatives**... Workers who are in contact with tar, pitch, phenol, etc., show generally a yellowish, or blackish-brown coloration of the skin of the face and uncovered parts, and very characteristic symptoms of cutaneous irritation: acne, ulceration, swellings, etc. The direct action of the sun exerts a photodynamic action and causes in addition among workers in pitch an acute erythema with swelling and itching, especially of the face. Among those suffering from chronic poisoning by benzene (see that article) haemorrhages from the gums are frequent at the time of teeth extraction.

**Mono and dinitrobenzene** cause a bad taste and a burning of the mouth and pharynx, tiny spots on the tongue, dryness and a sensation of thirst, as well as a greenish-blue coloration of the mucous membrane; the gums may show a bluish-black line (see articles relating to these substances). The nitro-compounds also cause an analogous clinical picture, although of less intensity.

Trinitrotoluene which often contains as an impurity tetrinitromethane causes, in addition to violent irritation of the respiratory passages (pulmonary oedema), salivation and tickling of the pharynx.

Similar effects are found with the aromatic amido-derivatives: aniline, toluidine, xylidine, tetraniromethane.

**Carbolic acid** causes a violent irritation of the mucous membranes with the formation of white slough.

Other aromatic compounds have an especially irritating action on the mucous membrane. Trinitrophenol, for example, causes in the vicinity of the mouth a bitter taste, a catarrhal stomatitis, a yellow coloration of the teeth, a greenish-yellow coloration, as well as irritation of the skin, the conjunctiva, and nose. The same symptom group may be seen with certain aniline colours. Trinitroanisol causes strong irritation with ulceration, inflammation of the mouth and pharynx.

(14) **Vegetable poisons** can similarly exert their properties during their manufacture; thus pilocarpine and eserine cause an excitation of the flow of saliva, atropine and morphine cause ulceration of the mouth; while euphorbia, veratrine and pulsatilla give rise to inflammation of the buccal mucous membrane. The ethereal oils contained in hops may cause eczema of the lips, stomatitis, inflammation of the pharynx and sometimes of the nose and conjunctiva. Inhalation of oil of turpentine, especially when it is used as an impurity oil of pine, extracted by dry distillation of pine roots, causes irritation of the mucous membranes and salivation.

Another ethereal oil, oil of mustard, 'attacked a man whose occupation required him to taste mustard seeds regularly. The teeth showed nine cavities with exposure of the naked pulp without any serious pain. The dental pulp seemed to be healthy, but was hypertrophied, and in the depth of the cavities were found carious masses. The extraction of the pulp was, however, painless. According
to the medical man in charge of the case
the lesions were undoubtedly due to oil
of mustard, or to substances which it con-
tained. Tobacco dust causes acute and chronic
gingivitis, principally in the middle of the
front teeth, a bitter taste in the mouth,
cough and irritation of the eyes. At the
end of a certain time immunity can be
acquired. Out of 158 tobacco workers,
Flescher found only 35 in whom the buccal
mucous membrane was unaffected. All
the others showed acute or chronic ginge-
vitis more or less serious.

LESIONS DURING INFECTIONS

Anthrax, in addition to its ordinary
manifestations, may sometimes cause a
pustule on the tongue developing as a
parenchymatous glossitis, in the course of
which the other symptoms of infection
are only slightly pronounced. As a local
complication oedema of the glottis has
been noted. The prognosis is inevitably
fatal in this case.

Glanders, actinomycosis, foot and mouth
disease, industrial syphilis of glass-workers
and musicians, and in general all in-
fec tious diseases with suppuration and
tuberculosis can attack the mouth or
adjoining parts during work. Koelsch
mentions a case of the transmission of
lupus by the glass-makers' blowpipe con-
fined to the vault of the palate after the
extraction of the second upper molar.
(See the different articles upon infection.)

Scurvy also, which is a disease due to
the absence of certain vitamins, and
attacks sailors and explorers, shows itself
by lesions of the skin and mucous mem-
branes which are situated especially in
the buccal cavity and particularly on the
gums.

PROPHYLAXIS

Among prophylactic measures, period-
cal inspection of the teeth by a
dentist should be placed first, especially
in trades which threaten to damage the
teeth (see article "Industrial Hygiene
(Workshops)"). The results obtained by
a similar medical inspection show the
value of the method. Leaflets and
spoken propaganda, beginning with
school life, among young persons and
parents will enable the object to be
attained in the near future.

LEGISLATION

Ulcerations of the mucous membra ne of
the mouth caused by dust are compul-
sorily notifiable in Holland (soap powder
factories), and are compensated as acci-
dents in Great Britain, Western Australia
and New South Wales. It is clear that
the poisoning and infections which are
the cause of lesions situated in the mouth
and teeth are notifiable and compensated
according to the regulations provided by
the different countries. (See the corres-
ponding articles.)

Nail-Works

The industry of screw-making is generally only a special branch of the industry of nail-making. The latter includes the manufacture of a great variety of nails, tacks, screws and horse-shoe nails and tackets, of different shapes and sizes.

Industrial Processes

Cleaning. — Iron rods used for making nails, on arriving from the rolling mill, are first subjected to the cleansing action of dilute sulphuric acid. The bundles of iron rods are plunged either by hand, by means of iron pincers, or mechanically by travelling cranes with immersion apparatus, into tanks lined with wood or lead, containing the acid solution. This operation has for its object the cleaning of the surface of the iron rod before subsequent operations.

Wire-drawing. — The iron rods, after being cleaned, are passed to the wire-drawing machine, where they are progressively lengthened and reduced in thickness by mechanical traction by being passed successively through draw holes, each of which is smaller than the last. Their calibre varies between 1 and 8 mm. On leaving the wire-drawing machine the wires are rolled up and placed in receptacles containing a lubricant mixture, consisting of acid, in order to continue the cleansing action, and of sulphate of copper, which is used as a preservative and also to prevent rust.

Liming. — This operation, which is not generally adopted, is an object of dispute among experts. It is intended to free the wires from excess of acid, to increase the preservative action and to facilitate the application of the knife in the cutting machines.

Nail-making. — The manufacture of all kinds of nails is always carried out in the cold state, the shape and particular calibre of the nails and tacks being produced by machinery only. These articles, which are very varied in shape and size, measure from 5 to 6 mm., for the smallest tin-tacks, up to 250 mm., passing through all the intermediate sizes.

The operations in question necessitate complicated machines and plenty of them. Average nail-works employ 300 to 400 machines, all in motion at the same time. Each of these machines is constructed in such a way that at each movement it cuts the iron wire, presses it to give it the shape and calibre required, and strikes it to shape the head.

The machines are at times driven with great rapidity. This rapidity varies between 65 and 525 movements a minute, which set in action the hammer striking on the end of the iron wire.

Nail machines are of two different types: machines with bow hammers, in which the striking hammer which makes the head is thrown back by a spring, sometimes made of wood; and pressure machines in which the hammer is fitted to a connecting rod joined to a cranked shaft.

In the first, the movement of the spring causes a percussion which is violent, sharp and sudden; in the second the shaping of the head is done by pressure, this being effected by a less violent blow, not so strong and consequently less noisy.

The bow-hammer machines were formerly used uniformly and generally in nail-making; pressure machines, which are more modern, are gradually, taking their place. Nevertheless, they seem to be always necessary for making convex-headed nails, for which a violent, sharp and considerable blow is indispensable. Pressure machines can only be used for simple flattening...
out of the ends of iron wire, as for nails with flat heads.

Apart from these general industrial processes, nail-making calls for certain special manipulation to meet special requirements.

(a) Whitening and polishing. — Finished small nails are mixed with sawdust and turned in a drum with polyhedral sides, actuated by machinery, in order to be cleaned, whitened and polished.

(b) Annealing. — Some wire is annealed before shaping. This process is intended to make the metal more malleable for making certain nails, such as nails for boots. This annealing is done in special gas or coal furnaces.

(c) Bluing. — Some nails are blued by heat in a special pear-shaped furnace with a rotary movement.

(d) Nails made from sheet iron. — Some nails of very small size are made from small bits of sheet iron which are cut up by machinery.

(e) Galvanising. — In some cases nails are galvanised in the following way. They are placed in drums worked by hand; a flux with an ammoniacal base is added, with sand to prevent sticking together, and solid lead and tin. The whole is heated to a temperature sufficient to melt the metals used for galvanising. The smoke, gases and fumes which are liberated are removed by exhaust ventilation. After heating, the nails are thrown into water, when ammoniacal fumes are given off.

(f) Screw-making. — Screw-making is really only finishing the rivets made at nail-works. The work is purely mechanical and carried out by machines which are very complicated and very accurate. Each rivet passes through two machines; the first is a cutting lathe, which turns the head of the screw and makes, by a stroke of a saw, the notch for the screwdriver. The second makes the thread on the screw, by means of a threading lathe, and finishes by making the point.

**Sources of Danger**

Quite apart from noise, which certainly constitutes a considerable nuisance in nail-works, the following operations must be noted as dangerous:

The cleaning process. — The workmen are subjected to fatiguing work when the rods are plunged by hand; they are inevitably exposed to the absorption of numerous acid fumes and vapours, and to burns which this caustic agent produces; they generally work in an atmosphere saturated with steam and with thick and opaque fumes, especially in cold weather. These workmen are exposed to chills, as the work is usually carried on in workshops which are mostly open to the air and exposed to continual draughts.

Wire-drawing and timing. — The men, in addition to being continually exposed to acid fumes, are also exposed to accidents peculiar to their work. The wire before passing through the draw holes is wound on a wooden reel; now, when the wire comes to the end of winding, it may be thrown up horizontally and strike the worker violently, so causing serious incised wounds; further, unskilful unwinding of the wire may twist it into what the workmen call "eights", which may fly out with a violent motion.

Dust is particularly abundant at the bluing of nails, both metallic dust and sawdust. When annealing, the CO given off exposes the workmen to poisoning and discomfort, while the possibility of lead poisoning in galvanising must also be borne in mind.

These various hazards are not, of course, peculiar to the industry of nail-making; but the noise deserves attention.

All the machines, the hammers of which strike the iron 60 to 600 times a minute, give rise to a complex of subintrant noises, of a violence and continuity which is not met with elsewhere. When, in addition to these noises, there are those of driving belts, of trucks running on rails, of drums for cleaning and bluing, and of the enforced shouting of conversation, some idea may be gathered of the importance of this occupational hazard from the point of view of the workers' health.

If an attempt is made to analyse this complex of noises, the following characteristics will be noted. When standing facing a machine with a wooden spring hammer, the hammer is seen and heard to strike the end of the wire in order to flatten the head; the blow is violent and sharp, without resonance; the hammer falls with a deadened thud and causes a noise, rather than a sound, absolutely unmusical, without timbre and without subsequent air vibrations; the noise is violent when produced, but muffled at once by the flatness of the head; a second noise follows the first immediately; the different noises repeat them-
selves on these machines at the rate of about 60 to 200 times a minute. The pressing machines, acting by the intermediary of a crank on a shaft, drive hammers which combine in their action blows and pressure. The noise is not so sharp or harsh; it is softer and more delicate; it has the same characteristics of suddenness, but its intensity is much attenuated, and may be 80 per cent. less than that of the machines with the wooden spring bow hammer.

The degree of noise varies with the variety of machine: heavy hammers emit a deep note, beating at from 60 to 200 times a minute; machines for small nails and tacks make a noise which is much shriller and less violent, but much more frequent (up to 550 a minute).

To these noises is added a particular tremor felt in the ground, which actually vibrates close to the large machines, and seems to shake after each blow.

The effect of these noises is to cause hardness of hearing; and an enquiry made by Langelez shows that among a group of men, working regularly and irregularly in the noise, 15 per cent. were normal, while 86.5 were abnormal from the single point of view of auditory acuity. This enquiry covered the whole personnel of a factory.

The proportion of those affected with deafness according to age and the number of years of work is as follows:

### TABLE A. — AGE GROUPS

In another enquiry, dealing with workmen belonging to different works in a Belgian town which specialises in nail-making, deafness was investigated by means of the Weber tests with tuning fork on the skull, of Bonnier tests with tuning fork on the patella, of Rinne tests with tuning fork on the mastoid, of Gelle tests with tuning fork on the vertex, and by means of those of Gradengio and of Galton with the whispered voice. Examination of the results obtained by these different tests shows clearly a predominance of disorders of the transmission apparatus over those of the receiving apparatus.

The appearance of lessened acuity occurs very early: between twenty and thirty years, 5 normal for 13 abnormal: between thirty and forty, 1 normal for 18 abnormal. Some workers are conscious of this infirmity, but others are quite unconscious of it, affirming that they hear perfectly well, even though they do not hear the tick of a watch at 10 cm. In these cases lip-reading becomes a characteristic habit.

**Prophylaxis**

On this subject, see article "Noises". As regards nail-works, in particular, it...
Naphthaline

**TECHNICAL DATA**

Naphthaline (C₁₀H₈), discovered by Garden (1819) and Kitt (1821) in coal tar, abounds in tars of high temperature (gas works and coke works). Naphthaline obtained by fractional distillation (between 170° and 300° C.) of tar, or by redistillation of the residues of the oils from which phenic acid has been extracted, is separated from the crude oils by cooling in large tanks where it crystallises. The naphthaline is purified by pressure in a hot state in order to eliminate the oils, then washed in sulphuric acid and soda and finally distilled. Special presses are used for making balls of naphthaline.

Pure naphthaline obtained by sublimation is in the form of brilliant sheets. It melts at 79.6° C. and boils at 218° C. Insoluble in cold water, slightly soluble in boiling water, very soluble in ether, it volatilises even at an ordinary temperature and is easily drawn off by steam.

Naphthaline is used in large quantities in the preparation of various colouring agents, phthalic acid, lamp black, varnishes, grease for greasing vehicles, as an antiseptic, etc.; mixed with camphor it serves for the preparation of non-inflammable celluloïd and is less explosive.

Amongst the most important derivatives of naphthaline are the a and the b-naphthylamine (see that article) and the a-chloronaphthaline (C₁₀H₈Cl) obtained by making chloride act on boiling naphthaline, or in denitrating a-naphthylamine and subsequently decomposing the compound obtained by means of copper chloride. The liquid in question, the density of which is 1:1938, boils at 283° C., and is used in the preparation of various chloro-sulphonic acids and of naphthaline green.

Perchloronaphthaline, used for impregnation of materials and as a substitutive for resins and caoutchouc, is a chlorinated naphthaline ("Perna"), which takes the form of a brownish black mass. It is soluble in lipoids and readily volatile.

The nitro-derivatives of naphthaline (molecules b-, tri- and tetra-nitronaphthalines) are very much used in the explosive and colouring matter industries.

The a-naphthol (C₁₀H₁₂O) prepared by starting from a-naphthylamine or from the a-naphthalenesulphonate of sodium, takes the form of brilliant monocalinous needles. It melts at 94° C. and boils at 270° C. It is used in the manufacture of azo-compounds, serving as colouring agents.

The b-naphthol is obtained industrially exclusively from b-naphthalenesulphonate of sodium. This product, which takes the form of brilliant white crystals, melts at 123° C. and boils at 285° C. It sublimes easily and distils with super-heated steam. It is used in the preparation of various numerous colours and in medicine. With salicylic acid it is used for the preparation of mixture applied to cotton materials with a view to rendering them impermeable and preserving them from parasites. Its methyl and ethyl ethers are used as "fruit essences".

Naphthaline constitutes the most advanced stage of the thermal transformation of non-saturated carbides. This naphthenic nucleus very readily absorbs hydrogen. The process, known even before the war, has been utilised successfully in Germany for at least twenty years.

Hydrogenation of cyclic hydrocarbides is applied especially during the manufacture of volatile solvents and liquid carburettants. It is particularly the hydrogenation of naphthaline which has provided a compound of great importance: tetraline used as a carburettant in the place of petrol (see the articles "Solvents" and "Strap").

The naphthaline is first purified by means of metals by utilising sodium or powdered metals. In this way it is freed from all its sulphur. If thereafter undergoes a method adopted successfully in the hydrogenation of oils and is transferred totally into a tetrahydrogenated derivative (tetraline). If hydrogenation is continued for a longer time there is obtained a decahydrogenated product (decaline).

The mercuric sulphate has been used for some years as a catalyst of
oxidation of naphthaline, in order to transform it with the aid of fuming sulphuric acid into ortho-phthalic di-oxide. In this branch of industrial manufacture, which has acquired a remarkable extension, there is obtained a compound which is at the basis of the method of preparation of synthetic indigo.

Pathology

According to far from recent observations made by Grandhomme (1893-1895) (factory at Hoechst s/M), naphthaline was said not to exert harmful action on the workers engaged in preparing or handling it. Modern experts, on the contrary, incline to the view that this harmfulness is by no means absolute. There has been reported in fact an irritant action of naphthaline fumes and even of mineral oils containing traces of naphthaline (Eisner) on the skin with production of red spots, papular eczema (Bourguignon) and of acne (Brussolle).

Dermatitis, usually localised on the uncovered part of the skin, may in certain cases, if the patient is hypersensitive, become generalised (Poluny) with anhydroses and an uncomfortable sensation of heat; cutaneous affections have been caused by products containing naphthaline even in very small quantities (1-1½ per cent.) (case of Eisner).

Amongst persons predisposed the irritant action of naphthaline is manifested by cheloids (Patschke and Plaut), but more frequently by chronic eczema (Pinkus). Handling of fur impregnated with naphthaline has caused, in the case of a strong man, temporary oedema of the face, hands, feet and abdominal region. Some erythrocytes were found in the urine.

Ocular troubles have also been reported: superficial punctated or vesicular spots on the cornea (Grünwald) which may even develop into ulceration (Uliman); chorioretinitis amongst workers engaged in sorting skins preserved with naphthaline with other workers in gas factories engaged in the naphthaline department (Van den Hoeve 1906).

A doubtful case of cataract1 has been notified by Caspar, as well as a case of bi-lateral optic neuritis, which was cured after four to five weeks, affecting a worker exposed for several weeks to the action of naphthaline fumes (Koelsch). Labbé and Lavagna have noted modifications of the acid-basic equilibrium of the fluids of the eye, and Lienhart in 1923 engaged in a study of hereditary ocular troubles amongst rabbits induced by naphthalinic poisoning.

Loewy and Grünwald met with catarhal irritation of the upper respiratory passages. Although naphthaline may also cause symptoms of general poisoning (headache, nausea, vertigo, weakness of the legs, unsteady gait, etc.) serious forms would only appear to occur exceptionally in industry. Naphthaline must, however, be considered as a fairly dangerous poison, for Prochownik reports a fatal case due to a dose of 0.25 grm. in a child of six years (methaemoglobinæmia, paralysis of the heart and respiratory centres). In an adult serious poisoning is manifested by tenesmus, jaundice, toxic nephritis, with haematuria and enlargement of the spleen. Experiment has also confirmed diminution of the red blood cells (Von Jodel, M. Loewy and Heine).

In 1926 a worker, in applying hot asphalt to a plank, diluted it by means of a product known under a fancy name. The mixture liberated abundant fumes of naphthaline. In the following weeks the worker became pale, anaemic, suffered from cardiac weakness and pernicious anaemia, which rapidly developed towards a fatal issue (Heubner).

A case of cancer of the bladder was reported in January in 1921 in Germany as affecting a worker who had for long years been in contact with naphthaline. Another case was encountered in Great Britain, being that of a worker who for sixteen years had worked with β-naphthol and for seventeen years had been engaged in nitration of naphthaline.

Amongst the chlorinated derivatives it is perchloronaphthaline which is responsible for the most serious effects on health. In 1918 Wauer described under the name of Perna disease (Pernakrankheit) the cutaneous troubles studied later by Koelsch and especially by Teley and due particularly to the fumes of the molten mass or to sublimated dusts. The affection in question is represented by cutaneous irritation and particularly by forms of folliculitis and of acne, at times of a very serious nature. The product may also exert a general action (see above). The injuries affect workers occupied in the preparation of perchloronaphthaline or in impregnation of materials, papers, etc., with the latter, as well as individuals only coming into indirect contact with the product.

1 Cataract due to the action of naphthaline has also been produced in an animal.
The cutaneous lesion is mostly localised on the uncovered parts of the body and zones of "friction" (Koelsch). Teleky has described the characteristic appearance of this affection as a superficial eruption localised on the cheeks, forehead and chin or in slight forms consisting of small narrow zones on the temples, cheeks, back of the neck and behind the ears, formed by numerous comedons and small yellowish-white nodules, probably constituted by small sebaceous cysts.

The gravity of the injuries would appear to depend on the halogen content of the product, for the more chlorine there is in the perchloronaphthalene used, the more marked are the clinical symptoms (Teleky). In fact, a very considerable improvement in the health of workers has been noted since the chlorine content of the mass has been changed from 35-40 per cent. to 7-8 per cent. On the other hand, individual predisposition would appear to provide an explanation of receptivity in regard to this disease, which is nevertheless of fairly frequent incidence. During the war, out of 90 workers exposed during nine months to the action of the toxic products, there occurred 50 cases of disease, and Koelsch estimates at 50 per cent. the average incidence of cutaneous affections.

In a group of 150 to 280 workers (including certain individuals very little exposed) examined by Teleky in 1926, there were recorded 33 cases of serious poisoning, 37 of average forms, 38 of slight forms and 62 in which mere traces of the harmful agent were noted. Experimental ingestion of Pernap causes anorexia to the point of preventing all consumption of food and leading to death by inanition. At the autopsy there were found lesions of the liver, reflecting the acute yellow atrophy. However, cutaneous troubles resembling chloric acne were not noted amongst the animals (Lehmann).

The various nitro-derivatives of naphthalene are said to exert a very slight toxic action (Koelsch) and it is for this reason that it has been suggested that they should be deleted from the list of industrial poisonings. Animal experiment appears to confirm this view.

The a-nitronaphthalene \((C_9H_7NO_2)\), which is only one of the two mononitro-derivatives of any importance from an industrial point of view is said to cause forms of conjunctivitis, a sensation of burning in the eyes amongst workers exposed to the irritant action of its dusts or fumes. In the clinic of Fuchs, Hanke and Frank were able to note slight cases with a chronic development of opacity of the cornea due to spots located on the middle region of the cornea. These spots of oval form, which, however, did not reach the limbus, consisted of a group of small vesicules on a greenish-grey background. The most important symptom was a slow, fairly marked diminution of sight.

On the other hand, the two cases described by Silex (1901) were characterised by a acute violent form with perikeratinous congestion reaching the middle layer of the substantia propria. Opacity in these cases extended even to the peripheral extremity of the cornea.

It is, however, necessary to insist on the fact that these cases, very few in number, were but the expression of neglected predisposition as affecting certain individuals exposed to the action of nitronaphthalene fumes or dust. Animal experiment has proved that exposure to the fumes in question for a period of eight hours by application of the toxic substance to the cornea of animals does not cause the opacity noted in the case of certain human beings (Lewin and Guillery, who recall the fact that very often experimental research fails to reproduce the clinical picture noted amongst human beings).

The observations in question are, moreover, of not very recent date, and in the last fifteen years no cases of keratitis due to nitro-derivatives of naphthalene have been reported (Koelsch). In conclusion, it should be recalled that these products have been said to cause formation of met-haemoglobin amongst animals (Röhl, 1890).

The a- and b-naphthols are considered by Lehmann as doubtful industrial poisons. American literature contains, however, evidence of one case of poisoning with fatal issue. Cases of eczema were reported as well as brownish pigmentation and epithelial desquamation of the cornea, cephalalgia and vomiting amongst workers exposed (Koelsch). For details relative to cancer of the bladder, see above.

**Hygiene**

The distillation room and the melting room in the manufacture of naphthalene should be separated, and likewise the store room should be separated from the melting room by means of doors which can be hermetically closed. Apparatus and piping should be airtight and withdrawal of gases liberated during the running off
of heavy oils should be perfect from a technical point of view (Grunwald). Mineral oils free from traces of naphthaline should be used.

The workers should be protected as well as possible against the action of harmful dusts and fumes, and rigorous personal cleanliness should be insisted on, supplemented by the provision of working clothes. Dusting of the skin with inert powders should be recommended prior to the commencement of work. There should be careful selection of workers, with a view to eliminating predisposed individuals. Periodical examination of urine should be effected in order to detect the presence of erythrocytes.

**Legislation**

Legislation is similar to that for the chemical industry in general and for nitro- and amido-derivatives in particular (see those articles). In Germany only chronic cutaneous or chronic recurring affections due to naphthaline can be compensated where naphthaline may be included amongst "allied substances" comprised under No. 13 of the list annexed to the Order dealing with extension of accident insurance to occupational diseases of 11 February 1929.

**Naphthylamine**

*(Aminonaphthalene)*

The naphthylamines, important from a technical point of view and characterised by the different positions of the amino group, are: the \( x \) naphthylamine \( (C_8H_7NH) \), of which the commercial product is found on the market in brilliant grey flakes, of a slightly reddish-brown tint and having a distinctly foecal odour. The pure product melts at 50°C. and boils at 300.8°C. The \( \beta \) naphthylamine occurs in brilliant colourless flakes, melting at 115°C. and boiling at 294°C. Only soluble in water with difficulty, these two compounds are easily soluble in alcohol and ether and can be carried away by steam.

**Technical Uses**

The manufacture and use of naphthylamine only take place in the aniline colour industry, where \( x \) naphthylamine is obtained by reducing \( x \) nitronaphthalene with iron and hydrochloric acid, as is the case with aniline. The apparatus used is not unlike that used in the manufacture of aniline (see that article): at the same time, the products used for the reactions and the final products are less readily carried away by steam.

It is therefore not necessary to furnish the reducing apparatus with an ascending cooling apparatus. After the gradual introduction of dry mono-nitronaphthalene into the mixture of iron filings and acid, heated by direct steam, the temperature is regulated in such a way as to remain within the desired limits. Once the reaction is over, the molten naphthylamine is decanted and the muddy deposit is rendered alkaline with lime. After cooling it is subjected to distillation with superheated steam at 250°C in order to recover the naphthylamine and condensed steam together.

The crude naphthylamine is solidified outside the receptacle in a blackish crystalline mass, is separated from the water, mechanically remelted, and distilled under a vacuum to obtain the pure product. This takes the form of an oil, as clear as water, which, when directed into moulds, solidifies in a white mass; this is crushed before it is used in the preparation of azotic colours.

\( \beta \) naphthylamine is only prepared by heating \( \beta \) naphthol in an autoclave at 150°C. with dry sal ammoniac or strong ammoniacal solution and sulphite of ammonia. The mass, when slightly cooled, is poured on to a filter, aspirated, washed with a dilute solution of caustic soda, and dissolved in dilute hydrochloric acid. It is then filtered to remove insoluble impurities and the sulphate of \( \beta \) naphthylamine is precipitated out of the solution by means of Glauber salts. If the product is not utilised in this form, the base liberated by an alkali is distilled afresh in a vacuum and the resultant crystallised product is ground down.

The two naphthylamines are almost exclusively used in the manufacture of azo-colouring matter, partly for their conversion into the corresponding sulphonic acids. To a lesser ex-
tent they are used in the form of alkyl and aryl compounds.

x naphthylamine is also used in the preparation of naphthol (when heated in an autoclave with sulphuric acid to 200° C.) and in photography for obtaining bluish tones.

Among the derivatives obtained as intermediate products, the most important are the sulphonylic acids. They are prepared only partly from bases (obtained also by heating the sulphonylic acids of naphthol with ammonia or by reducing the sulphonylic acids of nitro-naphthalene). They are generally obtained by the process of roasting, especially the sulphonylic acid of x naphthylamine (naphthionic acid) (see article "Aniline"); the acid sulphate of x naphthylamine is heated to 180-200° C. with the addition of carbonates to improve the output; solution proceeds; it is extracted from the mass by means of a soda solution, and the carbonate of soda formed in the filtered solution is separated out by crystallisation. The separation of the isomers which are formed is of no interest, since the sulphonylic acids are perfectly harmless (see also article "Aniline").

**Sources of Danger**

(a) In the manufacture of x naphthylamine: there is a slight danger of evolution of fumes while reduction is being effected; this is greater during distillation and emptying of the raw product and of the final product.

In the manufacture of β naphthylamine: evolution of steam containing naphthylamine only takes place if the autoclave leaks.

Distillation of the two products under a vacuum does not present any danger, as fumes are only evolved in the course of emptying receptacles.

(b) In their use: some danger from dust occurs during grinding and packing of the product, while placing the substances in the vats and in the course of the manufacture of the azo colouring matters.

**Toxic Action**

The two naphthylamines are toxic (but not their sulphonylic acids). The acute symptoms, however, of this toxic action have not been observed up to the present, except experimentally in animals. The principal channel of entrance of the poison into the organism seems to be, from the point of view of industrial practice, the respiratory organs (fumes and dust); unjured skin comes second.

The toxic effects resemble those produced by other aromatic monoamines and particularly by aniline.

According to experiments made by Pittini on rabbits, in addition to generalised paralysis, x naphthylamine causes haemorrhagic diarrhoea (fetal dose: 0.4 grm. per kg.). According to researches made by Engel on dogs, the two naphthylamines produce changes in the haemoglobin (methaemoglobinamaia), with marked cyanosis.

β naphthylamine causes the destruction of the red blood cells with haemoglobinuria and, marked secondary anaemia, generalised paralysis and sometimes, even with small doses, haemorrhages into the bladder and marked ischuria. The fatal dose of β naphthylamine is 0.5 grm. per kg.

Although, in fact, the naphthylamines are hardly less poisonous than aniline, no acute intoxication symptoms of characteristic poisoning in man have been observed so far.

Looked at in this way, the manufacture and industrial use of naphthylamine does not represent any considerable risk to the general health of the workman. On the other hand, those who handle naphthylamine are exposed to great risk of damage to the bladder, haemorrhage, papillomata and cancer of the bladder. Of all the aromatic amido derivatives, it seems that it is particularly the β naphthylamine which induces the greatest number of these maladies, especially among persons employed in the manufacture of β naphthylamine and of the sulphonylic acid of x naphthylamine and not in the course of their use.

According to Engel, β naphthylamine, which undergoes oxidation in the organism, is generally eliminated by the urine in the form of sulphuric acid of β amido x naphthol and of glycuronic acid. Unconverted β naphthylamine is only found in traces; x naphthylamine, on the other hand, is said to be largely eliminated untransformed.

In Germany a case of haematuria was reported. In 1912 in a workman manipulating β naphthylamine; in 1913 (Bavaria), four cases of tumours of the bladder; three of which were caused by naphthylamine (the workmen, however, had also come into contact with benzidine, chloro-aniline and chloro-toluidine); during the period 1914-1918 among thirteen cases of tumours of the bladder, five, in the Northern Palatinate, were due to β naphthylamine; in 1921, one case was
reported in the district of Wiesbaden and a fatal case in another district from \( \beta \) naphthylamine; in 1922, a case in Bavaria; in 1923-1924 nine cases, of which three were fatal, in Bavaria from naphthylamine and aniline in 1926, four cases.

According to Hamilton, \( x \) naphthylamine does not appear to give rise to serious lesions. At the same time, one of the first cases described in the United States was that reported by Apfelbach in 1913. It had reference to a case of cyanosis induced by an amido compound. Another case has been reported from a colour factory affecting a worker handling \( x \) naphthylamine.

According to the same expert, the \( \beta \) naphthylamine was the more toxic, as the workmen who manipulated it in an American factory showed symptoms of cyanosis and poliakuriia. On the other hand, this same factory never had trouble with the \( x \) compound.

In Great Britain, Wignall, in a report presented to the Industrial Hygiene Section of the British Medical Association (Manchester, 1929) brought to light the fact that, in an aniline colour factory, of which he was then works surgeon, eight cases of urinary trouble among workers, all ending fatally, had been reported between 1880 and 1900, but of these no precise details existed. He had seen three of them.

Since 1900 the factory has manufactured a great deal of \( x \) naphthylamine without the use of arsenic; the number of workmen employed varied from 100 to 200.

In 1902 Dearden reported acute cases of anilism among workmen employed on aniline black. From the year 1910 onwards Wignall had been able to follow very closely the cases occurring amongst workmen in the factory. He then knew of three fatal cases of tumours of the bladder caused by \( x \) naphthylamine and had knowledge of other cases which he had not been able to confirm. Since 1918 the number of cases occurring among workmen coming into contact with \( x \) naphthylamine was four, two of whom were fifty-six years old, had been employed in the factory for thirty years, and had been twice operated on for tumours of the bladder; one is dead and the other, tuberculous, is under treatment. The third workman, aged fifty-eight, with a record of employment of twenty years, was operated on once and has died of cancer of the bladder. The fourth, aged fifty-four, who was operated on once for tumour of the bladder, is at the present time under treatment.

The precautionary measures adopted in the factory have certainly improved the situation and enable detection at an early stage of bladder lesions. In the experience of Wignall, \( x \) naphthylamine cannot ever be considered as the cause of cyanosis, dermatitis, irritation of the eyes, nose, throat or larynx.

He insists also on the fact of the difficulty of affirming whether naphthylamine ought to be considered as the most important factor in the development of bladder lesions, because the workmen have been employed in so many different departments from time to time, where they have been exposed to the injurious action of products other than naphthylamine (see also article: "Industrial Diseases: Urogenital System").

**Detection in the Urine**

(a) \( x \) naphthylamine. — Acidify the urine in the cold state with hydrochloric acid and add a few drops of solution of nitrite of soda and a solution of \( 3-5\text{-7} \) phenylamidonaphthol, a violet colour is obtained, which is capable of dyeing cotton.

(b) \( \beta \) naphthylamine. — Acidify the urine with hydrochloric acid; let it boil rapidly (to saponify the associated compounds). Allow it to cool; add ammonia and agitate. A violet coloration is obtained with a dark violet precipitate.

**Diagnosis**

The early detection of bladder trouble demands a regular periodic examination of the urine for the presence of red blood cells; if the evidence is positive, the worker should be examined cystoscopically. Bladder tenesmus and haematuria may quite easily be the signs of a mild disease (haemorrhagic cystitis), but they are often also the first symptom of cancer.

---

1 At the Congress of the Association of Surgeons of the Middle Rhine (held at Tübingen, 8-9 June 1929), Schaer, of Basle, made a communication on the subject of the experimental production of cancer of the bladder. After inhalations of very small doses of naphthylamine lasting over a number of months, he was able to obtain positive results with rabbits. As a matter of fact, Schaer was able to show epithelial alterations of the most different kinds, including the formation of papillomata and carcinoma of the mucous membrane of the bladder. In the course of the discussion at Ludwigshafen, brought into prominence the fact that, in the manufacture of aniline colours, tumours of the bladder have been much more rarely met with since the manufacture and use of naphthylamine has been given up.
of the bladder which is already inoperable. With a view to the prevention of haemorrhages of the bladder, efforts have been made to detect periodically in the urine naphthylamine, by means of diazotisation and combination with the sulphonamic acid of phenylamidonapthol, but this seems to be a measure of doubtful utility.

HYGIENE

Although the toxicity of the naphthylamines, from the industrial point of view, is manifestly feeble, the risks of bladder lesions for workmen inhaling quantities of naphthylamine over a long time, however weak they may be, demand a meticulous health organisation in the processes of work.

All evolution of vapour in the room should be prevented during the preparation and distillation of the pure crude products; and use should be made of tightly sealed apparatus provided with localised exhaust ventilation. This last measure should be similarly adopted during emptying of the distillation apparatus, as well as in the preparation of the sulphonamic acids.

All evolution of dust should be avoided by carrying on grinding processes in a closed apparatus and by emptying such apparatus and packing the ground products subject to adequate precautions. Where necessary the workers should be supplied with respirators. In order to avoid scattering dust on the floor or its escape into the air, several factories place flat tubs filled with water and covered with an iron grill under the casks, which is filled with water and covered with an iron grill under the casks, which is a very effective precaution. Localised ventilation, smooth and impermeable floors easy to clean, and working clothes fitting closely round the neck and wrists and washed and changed frequently should be provided. Periodic medical examination, always completed by regular analysis of the urine, should be arranged for.

LEGISLATION

For statutory regulations on the installation and equipment of these factories, see article "Nitro-Amido Derivatives", as well as for the statutory provisions as to notification and compensation of diseases due to the products in question.

(Berlin).

Native Labour (Hygiene)

Measures of hygiene to protect the health of native workers are distinguished from those laid down in ordinary industries by the fact that in the case of the latter the attention of the health expert is concentrated specially on the factory and on the industrial work carried on in it, whereas as regards the former, the hygienic measures are rather general in character.

The opinion has been expressed that it is more accurate to speak of accidents only in regard to native labour, the use of the term "occupational disease", or illness caused by work, being inappropriate, seeing that most of the activities engaged in by natives take place in the open under very healthy conditions (Merlin).

However, even leaving out of account work in mines and other industrial concerns with risks similar to those met with in temperate climates, native workers are frequently, if not always, subject to conditions forming an extraordinary contrast to those of their normal life. These conditions involve considerable distress, even for individuals in perfect health, from the moment they leave their homes until they are free to quit the workplaces or plantations.

In the colonies, as is well known, the villages from which these workers are drawn are often at a considerable distance from the place where they work and the journey exposes them to certain dangers. In some cases, they are recruited from regions presenting conditions of climate and of life radically different from those in which they are called upon to work. Thus, for example, the natives of the Rand Mines (South Africa) are recruited partly from certain Bantu tribes or from
parts of Mozambique south of 22° S. latitude (Orenstein).

Very often during the journey a number of those recruited break down under the hardships endured, for, as is stated in the Annual Report for 1925 of the Tanganyika Territory, rest-houses are few in number or non-existent and the food of the workers differs greatly from that to which they have been accustomed at home. Further, the workers travel under conditions devoid of adequate hygienic measures and are exposed to various maladies.

The risks run are much greater for races not in possession of immunity against certain infections. These workers, on arriving at their destination, may thus be in a miserable condition and incapable of carrying out the work assigned to them, which they generally find difficult owing to their inexperience. Those who arrive free from disease are nevertheless weakened by fatigue and by the privations undergone on the journey, and are ready to fall victims to any disease raging in the district, such as malaria, yellow fever, sleeping sickness, etc.

For these reasons the healthy worker is exposed to a risk in direct relation to his employment, a fact which has been recognised on various occasions, amongst others, at the National Colonial Congress at Brussels in 1924. For example, on the subject of sleeping sickness it has been said that one of the causes of the spread of this disease is "certainly the harvesting in contaminated regions of certain natural products: coconuts, copal, rubber, etc. This harvesting causes a more intense circulation of the population and subjects it to conditions of life which diminish the resistance of the body to disease ".

Colonial authorities and employers do take into consideration the importance of hygiene in dealing with native labour because of its effect on output (Noel Bernard, Heckenroth) and an ever-increasing attention is being paid to this aspect of the problem. At the same time, much progress has still to be made, and in order to arrive at a satisfactory situation in regard to the matter, attention must be paid, from the hygienic point of view, to general as well as particular aspects of the employment of native labour and to the procedures to be adopted before and during employment.

Up to the present, information on the subject of native labour only exists with regards to certain industries: gold mining, diamond mining, tea and coffee plantations. Apart from these spheres of employment only a limited amount of data is available as to food and lodging, but such information is really of no value in regard to morbidity and mortality. This state of affairs is comprehensible, bearing in mind the rudimentary state of the sanitary and medical organisation in the countries in question, and the difficulties which it encounters.

Obviously, resistance to exhaustion and disease is increased if food is sufficient and healthy. The colonial sanitary authorities have from the outset paid particular attention to the rations suitable for native labourers.

In the Belgian Congo, the authorities of the province of Katanga have drawn up regulations as to the hygiene and safety of workers (1927) which lay down the weekly ration for workers in industrial, agricultural and commercial enterprises, both public and private. This ration gives as a minimum: manioc flour, 1,200 grm.; beans, 500 grm.; ground-nuts, 500 grm.; vegetables or fruit, 1,000 grm.; fresh meat, 1,400 grm.; salt, 105 grm.

In this ration, 1 kg. of maize or rice flour, 1,20 kg. of sorghum flour, or 1,10 kg. of millet flour (eleusine) can be substituted for the manioc flour.

The haricot beans can be replaced by equal quantities of peas or lentils; the ground-nuts can be replaced by 300 grm. of palm-oil or any other animal or vegetable fat.

As regards the fresh meat, 1 kg. can be replaced by 1 kg. of chilled or frozen meat or fresh fish, or by 600 grm. of preserved meat or 500 grm. of smoked meat or 800 grm. of dried fish. In any case, the meat must not contain more than 20 per cent. bone, and only in cases where it is impossible to procure fresh meat is chilled or frozen or preserved meat or fresh or dried fish to be substituted for it.

Still other modifications can be allowed, but only with the written permission of the medical inspector supervising the workers.

No worker is allowed to give up any portion of his ration and it must be delivered in kind, the corresponding value in money not being authorised except in the case of those workers in receipt of a daily wage of at least 4s.

Another example of the type of food supplied is shown by the ration furnished to Indian workers in the Federated Malay States. This ration comprises: rice, 18 tahils; fresh vegetables, 6; fish or meat, 4, or dhal, 5;
The workers also receive hot coffee or tea in the morning before starting work.

In the French mandated territories there are sometimes considerable differences in the quantity of foods allowed to workpeople from two adjacent countries and subject to exactly analogous conditions of existence and climate. Thus, for example, the daily ration of food for workers in Togoland is entirely different from that for the Cameroons, as will appear from the following table:

<table>

</table>

All these recommendations would be extremely useful were it possible to apply them in full. The difficulty in doing so makes the question of the insufficiency of the diet of the natives one of general import and not particularly a question affecting the workers only. The Academy of Colonial Sciences in France has called attention to the fact that of all the causes leading to depopulation of the colonies, this problem of alimentation was the chief one, and it expressed the view that "under-nourishment, which is very frequent, must be looked upon as an essential factor in connection with mortality, and the low birth-rate brought about by epidemics, bad conditions of living and lack of hygiene among the natives, syphilis, alcoholism, etc. In order to remedy this deficiency in food which is so prevalent, the Academy lays down as a necessity the fullest possible development in all the colonies of the cultivation of foodstuffs, of fishing and of stock-rearing, coupled with the pursuit of a rational, policy relative to the education and reconstitution of the native races." (Roubaud)

So far as clothing is concerned, sufficient attention has not yet been paid to this problem as it affects the native workers, although it is certain that if the negroes were more suitably clothed, they would be in a better position to resist the most widespread maladies, especially pneumonia, the high incidence of which amongst the natives is partly due to the fact that they are insufficiently clad (National Colonial Congress, Brussels, 1924).

The reason why the black races do not dress like Europeans is due to their poverty, which prevents them from buying other clothes than those which they have always worn. A first step towards providing them with a suitable dress has been taken in the Belgian Congo, where the legal requirements provide that each individual who is recruited must be supplied with a blanket of mixed cotton and wool; in West Africa, in Togoland and the Cameroons, similar provision is made, the native worker receiving a large, heavy and thick blanket for the duration of his contract. The conditions are better in Madagascar, where men who are sent to work at altitudes exceeding 800 metres have warm clothing given to them on their arrival. In Oceania the workers have the right to two "changes" yearly, each change including a blanket, two shirts, two pairs of cotton trousers and a head kerchief.

The question of the native worker's dress demands an equitable solution. The clothing with which he is provided becomes worn out while he is at work and it is only just that it should be replaced (Heckenroth).

In the province of Katanga in the Belgian Congo, the construction of camps and rest-houses is regulated in detail by the Order of 4 October 1927, No. 28, on the hygiene and safety of workers. The quarters of native workers employed outside the cities take the form of camps, the construction of which in certain cases is undertaken by the employer. He is obliged to submit the detailed plans of the situa-
tion of the camp and of the nature of the dwellings and annexes to the approval of a medical man. The site has to be kept in good condition, as have also the quarters and their annexes. The ground must have a natural fall so as to allow the water to run off; it must be provided with a supply of drinking water and water for washing and for the preparation of food. The ground must also be cleared of brushwood to at least 25 m. from the outside buildings. So far as dwellings are concerned, special measures are laid down as to their durability and situation according as to whether they are built of straw, concrete, sheet-iron, dried or baked bricks, or stone. In the absence of a more perfect installation, the use of a system known as “fosse de fumigation” may be employed for latrines.

In the absence of a more perfect installation, the use of a system known as “fosse de fumigation” may be employed for latrines. Finally, the camps must be provided with suitable washing accommodation and incinerators. The incinerators and the latrines must be at a distance of at least 30 m. from any living quarters. When workers have to be recruited from distant regions, rest-houses must be constructed, which may not be more than 30 km. distant from one another if the workpeople travel on foot. Every rest-house must comprise quarters for the workpeople corresponding to the maximum number to be housed, lodging for the staff, a store for obtaining food, a kitchen and latrines. The rest-houses should satisfy the same conditions as those made for camps and dwellings. The premises must be provided with individual and immovable beds.

Among the operations which native workers most frequently engage in is that of porterage. The measures of protection for workpeople employed in this kind of work have attracted the attention of the authorities and in some colonies, notably the province of Katanga, the maximum of effort required and the loads to be carried are prescribed statutorily. As a matter of fact, any native employed in porterage may not be asked to cover in a day a distance exceeding 25 km., in exceptional cases 30 km. The weight of the load must not exceed: (a) 25 kg. if the load is carried by one man, (b) 45 kg. if carried by two, (c) 60 kg. if by three, and (d) 75 kg. if the porters number four. For each increase of 15 kg. another porter must be employed, and the weight includes, in each of the cases cited above, the object to be carried and where necessary the food of the porter. Finally, one day of complete rest must be given to the carriers after every six days of porterage.

**Pathology**

Data as to mortality among native workers are very scarce, and those that exist only relate to mine or factory workers (South Africa). The few figures which can be quoted give some idea of the situation in this country. Thus, in the Luderitz Diamond Mines, where the number of workers employed was 6,619 and 8,658 in 1925 and 1926 respectively, the mortality per thousand per year was as follows:

<table>

In the vanadium mines at Grootfontein, where a total personnel of 947 workers was employed in 1926, the mortality was 40.12 per thousand per year, while much lower figures were registered for the tin mines of Karibib and Omaruru, where the mortality was only 6.76 per thousand per year for an average number of 297 workmen in 1926.
The workmen of the Rand Mines number about 80,000. Native workers, however, usually stay less than a year, and this necessitates the engagement of an average of 110,000 workers during the course of the year. The mortality among the natives, about 40 per thousand per year before 1912, was due primarily to pneumonia, which accounted for nearly a third of the deaths. In 1912, the recruitment of natives particularly liable to pneumonia was suppressed, and an enquiry was undertaken into the methods possible for reducing the high mortality from this disease. Prophylactic vaccination (Almroth Wright) and the improvement of general conditions of sanitation and particularly of dwellings was recommended (General W. C. Gorgas). The adoption of these measures led to a reduction in the pneumonia mortality of at least 10 per thousand.

The campaign against scurvy has been carried on with success by modifying the diet as to quality and quantity and recognising the importance of antiscorbutic foodstuffs (see article "Gold Mines").

For further details, see the Report of the International Silicosis Conference held in Johannesburg in 1930, published by the International Labour Office.

In the Belgian Congo, more than 50 per cent. of the deaths are due to pneumonia and pneumococce affections, which shows the connection that exists between the nature of the work and these affections (Trolli): special conditions of work, notably heat and humidity, and, as a predisposing factor, fatigue due to what is called the "inaptitude" of the native which makes him expend more energy than would a white man. This makes it essential, in order to diminish the mortality and the morbidity, especially among the natives of the Congo, not only to supply them with every hygienic precaution (adequate clothing, food, lodging, means of adaptation to the climate and new conditions of life), but also to establish the limit between fatigue and over-exhaustion and to determine the amount of energy which the black race can put into each required piece of work (Trolli).

Illness from intestinal parasites has attracted the special attention of colonial doctors. Among the coffee plantation porters in Central America, the following percentage frequency has been noted (Zschucke):

As regards the plantation workers, the causes of death among the workers on coffee plantations in Central America are shown to be as follows, according to the entries in the civil registers between 1907 and 1924 (Zschucke): (for eleven plantations) absolute number of deaths: 2,796; deaths from helminthiasis, 22 per cent.; diseases of the digestive organs, 22.5 per cent.; diseases of the respiratory organs, 13 per cent.; acute infectious diseases, 30 per cent.; rare diseases, 3.5 per cent.; old age, 3 per cent.; undiagnosed, 6 per cent.

Amongst workers on coffee, cocoa, and rubber plantations, especially in Brazil, there occurs an excessive mortality from snake bites.

Ankylostomiasis is particularly frequent among natives, as the development of the larvae is favoured by a temperature corresponding to that of the tropics. In certain tropical regions, 50, 75 and even 90 per cent. of the total population are carriers. Among plantation workers and especially in places where health conditions and sanitary arrangements are defective, the number of the infected is reckoned at 100 per cent. (H. Bruns).

Among the infectious and epidemic diseases, those which most frequently invalidate the native workers are influenza, measles, chicken-pox, mumps, whooping-cough, dysentery, typhoid, typhus, malaria, syphilis and sleeping sickness. Finally, heat stroke and "tropical ulcers" constitute causes of incapacity which must be taken into account.

Particular mention ought to be made of cutaneous infections among wood-workers and those who handle tropical plants and their products (lacs): cutaneous irritations among wood-choppers from the resin of *Rhus vernicifera*; formation of papules and vesicles due to the wood of *Rungus* (Hornsey); nettle-rash among workers handling iroquois wood, etc.; a certain number of cases of occupational dermatitis are caused by parasites (*Pediculoides ventricosus*, *Tyroglyphus longior*, etc.) which grow on grasses and vegetation, etc., which dock labourers, for example, have to load and unload.

Finally, the work of cleaning hemp, practised especially in regions that are particularly dry, exposes the workers to infections often complicated by severe ulcers of the legs as a result of work in irritant stagnant water.

**Prophylaxis**

The most generally adopted measure for protection of the native workers, apart from prophylaxis in regard to tropical diseases, consists in rigorous medical examination on admission.
Every worker in tropical regions ought to have a certificate of fitness before commencing work, which should be attested by a duly qualified doctor. The initial medical examination is now compulsory, for instance, in the province of Katanga in the Belgian Congo, where the causes of disability have been thus classified:

(a) General inaptitude for work (absolute unsuitability): tuberculosis, leprosy, severe and incurable elephantiasis, malignant growths, large goitre, Basedow's disease, trypanosomiasis, trachoma, blindness, severe diseases of the internal organs and bones, extensive ulceration of the soft tissues.

(b) Physical inaptitude for general work, compatible with the performance of light work: old age, insufficient development (Pignet's index above 24), weight less than 50 kg., chest measurement below 78 cm., elephantiasis, oedema, pronounced varicose veins, running ulcers and scars on the legs with permanent adhesions, functional and definite paralysis of a limb, atrophy of a limb, loss of the thumb and index finger of one hand, deformity of certain limbs, flat-foot, hunchback and pelvic deformity, deafness and dumbness, loss of an eye, slight inguinal, scrotal and umbilical hernia.

At the physical examination, attention must be paid to the particular constitution of the different native races. Large chest measurement does not always signify robust constitution; the figure can be small and yet possess great powers of endurance and capacity for work (Bantu race of tropical Africa). Before commencing work the recruit should be brought together in camps described as "detention" camps, for several reasons (Pearson and Mouchet): necessity of a period of rest for workers coming from a distance; possibility of acquiring immunity under most favourable conditions without the effort that the work entails; possibility of administering special diet so essential in the case of natives arriving from regions where the food supplies are subnormal; possibility of deñsensitisation of the new arrivals in order to avoid infection of the camp; necessity of quarantine to detect any contagious diseases contracted in travelling; possibility of effecting necessary vaccination before beginning work.

Apart from the initial medical examination, the usefulness of a periodic examination has been recognised. The Committee of Experts on Native Labour (at Geneva, July 1927) has suggested, particularly for so-called forced labour, the following measures: "Medical examination of every forced labourer ought to be made at fixed intervals during the period of employment, in order to determine whether the worker has remained as fit for the required work as he was at the moment of his engagement, as shown by the medical certificate."

These medical visits necessarily raise the question of the creation of a health organisation to protect the health of native labourers. The Expert Commission mentioned above had recognised the necessity of having sufficient personnel to undertake medical examination and give the necessary treatment. Health measures in places where natives are collected together are all the more essential since the attitude of the native in regard to the doctors is far from satisfactory (reports of the Permanent Committee of the Belgian Colonial Congress, 1921, the Commission for the Protection of Natives, 1922, and the Committee for the Study of Labour Problems in the Belgian Congo in 1925). The application of these measures seems to have been effective, since health conditions are certainly better in States possessing protective legislation in regard to labour.

The medical men sent to the colonies ought naturally to know the conditions under which natives who are recruited in regions far removed from the concentration camps live. Enquiries undertaken in these regions ought to hear especially upon the dwellings and villages, diet, nature of the country, climatic conditions, kind of life and occupations, history of all previous recruitments and history of the race, possibility of women accompanying the recruits (Pearson and Mouchet).

Particular attention ought to be paid to the application of sanitary measures, the simple prescription of sound rules of health being insufficient in countries where education of the individual has yet to be done. As was said in the Annual Medical Report for the Tanganyika Territory for 1925, in the best-equipped camps difficulties are always greatest with natives who cannot be compelled to make proper use of the existing sanitary installations.

Sanitary supervision is especially needed in places of work where workers are engaged who have been abruptly removed from their habitual surroundings, sometimes being placed under new climatic conditions, subjected to a different kind of diet from that to
which they have been accustomed, obliged to execute from day to day regular and often arduous work for which they have not been trained and placed — indeed, morally and physically in a situation where their physiological equilibrium is constantly broken and their organic resistance to disease diminished, at any rate for a time."

Good sanitary conditions cannot, however, be maintained where workers are herded together if the authorities do not possess power to punish infringement of the most elementary sanitary rules. Besides, in such cases something more than simple persuasion is required. It has been said that much could be done by dividing up the concentrations, each having its own proper latrines and incinerators, and placing a responsible head in charge of each of these sections. Regular inspections should be carried out by a European. The institution of incentives, such as extra rations or food to those who have practised the greatest cleanliness, might do something to improve the sanitary condition of camps. Experience so far acquired on these lines would appear to be most encouraging, showing that improvements not to be obtained by compulsion may result from a spirit of emulation amongst individuals.

The organisation of a medical service and of a hospital installation for workers in plantations and working centres in the colonies meets with great obstacles: the expense of engaging a qualified medical man; difficulty in finding a health staff equipped to cope with the multiple demands of the situation. The needs of the colonies and the difficult conditions of the life would not appear to be adequately met with by the engagement of an exclusively European medical service. Thus, for instance, even in 1923, in the French Congo, there were only twenty medical men for 2,450,000 inhabitants (K. Mense). Although efforts have been made to fill the gaps by native health officials, their number is still far from sufficient.

According to information furnished by W. Kouwenaar, Director of the Pathological Laboratory of Medan, the sanitary and medical services are becoming more and more perfect in the agricultural estates on the East coast of Sumatra, thanks to the methods instituted in 1871 by Drs. Schuffner and Kuenen, who were able to reduce the general mortality among coolies from 60 to 11 per cent. during the first eight years of their work at Deli. To day, the centralised hospital service allows of rapid and precise diagnosis and adequate treatment, which were not possible when the medical service was decentralised for each undertaking.

Treatment of slight cases represents a very high percentage (70-80 per cent.) of the medical activities. The normal number of sick undergoing treatment can be placed at about 2 per cent. of the workers, although this figure varies greatly and often reaches a higher rate (25 per cent.) for the members of the workers' family who have the right to treatment.

It has been estimated that a doctor can look after 6,000-8,000 coolies with their families, and that a hospital is needed for 4,000-8,000 workers. In the old plantations, where conditions are good, these figures can easily be exceeded.

The medical service of the Deli agricultural estates actually numbers forty-six physicians, two assistant physicians attached to the laboratory, and a physician-in-chief at the Batak Hospital. There are forty hospitals, with a total of 14,250 beds serving a working population of 300,000 employed persons and an equal number of their dependants.

A very important work is that of hygienic propaganda among the working population. A general inspection of the whole of the personnel (men, women and children) of the plantations is made once or twice a year, with the object of finding out by means of a rapid examination the presence of external visible maladies (such as skin troubles, itch, ulceration, venereal diseases, diseases of the eyes, etc.), making a determination of the haemoglobin (by Tallquist's method), and administering a dose of chenopode oil against ankyllostomiasis.

In marshy regions the size of the spleen is determined and the type of malarial parasite. From time to time, the whole of the population is vaccinated against smallpox; typhoid and paratyphoid.

Every worker who has reported sick is obliged to enter a hospital to undergo treatment or else becomes an outpatient. Every person found to be suffering from ankyllostomiasis is naturally subjected to appropriate treatment.

The medical service has favoured the distribution of tea during work in the fields, in order to prevent the workers from drinking from the small
streams, which are often contaminated. A campaign is waged against flies and for the installation and proper maintenance of latrines, etc.

The danger of beri-beri has been almost overcome, but in cases of the disease, which usually only occurs among recruits, foods prepared from a specially calculated composition are distributed.

Particular care is taken of the children, infants and mothers, etc. Naturally, the medical service carries out a very close inspection as regards affections and infectious diseases.

The expense of such a service can be reckoned at about 12-15 florins per worker per annum. The hospital expenditure, including the payments to the medical service and sinking fund costs, is from 80 cents to 1.20 florins per day.

KOUWENAAR. Data supplied to the International Labour Office, 1930.

***

**Nickel**

**TECHNICAL DATA**

Nickel (symbol Ni) resembles silver in appearance; its specific gravity is 8.8 and its melting point 1,435° C. It is hardly attacked at all by the air or by weak acids; it lends itself easily to rolling and can be drawn into extremely fine wire.

It is found in its natural state in meteoric iron and also combined with sulphur (pyrothine) and with arsenic (nickeline); but it is mostly obtained from garnierite, which is a hydro-silicate of nickel and magnesium. Almost all the nickel-containing minerals contain cobalt (see that article).

The preparation of nickel differs according to the nature of the mineral; thus, for example, in New Caledonia garnierite which is very rich in iron oxide is treated with gypsum in a melting bath in order to transform the oxidised mineral into a double sulphide of nickel and iron. The matte when freed from iron in a converter liberates pure nickel sulphide which is roasted and converted into oxide of nickel. This is reduced without melting in the form of little pellets or small cubes by contact with wood charcoal in gas furnaces.

A method recently employed comprises melting of the mineral with a view to preparing ferro-nickel followed by electrolysis of the pure nickel.

The Canadian mineral after melting and freeing from iron is subjected to a treatment with the object of separating the two sulphides of nickel and copper. To effect this sodium bisulphate is introduced and converted into sodium sulphate with dissolution of copper sulphate. The nickel sulphate is separated out by liquidation, while the copper sulphate collects in the upper part of the ingots. Refining is done electrolytically.

The production of nickel by the nickel carbonyl (Mond) process consists of the following different operations: sorting of the mineral by means of magnetic separators; concentration; foundry work, where the fritted mass mixed with calcined coke, etc., is heated in a blast furnace. The matte of the nickel and copper sulphides is deposited at the bottom of large basins and there separates from the slag. After passing to the Bessemer converters (to eliminate the iron); the matte of nickel and copper sulphide is broken up, ground and sent to the refinery. Calcination converts the sulphides into corresponding oxides. After intimate
contact with dilute sulphuric acid, copper is extracted. The filtered solution passes to driers and the powder is subjected to reduction in steel towers. The mixture obtained goes to volatilisers where a current of carbon monoxide combines with the nickel and yields nickel carbonyl.

This is decomposed with liberation of carbon monoxide which re-enters the cycle, and nickel is deposited on small pellets which fill the towers. The nickel so obtained is 99.5 to 100 per cent. pure and free from cobalt.

Nickel is used in alloys with iron, chromium and tungsten. The non-ferrous nickel (nickel-copper-zinc) is used in iron and steel works and in metallurgy. Its salts (sulphates, oxides, nitrates, etc.) are used for hydrogenation of oils, for nickel plating purposes, manufacture of accumulators, in chemistry, etc.

In nickel plating the objects are freed from grease electrolytically in a bath of boiling soda, followed by rinsing in water and electrolytic cleaning in a sulphuric acid solution. A further rinsing is carried out and sometimes also a slight fresh treatment with dilute hydrochloric acid.

The nickeling bath contains nickel chloride and boric acid in addition to nickel sulphate.

Mordanting of the pieces can be carried out also with nitric acid or with benzine and lime.

**Sources of Danger**

The sources of danger in the Mond process arise from the carbon monoxide (especially from nickel carbonyl) (see that article). The first enquiries as to the toxicity of this product were made for Mond by Mackendrick (1883), and, following on a serious accident in the factory (1893) causing the illness of twelve workpeople (with two deaths), researches were undertaken at the request of Mond himself by A. Mosso and Armit on the toxic properties of this compound. Since then no accidents have occurred, thanks to the rigorous application of precautionary methods (operations in closed apparatus, totally automatic processes, etc.).

In the other methods the risk of poisoning depends on the different gases and vapours given off (sulphides, oxides, etc.).

The source of injury in nickeling comes from the salts, of which the irritating and caustic action is favoured by the alkaline or acid baths, lime, benzene, etc., which are utilised in the operation of removing the grease from the objects to be nickeled.

**Poisonous Action**

The poisonous nature of nickel and its salts has for long been the subject of discussion. Generally speaking, it is admitted that the oxides and certain of the salts are not poisonous. In the form of pure nickel or of nickel iron it is used for making domestic utensils such as pans, jugs, etc., which in use have not been shown to cause injury to health. Careful experiments by Birnbaum, Geerkens, etc., have shown that considerable amounts of nickel given for a long time with food have not brought about any obvious pathological changes. Other research workers however have brought about in dogs by means of very strong doses (1 to 3 grm. per kg.) intestinal derangement with vomiting, convulsions, collapse and asphyxia; but there is general agreement that fatal poisoning by nickel cannot occur.

The most important of the nickel salts is the sulphate (NiSO₄), which is used especially in galvanic nickeling of copper, brass and iron, etc. It is obtained by dissolving nickel, or nickel waste in sulphuric acid, and then evaporating the filtered solution.

According to the experience of Kohn-Abrest and Agasse-Lafont, every effort should be made to prevent workers handling oxide of nickel from coming in contact with the abundant dust which is liberated. They cite the case of a young woman worker employed for five years in a factory where oxide of nickel was handled ('grey powder'), as well as "black powder" (a mixture of mercuric oxide and iron oxide), intended for the manufacture of accumulators. She was solely engaged in keeping clean the workrooms where oxide of nickel was used. At the end of five years' employment she showed signs of poisoning characteristic of mercury. Neither mercury nor nickel was found in the blood or urine, but both were found in the hair. The authors consider that the presence of nickel in the hair renders probable the influence of nickel in the poisoning in question and that it shows how easily the organism absorbs the substances handled.

In Great Britain cases of poisoning due to nickel chloride and nickel carbonyl are said to have been reported in workers engaged in the extraction of nickel from minerals, but in Germany no similar observation has been made (see article "Nickel Carbonyl").
1925 Chomiakow showed that in a Russian soap factory workpeople engaged on the contact process with a duration of about twenty years' employment on nickel showed no symptoms with the exception of severe headache, which was, however, attributed to vapours of acrolein resulting from insufficient cleaning of the boilers. However, analysis of the air did not show the presence of acrolein and examination of the blood was negative.

In Switzerland three cases of dermatitis were reported from nickel plating in 1922, four in 1924, ten in 1925, seven in 1926 and eighteen in 1927. One case only (1922) was caused by sulphate of nickel.

**PATHOLOGY**

A malady peculiar to persons employed at nickel-plating baths is a dermatitis to which the workpeople have given the name of "nickel itch". According to detailed reports on its occurrence and evolution taken from annual reports of the German factory inspectors, as well as from the observations of Fischer in a large number of factories, the clinical picture varies remarkably. Nickel itch resembles particularly, especially at the beginning, ordinary industrial eczema. Some authorities consider this lesion as the expression of the phenomenon of anaphylaxia (Walthard, 1926).

As a general rule the malady commences by a sensation of burning and itching in the hands, then a pruriginous eruption appears in the web of the fingers and on the wrists and forearms. The finger lesions may extend and involve the nails (Heller). The erythema and the eruption or nodular ulceration may often weep and become pustular, extending at times to the arms and chest, face and all over the body. The cracks in the skin, vesicles and pustules, etc., thus formed set up itching which is increased particularly in the evening and at night. In some isolated cases the affected persons complain of a bitter, metallic taste in the mouth.

Recovery takes place as a rule after a week, although cases are known where the condition has lasted for thirteen weeks.

Sensitiveness to the action of salts of nickel is quite individual. Generally the majority of persons employed at the nickel baths are not affected; nickel itch attacks particularly individuals of weak constitution and women. There is a predisposition to recurrence among those who have once been attacked, so that a change of employment is often required.

Action of the salts of nickel occurs naturally mainly on the hands and arms of the persons employed in the nickel-plating baths who have to dip their hands into the bath in order to hang up the articles or to remove those which are ready, etc. Where contact with the nickel-plating solution is not direct the worker may even be affected when he rests his fore-arm on the edge of the baths or vats or by being wetted from the bursting of bubbles at the surface of the solution, as such bubbles act as a vehicle for particles of the metallic salts. This is the reason why the first signs of the disease always affect the hands and arms. As soon as the workers show the first symptoms they give up their work until the cure is complete. Owing to this, nickel itch rarely assumes a grave character.

According to Helene Kolzowa (1927) the persons who are most exposed to risk are those employed in degreasing, such operations as nickel plating proper being in her opinion less dangerous. On the other hand, Kolzowa has been able to show that women have a more marked predisposition than men. Her enquiry extended over 56 workers engaged on nickel plating, of whom 23 (41 per cent.) showed cutaneous affections; 10 cases were confined to cleaners and degreasers of the articles to be nickel plated, 12 to degreasers and nickel platers and one case affected a nickel plater. In the first group (degreasers) 7 were cases of dermatitis and 3 of eczema; in the second (degreasers and nickel platers), 5 were dermatitis and 7 eczema, and the third (nickel plater) was dermatitis. The cutaneous troubles were more often amongst those newly employed; and after employment for two months the diminution in the cases was obvious.

In studying a large number of cases, Bulmer and E. A. Mackenzie (1925) arrived at the conclusion that the most important factor in causing the eruption is lack of a sufficiently cool atmosphere around the workers. Increase in the temperature of the skin, together with the action of the alkaline sweat, accentuates the irritability of the parts exposed and diminishes their resistance.

A considerable reduction in the number of cases may be obtained by providing adequate ventilation and means for cooling the atmosphere. The eruption once produced may be effectively dealt with, according to these authorities, by the administration of calcium chloride.
Jadassohn and Schaaf (1929), of Zurich, dispute the opinion of Schittenhelm and Stockinger that the handling of nickel is a most frequent cause of eczema and that dermatitis is present in almost all persons employed in nickel plating within eight to twenty days after commencement of the work in question.

According to their enquiries and experimental researches, these authors conclude that the injurious factor is not nickel but perhaps a substance used in the industrial processes (in some cases the cause has been Viennese chalk). Among 700 Swiss nickel platers they only found between 1922 and 1927 39 cases of eczema, of which only one had been with certainty caused by nickel (and this was one of idiosyncrasy). Jadassohn and Schaaf are of the opinion that nickel only causes eczema in persons who have an idiosyncrasy for this substance.

Du Bois (1931) has reported numerous cases of nickel dermatitis amongst workers engaged in nickel-plating using baths at 85° C. The vapour liberated impregnated the working clothes, which, once wet, irritated the skin. Of 570 workers employed in 1928-1929, one-twentieth remained immune. The hot season, abundant perspiration and alcoholic excess constitute predisposing factors as regards this disease, which is very rare when plating is done by the cold process. A first attack, far from conferring immunity, renders subjects more sensitive to later attacks.

**DEMONSTRATION**

Lawrence Fairhall (1926) suggests di-thio-oxalate of potassium as a reagent for the determination of nickel. This method has the advantage of being more sensitive than the other methods proposed, and it allows of a calorimetric determination of very small fractions of a milligram.

**HYGIENE**

Careful persons and those who have already suffered from the effects protect themselves by minute cleanliness, washing the hands and arms with soap and water and especially by the application of grease, glycerine, etc., and treatment of the parts affected by means of an emolient ointment.

Persons who are sensitive or show predisposition should be excluded. Hooks or pincers should be used in order to protect the hands, as well as rubber gloves for use in taking out objects that have fallen into the nickel bath. Careful emptying and cleaning of the vats to remove deposits forming there should be carried out. Good ventilation of the workrooms, removal of steam from the baths and rigorous cleanliness of the workrooms, benches, etc., should be observed.

**LEGISLATION**

Dermatitis set up by nickel is brought under Workmen's Compensation Acts in certain cases (see, for example, the lists of certain chronic maladies of the skin; see also the articles "Nickel Carbonyl" and "Electroplating").

**Nickel Carbonyl**

**CHEMISTRY**

Nickel carbonyl or tetracarbonyl of nickel, Ni(CO)4, is a compound of nickel and carbon monoxide. Discovered in 1890 by L. Mond and C. Langer, it is a colourless or faintly pale straw-coloured liquid, highly refractive, boiling at 43-44° C., volatile at the ordinary temperature, and solidifying into a crystalline mass of needles at 83° C. The vapour at a temperature of 50° C. has a density of 869, and at 60° C. decomposes with explosion. The vapour burns in the air with a very sooty flame. Nickel carbonyl is soluble in alcohol, benzine, and chloroform; it is not attacked by dilute acids or alkalis, but is decomposed by the action of nitric acid or aqua regia. It gives off a peculiar odour like soot, which is perceptible when the air contains 1 part in 2,500,000. The flame of a Bunsen burner becomes luminous when the air contains 1 part in 400,000. By means of nickel carbonyl pure nickel is isolated industrially from its ores (see article "Nickel").
Nickel carbonyl is formed at the ordinary temperature when carbon monoxide is passed over powdered nickel, but it is made in a quite special manner for the production of pure nickel by the Mond process (see article "Nickel").

**TOXIC ACTION**

Toxic action may be due to accidental emissions of fumes during the manufacture of large quantities of nickel. The channel of absorption is through the respiratory tract. Henriot and Richet (1891) believed that nickel carbonyl absorbed by the blood decomposed slowly and produced carb-oxyhaemoglobin. Langlois (1891) also was of opinion that it combined with haemoglobin; J. Mackendrick and W. Steedgrass (1891) on the contrary concluded, as the result of their experimental researches, that the metal nickel itself was poisonous, which they found not only at the point of subcutaneous injection, but also in the blood, and Wahlen (1902) that nickel carbonyl itself was toxic. Armit (1907 and 1908) could not make out any chemical combination between the haemoglobin and the carbonyl which is absorbed by the serum. If the quantities absorbed, however, are high, the volume of carbon monoxide resulting from their decomposition is sufficient to fix part of the oxyhaemoglobin and induce intoxication. On contact with air, humidity, and carbon dioxide (as is the state in the lungs) the nickel carbonyl decomposes rapidly into carbon monoxide and a compound of nickel. This compound is probably a hydrous basic carbonate slightly soluble in water and two and a half times as soluble in serum, with which it forms a colloidal solution. The toxic property then, does not come from the carbon monoxide, but from this compound. Ogler, however, has not found nickel in the blood. The animals treated by Armit died when their blood contained not more than 0.072 to 0.16 per cent. of carbon monoxide and were not poisoned by iron carbonyl, which contains more carbon monoxide than nickel carbonyl. Rabbits die in 65 minutes after breathing air containing 0.018 per cent. of nickel carbonyl, dogs and cats in 12 to 14 hours.

The peculiar toxicity of nickel carbonyl is due, in Armit's opinion, to the fact that this enters the system as a gas and becomes deposited in the form of a slightly soluble powder in an extremely fine state of division over the immense surface of the lungs. The nickel is dissolved, absorbed by the blood and carried to the organs where it exerts a specific action on the endothelium of the capillary vessels (especially of the brain and suprarenals), setting up haemorrhages.

Its action on the lungs sets up irritation, congestion, and oedema. Elimination takes place through the intestines and kidneys.

Other writers, however, attribute the toxic action of nickel carbonyl to carbon monoxide, which can easily be detected in the blood of the victims, rather than to any specific action of nickel. Whether this be so or not, the toxicity of nickel carbonyl is much greater than that of carbon monoxide.

**Pathology**

In man, inhalation of the gas immediately gives rise to vertigo, sometimes dyspnoea, fever, and vomiting, which soon cease in the open air; 12 to 36 hours later the dyspnoea returns with cyanosis, rise in temperature and cough, accompanied after the second day by bloodstained expectoration. The rise in the pulse rate is not proportional to the rise in the respiration rate; the heart is normal. A fatal issue is ushered in by delirium and other symptoms indicative of involvement of the central nervous system. Death occurs on the
fourth to the twelfth day. On postmortem examination there is found haemorrhage in, and oedema of the lungs; punctiform haemorrhages sometimes extensive, in the white matter and especially in the corpus callosum of the brain (Armit), in the medulla, the cerebral, and upper dorsal portion of the spinal cord; fatty degeneration of the heart, cerebral vesicles, liver, and kidneys (Mott). The same pathological lesions are found in animals poisoned with nickel carbonyl.

HYGIENE

Prevent escape of gas and fumes by carrying on the process in hermetically closed iron chambers. Air containing one-half per cent. of nickel carbonyl is already dangerous. In addition, compressed air should be supplied on each floor of the nickel shed with suitable joints at frequent intervals for fixing a face piece and tube through which to breathe in the case of repairs. The air should be delivered into the face piece at sufficient pressure to keep out any gas.

Instruct the men to test for the gas by holding a flame derived from methanated spirit, which is blue in colour, against it. With a large leak the gas would burn with a yellow flame, but with a small leak a yellow film forms on the surface of the blue flame. This test shows a proportion of 1 part in 400,000 of air. Instruct the workers by notices, etc., as to the necessity of care is advisable.

LEGISLATION

Cases of poisoning by nickel carbonyl are brought under the Workmen's Compensation Act in Great Britain, New South Wales, Minnesota, and New York.

Nitric Acid

PROPERTIES

Pure anhydrous nitric acid (HNO₃) is a colourless liquid of which the specific gravity is 1.559. It is not used industrially. Nitric acid is found in commerce in the following forms: (a) crude nitric acid, more or less diluted, has a yellowish colour (due to the impurities it contains) with specific gravity varying according to its concentration (1.33 for 53 per cent.—HNO₃ by weight, 1.49 for 90 per cent.); (b) pure nitric acid, colourless, with variable specific gravity of about 1.40; and (c) red or fuming nitric acid, of which the reddish yellow colour is due to the nitrogen dioxide it contains. It gives off bright red fumes and has a specific gravity of 1.50 to 1.54.

The boiling point of the acid increases at first with concentration, reaches a maximum, and then falls; acid of 25 per cent. strength boils at 194°C. The maximum (123°C.) is reached with a solution of 69.8 per cent.

Nitric acid is a compound only slightly stable under the influence of heat. Even at ordinary temperatures it decomposes under the action of light. This explains why it is generally coloured yellow by the nitrogen dioxide.

It is a very strong acid, acting as a powerful oxidiser especially when heated. It attacks the majority of organic substances and often forms with them nitroderivatives (introduction of the NO₂ group into the molecules). With albuminoid matter it gives a yellow colour (xanthoproteic reaction); and this explains its colour reaction on skin and hair.

Nitric acid oxidises similarly a large number of metals. It converts phosphorus into acid, sulphur into sulphuric acid, and carbon into carbondioxide.

It attacks almost all metals except platinum, gold, and certain metal-forming nitrates. Action is favoured by dilution of the acid (iron only attacked by dilute acid) and is accompanied by a reduction to nitrogen dioxide (N₂O₅). In contact with the air the nitrogen dioxide given off is immediately converted into nitrogen peroxide, which has an extremely irritating and toxic influence (nitrous fumes).

Commercial nitric acid often contains sulphuric acid, hydrochloric acid, iron, and other elements (chlorine, arsenic, iodine, etc.).

MANUFACTURE

Nitric acid is made by:

(a) treating Chile saltpetre with sulphuric acid;

(b) direct synthesis, by combination of the nitrogen and oxygen of the air;

(c) by the oxidation of ammonia.
Nitrous fumes into nitric acid.

Air may be composed of weak nitric acid drips. They then pass into an apparatus for cooling and condensing, of which several types exist.

The Valentiner process, which carries on at the furnaces, the gases arrive at the bottom of the towers, while from above water or weak nitric acid drips. Similarly, air may be injected to convert the nitrous fumes into nitric acid.

Direct Synthetic Process

A mixture of nitrogen and oxygen carried to a temperature of 3,000° C. becomes the seat of a reaction equilibrium $N_2 + O_2 = 2NO$. The nitrogen dioxide content diminishes as the temperature is lowered, but it can be fixed by rapid cooling and is then changed into nitric acid and nitrates (see later).

The operation, improperly designated "distillation", is carried out in cast-iron retorts arranged over a furnace in which very often a current of hot air is made to pass.

The most common mixture used is air. Oxidation is effected by means of an electric arc at high tension — 3,000-7,000 volts — in special furnaces, which usually present the following characteristics:

1. an arc completely filling the chamber of oxidation;
2. rapid and constant renewal of the gases submitted to the discharge; and
3. brisk chilling of the gases immediately after oxidation.

Numerous models of furnaces have been constructed on these principles. The lengthening of the arc is achieved by a magnetic field (Birkeland and Eyde-Moscicki) or by a strong current of air (Schoenher-Guye and Naville-Pauling-Rossi, etc.). The efficiency is increased by 25 per cent. if, instead of air, a mixture of oxygen and nitrogen in equal proportions is used.

On leaving the furnaces, the gases containing 1-2 per cent. of nitric oxide pass into cooling devices constituted of aluminium tubes, around which water circulates. They then pass into a large empty tower. The temperature being then below 100° C., the nitric oxide ($NO_2$) is converted on contact with the air into peroxide ($N_2O_5$). Subsequently apparatus comes into use, with the object of recuperation, which can be done in four ways:

1. The gases are absorbed by water sprays in towers provided with fragments of quartzite. As the operation takes place in the presence of air, all the nitrogen peroxide is
converted, after several intermediate reactions, into nitric acid. A 20-30 per cent. acid only is obtained in this way, and absorption of the last traces of nitric oxide takes a long time.

Concentration of the acid is done sometimes by distillation either at ordinary atmospheric pressure or under a vacuum until an acid of 62 per cent. strength is obtained. To obtain, however, concentrated acid, use is often made of dehydration by sulphuric acid. This is carried out in a large column, where sulphuric acid is introduced above, the nitric acid entering at a lower level. The mixture of the two acids and injection of a current of steam furnish the heat necessary for the distillation of the nitric acid, which is collected in a cooling chamber.

(2) Absorption of the gases commenced by water is finished in towers, through which milk of lime flows. A mixture is then obtained of nitrite and nitrate, which is converted into nitrate by the addition of acid.

(3) The oxides of nitrogen are sometimes absorbed by means of concentrated sulphuric acid. A mixture is then obtained of acid sulphate of nitrosyl and nitric acid, which is used directly in the manufacture of sulphuric acid in the leaden chambers, or when distilled with a sufficient quantity of water yields nitric acid.

(4) The absorption towers are large and costly apparatus. In some factories the nitrogen peroxide has been condensed by cooling before bringing it into contact with water to form nitric acid, but the cooling liquid used has been toluene, cooled by a refrigerating machine. This has given rise to very severe accidents, as it is impossible to prevent escapes at joints of the apparatus, and the mixture of nitrogen peroxide and toluene is a violent explosive ("pancestite"). The tendency, therefore, is to replace the toluene by an incombustible fluid—air.

The Haessuer process does not utilise the electric arc. The nitric oxide is produced by explosion in steel bombs of a mixture of air, oxygen and lighting gas.

Manufacture by Oxidation of Ammonia

Gaseous ammonia obtained by synthesis, or from calcium cyanamide as a starting point, is oxidised by making it pass, mixed with air or oxygen, over a catalyst, heated to 300° C. The duration of contact should not exceed 1/1,500 of a second; and a yield of 85 per cent. is theoretically possible.

The oxidation can be carried out in converters of different models, using the most varied catalysts—platinum, iron-oxide, mixed with other metallic oxides, etc.

This process furnishes a gas with a stronger nitric oxide content than the arc process.

The principal industrial methods of concentration of nitric acid are based either on neutralisation of the acid with soda or ammonia, followed by evaporation and treatment of the dry nitrate with concentrated sulphuric acid, or again by fractional distillation.

This last method is applied in industry with towers for the residual nitric acid coming from the manufacture of trinitrotoluene, of nitro-glycerine, of gun cotton, and for the synthetic acid obtained by the arc process.

Sources of Poisoning

In the course of manufacture these are: escapes from retorts, pipes, and condensers (absolute airtightness in the apparatus is practically achieved, and from this point of view the Valentinier apparatus, which is carried on under a partial vacuum, offers appreciable advantages); inhalation of fumes during emptying of retorts and evacuation of the acid-sulphate in the process, with bi-nitrates; risk of burns and inhalation of nitrous fumes from filling and despatch of carboys due to breakage of receptacles (in warehouses especially); when the acid comes in contact with organic substances (saw-dust, paper, leather, etc.) there is risk of fire, and inhalation of poisonous fumes. Massive poisoning is reported with rapidly fatal issue in the cleaning of receptacles which had contained nitric acid. A fatal case is reported affecting a workman who had been employed for only fifteen minutes in a reservoir which had been washed out several days previously with an alkaline solution made with quicklime (Rambousek).

Lead and mercury poisoning have to be taken into account in connection with the different processes.

In the course of its industrial use: danger here arises chiefly from the nitrous fumes given off in numerous operations during the manipulation of nitric acid of which the following are the most important: preparation of the nitrates of iron (dye industry), of baryta, ammonia, lead, silver, barium,
borne for a short time; and 0.3-0.4 mg.
of for an hour with the usual symptoms
litre of air can be borne without injury

nitro-naphthaline,
picric
acid, and of all the organic bodies
undergoing in their manufacture the
process of "nitration", that is, the
introduction of the NO₂ group),
of indigo black; in the dye industry
(fixing and mordanting); in the metal
industry (refining, pickling, scouring
damascening, gilding); in goldsmiths'
and jewellery trades; in electro-plating
(gilding of copper and brass); in the
printing industry; in etching on zinc,
copper, and steel; in the "carrotting"
of rabbit skins; the manufacture of
felt hats and that of glass pearls
(silvering, etc.).

**Nitrous fumes** may be given off in
the manufacture of superphosphates or
when Chile saltpetre and very acid
superphosphates are mixed. They are
similarly given off in the heating of
manure composed of saltpetre, lignite,
and woollen refuse. The risk of
poisoning by nitrous fumes should
also be borne in mind in fires in
factories or workshops dealing with
nitric acid, celluloid, films, etc.

**Toxic Action**

According to Fischer nitric acid is
the more dangerous on account of the
fact that its toxicity is generally
underestimated. Its action must be
considered both in relation to its use in
solutions and in the form of fumes.

The former exert an oxidising and
nitrifying action on albuminoid matters
which they coagulate (xantho-proteic
reaction). The action of the latter
differs according as pure nitric acid
vapour or nitrous fumes are in
question. Both have a local action on the
skin and mucous membrane, but it is
pre-eminently on the respiratory system
that they provoke symptoms of general
poisoning. The vapour of pure nitric
acid has a slight irritating action similar
to those of other acids: 0.03 mg
per litre of air can be borne without injury
for an hour with the usual symptoms
of irritation; 0.2 mg. can only be
borne for a short time; and 0.3-0.4 mg.
per litre are dangerous doses (see
below).

The great danger of nitric acid
arises from the development of nitrous
fumes, which are no longer respirable
at a strength of 1 per cent. Nitric
acid, as matter of fact, readily,
becomes converted in the course of dif-
f erent industrial reactions into nitric
oxide and peroxide; nitrous fumes are
also evolved spontaneously from fum-
ing nitric acid (see article "Nitrous
Fumes").

**Statistics**

According to Leymann (1906) the amount
of morbidity in nitric acid factories is
fairly high. As a matter of fact, during
the period 1851-1890, 1890-1900, and 1900-1904,
for about 1,044 persons the cases (per cent.)
numbered 33, of which 13% were due to
nervous diseases, 8.7% to respiratory, 11.88 to
circulatory, 12.6% to digestive, 9.39 to
infectious diseases. These values are
generally (except for digestive diseases)
somewhat higher than the average calcu-
lated for 22,547 workers employed in the
chemical industry.

In regard to external lesions, nitric acid
workers show figures considerably higher
than those of the other groups from burns
—11.97 per cent. as against an average of
4.7. Naturally, nitrous fumes play an
important role in respiratory diseases,
while the strong caustic action of nitric
acid is responsible for the occurrence of
burns.

According to the Swiss National Acci-
dent Insurance Fund, reported cases of
poisoning due to nitric acid numbered 4
in 1918, 9 in 1920, 9 in 1921. No case of
burns had been reported or received com-
ensation since 1918.

Generally speaking, the small number of
cases reported as set up by this acid is
accounted for by the reason that cases are
usually included under the statistics for
acids or nitrous fumes.

**Symptoms**

Acute and chronic effects have to be
distinguished. The former include
especially lesions of the skin and
mucous membrane by nitric acid,
more or less profound, according to
the concentration of the liquid and
duration of contact. They appear as
yellow stains and characteristic scars.
Severe cases of necrosis and thrombosis
of the vessels have even been reported.
The severity of these burns can be
judged by remembering that the acid is
strong enough to set fire to clothing
saturated in it.

When inhalation of nitrous fumes has
been slight, no important general
manifestations show themselves beyond
some symptoms of excitation. Persons
suffering from respiratory distress are
particularly sensitive. On the other hand some degree of acclimatisation to small doses of the fumes seems to occur.

In serious cases after inhalation of a large dose those severe symptoms, described in the article "Nitrous Fumes", come on at once.

Chronic intoxication of the respiratory tract by acid fumes is not known, but on the other hand chronic lesions affecting the skin and teeth are met with.

Amongst workmen employed in the manufacture of nitric acid, Weyl has noted a yellow staining of the beard (Xantho-proteic reaction), the hairs of which in time become damaged by it. Eczematous lesions on the hands and forearms have been observed by Combilat among painters using nitric acid. Similarly, lesions are found, or may be found, on the lips and mucous membrane of the mouth, with formation of scars, ulceration and cicatrices, yellow in colour.

The most common lesions are those of the teeth as shown in a necrosis, developing over a period of two or three years and affecting at first the most exposed teeth (incisors). The eroded teeth, of a yellow brown colour and lacking the characteristic brilliancy, become sensitive to changes of temperature, to acids, and the pain is increased when chewing, but gradually ceases as the destructive process advances. Slowly the teeth deteriorate and disappear as far as the crown, this form of destruction being characteristic.

The necrosis begins some weeks after commencement of work—in some cases, only after some years—and is hastened by the habit adopted by certain workers of placing, as a kind of respirator, between the teeth already soiled by acid a piece of stuff on which the acid vapour condenses, and so attacks the teeth directly. The direct action of the air charged with acid vapours given off by the nitration apparatus and nitrated material and inspired through the teeth must also be borne in mind.

The diagnosis of acute intoxication by nitric acid is not generally difficult. On the other hand, serious difficulties do present themselves in many cases where, as commonly happens in industrial processes, nitrous fumes are present. (See article "Nitrous Fumes ".)

**DEMONSTRATION**

Nitric acid stains are quite distinct from those of either hydrochloric or sulphuric acid (orange and yellow tint not disappearing with ammonia).

The determination of free acid can be made volumetrically by means of an alkaline solution of soda or potash. Determination of nitric acid in the visceras is the business of the expert chemist. Different processes have been proposed: that of Schloesing is based on the conversion of the acid into nitric oxide under the influence of protochloride of iron; that of Arnaud and Pade on the insolubility of nitrate of cinchonamine, etc.

Several reactions have also been suggested to bring out the characteristic of nitric acid and the nitrates, but the majority are too sensitive. The expert would know how to select that best adapted to the case in question.

**HYGIENE**

In the course of manufacture all escapes of the gas should be prevented by making the apparatus absolutely air-tight and by frequent testing of the piping; good ventilation and localised exhausts with hoods over the boilers should be provided. Gases that have not been condensed should be carried away by a very tall stack. Liquids should be neutralised by lime or calcium carbonate before they are allowed to enter water courses.

The floors should be of cement and so arranged that in the case of fracture of the receptacles the escaping nitric acid should not present danger. Shaking or upsetting the receptacles should be avoided, and the quantity of acid stored in any one place should be small. Stringent measures should be adopted in the cleaning of retorts, receptacles, reservoirs, piping, fans, as well as in the opening of all vessels containing the product. Similar care is needed in transport by tank wagons. Any room in which the acid has been spilt should be immediately cleared of workers and sawdust should never be used for mopping up the acid, but this would cause evolution of nitrous fumes. Every escape should be immediately stopped up. Workrooms in which gas is present in dangerous amounts should not be entered unless by persons wearing breathing apparatus (oxygen self-contained apparatus or canister respirators containing neutralising material). For first aid see article "First Aid" and "Nitrous Fumes ".

The personnel should be given precise instruction as to the danger, and the best means of preventing it. The wearing of goggles and gloves should be obligatory.

Meticulous care and attention to rinsing out the mouth with alkaline solutions (1 per cent. boracic acid) should be taken to protect the teeth.
Nitric Acid should be reduced to the indispensable minimum. Emptying or pouring should be effected by safety devices. (For details apply to the Inspector.)

In its use: avoid inhalation of the fumes. Ventilating hoods should be provided over the mordanting vats. (For details apply to the Inspector.)

After fracture of carboys avoid especially the acid coming into contact with wood shavings, sawdust, cinders, etc. When acid has been upset it should be collected and washed with water, or sand should be scattered over it which then should be thrown into water to neutralise it. Windows should be opened and the room evacuated as quickly as possible.

Call in a doctor as soon as possible after inhalation of the fumes or as soon as symptoms appear. Those suffering from heart or lung trouble are more susceptible to the toxic action of the acid; they ought to avoid manipulating it. Initial medical examination is desirable.

In Great Britain the chemical regulations (11 July 1922) deal with the manufacture and certain uses of nitric acid. In Norway very stringent regulations have been issued (29 June 1923) for factories manufacturing sulphuric and nitric acids and nitrate of ammonium without making use of electricity in the chemical processes. For electro-chemical factories special measures are enforced in Norway.

In Russia the Order of 10 April 1922 prescribes the individual safety measures in nitric acid factories.

So far as concerns the notification of injury produced by nitric and nitrous acid, this is required in Missouri (United States), and in the U.S.S.R., Switzerland, Great Britain and Finland treat poisoning by nitric fumes as coming within the Workmen's Compensation Act (see also article "Nitrous Fumes").

***

Nitro and Amido Derivatives of Benzene and its Homologues

By the term "nitro and amido derivatives" is designated the nitrated or aminoated compounds of the following aromatic hydro-carbides:

1 In the French edition the term "amino derivatives" has been used instead of "amido derivatives" used in legislative texts, since it is a question of the substitution of the group NH for the hydrogen of the aromatic nucleus and not of the substitution of the hydroxyl group of the carboxyl: It is consequently a case of the formation of an amine and not of an amide.
The benzenes, toluenes, xylenes, etc., having undergone nitration once or several times (nitro, dimitro and trinitro benzene and its homologues) and their alkylated and arylated compounds (toluidine, xyldine, cumidine), anisidine, phenetidine and their chlorinated, nitrated, alkylated and arylated compounds (o- or p-anilino, diethylamino-diphenylamine, etc.); phenylendiamine, tolyldiamine; benzidine, toluidine, diaminidine; naphthylamine (α and β), phenylhydrazine and para-phenylhydrazine.

For further details regarding the above, the reader is referred to the articles dealing with the above-mentioned products printed in italic in the preceding paragraph. For the preparation of the nitro derivatives, see the article "Nitrobenzene" and for that of the amido compounds see the article "Aniline".

This article is restricted to information of a general order to be found in various publications under the heading: Nitro and amido derivatives of benzene and its homologues.*

Statistics

Statistics relative to nitro and amido derivatives of benzene and its homologues are to be found in the various articles already referred to. It occurs, however, in practice that a number of cases of poisoning are notified under the general denomination in question here or under the denomination benzene, its homologues and their derivatives*. Thus, for instance, it is found that in Great Britain compensation was awarded in 52 cases in 1920, 29 in 1921-1922, 63 in 1923-1924, 18 in 1925, 17 in 1926, 9 in 1927, etc. Elsewhere it is recorded that 31 cases of chronic poisoning due to aniline were notified in 1925, 33 in 1926, 38 in 1927, 41 in 1928, 26 in 1929 and 24 in 1930.

The 64 cases which occurred between 1925 and 1928 were distributed as follows: 17 due to dinitrobenzene, dinitrotoluene and trinitrotoluene; 14 in the manufacture of aniline; 13 due to paranitraniline; 3 to paratoluidine; 6 to aniline black; 3 to aniline colours and 4 to various products; the remaining 4 cases (2 fatal) were tumours of the bladder reported in the chemical industry.

In Germany (Bavaria) there were reported in 1923-1924 33 cases of poisoning by the derivatives of benzene and its homologues (chiefly amido derivatives); in 1926 18 cases due to the same substances occurred. The cases mostly consisted of skin diseases, bladder trouble and chronic poisoning.

In the State of Ohio, during the period 1921-1927 74 cases were recorded as due to nitro and amido derivatives, 5 of these being fatal; 35 of the cases involved a duration of incapacity exceeding seven days, 24 under seven days, and 10 no incapacity.

In Switzerland, from 1922 to 1927, the various cases caused by these products amounted to 86, 5 involving invalidity and 4 proving fatal. The products in question gave rise to 64 cases of skin disease.

It often happens that serious and even fatal cases cannot be accurately attributed to one definite product, and that they are described in medical journals as cases of poisoning due to a nitro or amido derivative. Thus, for example, the reports of the German factory inspectors contain the statement that 11 cases of poisoning by nitro and amido derivatives were notified in 1920, and 10 cases of dermatitis due to contact with aniline, alizarine, and nitrochlorobenzene colours, etc. In 1921 there were reported 18 cases of poisoning due to nitro-amido derivatives, and numerous cases of dermatitis due to safranine and violetrene. In 1922 38 cases were reported as occurring in two chemical undertakings of the Wiesbaden district. They were, with one exception, which proved fatal, but slight cases. Sixteen cases of aniline poisoning were ascribed to aniline, paranitraniline and paratoluidine, etc.

In 1930 Rosenthal-Deussen reported cases of subacute poisoning due to an aniline homologue in a factory making flypaper. The product in question was an amido compound of the aromatic series used in the preparation of the paste applied to the flypapers and it set up a clinical picture analogous to that caused by aniline and toluidine, as well as characteristic disturbances of the blood; besides cyanosis, irritation of the bladder, haemorrhages, diuresis troubles and derangement of menstruation affecting the women workers in question, there was noted a marked diminution of neutrophil leucocytes and an increase of eosinophils without alteration of the haemoglobin and the red cells.

The nitro derivatives possess properties which are generally similar, and which manifest themselves by a toxic effect on the colouring matter of the blood. In the majority of cases poisoning takes place by way of inhalation and swallowing of times and dusts in which very fine droplets of the various products are present in suspension. Poisoning by way of the skin occurs chiefly favoured by the liposoluble action of certain derivatives, their degree of volatilisation, mechanical friction, perspiration, various skin diseases, etc. Very marked individual variation exists in regard to receptivity for these diverse substances, certain individuals even possessing relative immunity in regard to them. As a general rule, various pathological troubles favour poisoning, which is specially serious amongst anaemic subjects, those with a lymphatic constitution, and those suffering from heart or kidney trouble. Very young, or very elderly, workers are more liable to the risk of poisoning than adults.

As regards amido derivatives, the symptoms of poisoning resemble to some extent those caused by nitro derivatives. It should be noted, however, that the irritant action on the mucous membrane of the bladder which sets up cystitis and
cancer of the bladder is to be attributed to amido and not to nitro derivatives. (See articles "Occupational Diseases: Urogenital System" and "Naphthylamine.") According to R. L. Meyer (1930), poisoning by the amines of the aromatic series is said to be due to a direct reaction between the intermediary products of oxidation and certain elements in the body haemoglobin for instance. However, clinical symptoms like forms of eczema and asthmatic affections are considered by this author as constituting individual idiosyncrasy or as allergies to be distinguished from poisoning properly so called.

As regards cancer of the bladder, Meyer is inclined to attribute it to the pathogenic action of the said intermediary products of oxidation, and he believes the pigment deposited in the neoplastic epithelium to be due to polymerisation of these products.

**HYGIENE**

Hygienic requirements exacted in establishments in which nitro and amido derivatives of the aromatic series are prepared refer on the one hand to the workers and on the other to the workshops.

Workshops must be spacious and well ventilated. Buildings consisting of several floors are not to be recommended since it is difficult to obtain adequate air renewal in these. Construction of platforms is permitted provided that a free space equal to a quarter of the surface of the workshop remains, and that there is between the platform and the wall a space which is either free or covered with a grid having a width of 50 cm. to a metre for the purpose of improving the ventilation. The distance of these platforms from each other, or above the flooring, shall be, wherever possible, 3 metres. A lesser figure may be tolerated in the case of small platforms not likely to interfere with air renewal.

The installation of platforms above boilers for milling and distillation purposes should not be permitted except where absolutely necessary for technical reasons, in which case they must be provided with adequate apparatus and devices calculated to prevent all liberation of gas or fumes from the boiler, etc.

The flooring should be impermeable, have a level surface, and should permit of ready cleansing. It should be conveniently sloped towards a gutter for running off liquid. The material of which the flooring is composed depends on the properties of the products dealt with in the establishment.

Flooring formed of stone flags or tiles with a cement foundation certainly permits of easy cleansing, but it would be necessary to avoid deep grooves between the flags. Concrete, which has not always given good results, should, if used, not be porous and must have a uniform surface. It offers, however, less resistance to attack by acids and hot liquids. Where acids are manipulated, the flooring should be made of earthenware tiles impregnated with tar, the seams between these being filled with asphalt. A flooring of this kind is very acid-resistant, but is not advisable in departments where nitrated and amido compounds which enter into combination with tar and asphalt are manipulated; platforms constructed should be equally impermeable and readily cleansed when used regularly for manipulation of nitro and amido compounds. The walls of the workshop should be so constructed, and the joints in these such, that they can be readily cleansed or limewashed.

Abundant ventilation of the workshops should be provided for, without, however, causing draughts. The roof should be provided with an adequate number of ventilating apertures or windows. Where the workshops are extensive and very high, and especially where platforms are used, they should possess, on one side at least, windows which open.

Buildings in which nitrated compounds of benzenes or trinitrated, etc., compounds of the naphthalene series are manufactured should be constructed of incombustible materials. Processes and working conditions should be so organised that as far as possible the workers are not brought or to direct contact with the nitrated and aminated derivatives.

When these compounds are in a liquid form they should, wherever possible, be transported by means of close piping (pumped, exhausted or compressed). When they are in a solid form, or in powder the best method of transport is by transference from one vessel to another or by withdrawal in closed apparatus or by exhaust. The compressed air used should be led through piping above the roof; where it is likely to prove a source of inconvenience to the workers or to those living in the neighbourhood, it should undergo purification in adequate apparatus. All work involving liberation
of dusts, gases or fumes should be effected in closed apparatus where technically possible.

Distilled products should be collected in receptacles which are constantly kept closed. Substances readily liable to melt should be transported in a liquid state. Solid substances melting at a low temperature should be collected at distillation in closed receptacles connected up with an exhaust device heated by means of a steam jacket or similar device. During work of this nature all contact with the products is to be avoided and likewise all liberation of steam. The operation of withdrawing the cool substances from the receptacles in which they have undergone treatment is always dangerous.

Drying should be effected in hermetically closed apparatus. The back apparatus charged with dusts and gases should be re-utilised in such a way as to form a closed circuit. The drying chambers should be emptied after cooling has been completed. During the operation of emptying, the exhaust apparatus should continue to function.

All efforts must be made to prevent the workrooms becoming soiled with the nitrated and aminated products. Where these products are poured or spilt on the ground they should be removed as quickly as possible. The most practical manner to effect this is to scatter sawdust over them prior to sweeping. The moist sawdust should then be carefully burnt in small quantities at a time. Powdered substances can easily be removed by vacuum.

The workers should be instructed as to the dangers to which they are exposed, and the requisite precautions to be taken as a means of protection, and every effort should be made to convince them of the advantages of abstention from all kinds of alcoholic drink. Necessary articles for individual protection such as clothing, shirts, headgear, shoes, etc., should be provided.

Working clothes should be washed regularly and kept in a good state of repair. Clothing which has become contaminated with nitrated and aminated compounds should be immediately removed in order to prevent the skin coming in contact with these products.

Measures of personal hygiene comprise provision of washbasins, douche baths, etc.; prohibition of all operations in connection with repair or alteration of apparatus, etc., prior to having effected thorough cleansing of the same; prohibition of entry of workers into chambers and recipients without adoption of requisite safety measures, etc.

Workers should not be allowed to keep or to consume food in the workrooms, to change their clothing there, or to leave their town clothes there. Medical supervision: this should include examination on engagement, and periodical examination thereafter. Adequate organisation of first aid includes provision of respiratory masks, oxygen, etc.

Legislation

Women are excluded from factories where nitro and amido derivatives of benzene and its homologues are manufactured, and from those in which these substances are used in France, Germany, Japan (aniline fumes), and in Argentina, etc.

Girls under eighteen years of age are excluded from work of this kind in Great Britain, Greece and the Netherlands, and from twenty-one years of age in Spain and Italy, and from persons under sixteen in Belgium, Greece, Spain, etc. Work in establishments engaged in making or handling nitro and amido derivatives of benzene and its homologues is subject to regulation in Germany, Great Britain, New Jersey and Pennsylvania.

In Germany instructions relating to hygiene as affecting workshops and workers, including medical examination on engagement and periodically thereafter (monthly) as well as prohibition of the work of women and young persons, were issued in 1911 and were published also in Prussia (1911) and other States of the Reich.

In Great Britain the Regulations of 30 December 1908, No. 1310, lay down hygienic measures (working clothes, facilities for personal hygiene) which the employers are obliged to adopt and the workers to utilise as a protection against the risk of poisoning.

Regulations in the two American States referred to above include provisions relative to hygiene in the workshop, to industrial operations, to medical examination on engagement and periodically thereafter, and first aid, etc.

Other States provide for medical examination either on engagement or periodically (Bavaria, Hesse, Italy, etc.). Compulsory notification of cases of poisoning by nitro and amido derivatives of benzene and its homologues is required in France, Germany (Bavaria), Great Britain, the Netherlands, the U.S.S.R., etc.

Compensation is granted in Alberta, Austria, British Columbia, Finland, Germany, Great Britain, Italy (not for amido derivatives); in Massachusetts, Minnesota, New York, Ohio and Porto Rico, Queensland, Switzerland, Venezuela, Western Australia, and in those countries in which occupational diseases coming within a specified definition are compensated.

***
Nitrobenzene
(Mirbane Oil)

French: Nitrobenzène (Essence de mir-
bane). — German: Nitrobenzol (Mirban-
öl). — Italian: Nitrobenzolo (Essenza

Nitrobenzene \((\text{C}_6\text{H}_5\text{NO})\), or mirbane oil, is a liquid which is almost colourless or of a slightly yellowish straw colour; it is refractile, and has an agreeable smell of bitter almonds, which is present even in very great dilution.

The specific gravity is 1.099 at 15° C. When solidified by cooling, it melts at 3° C. and boils at 206° C.

It is hardly soluble in water, but mixes in all proportions with alcohol, ether or benzene. It is non-explosive and can only with difficulty be carried away by steam.

Amongst its homologues and derivatives, the most important from the technical point of view are the various nitro-
toluuenes and nitroxylenes, as well as the nitro-chlorobenzenes. Among the nitro-
toluuenes the ortho- and meta- are liquid, the para- is solid. It is very difficult to carry away these products by steam; they are hardly soluble in water, but are readily soluble in alcohol and ether. The five nitroxylenes, some liquid and some solid, present the same capacity for solubility as the nitro-benzenes.

The ortho- and para- chloronitrobenzenes are solid products, which have the same properties regarding solubility as nitro-
benzene.

Nitrobenzene was discovered in 1834 by E. Mitscherlich, and prepared in small quantities from benzene in 1847 by Mans-
field in England, and Collas in France, as a substitute for the natural essence of bitter almonds in the perfumery industry, and sold under the name of "mirbane oil". The manufacture of nitrobenzene on a large scale coincides with the rise of the aniline dye industry (1856), in which it constituted from the start the most important of the intermediate and final products. It is manufactured and used today almost entirely in connection with this industry.

**TECHNICAL FACTS**

Nitrobenzene is prepared by the nitration of benzene by nitric acid. The introduction of the nitrous group (NO₂) in the place of a hydrogen atom into the benzene ring is accompanied by the formation of water, which would cause a gradual dilution of the nitric acid, and, in consequence, a premature arrest of the nitration, before the nitration is exhausted. The sulpho-nitric mixture, composed of concentrated nitric acid and sulphuric acid, were not used, the latter acting as a dehydrator. In consequence, a less concentrated nitric acid can be used with several advantages: larger output, lower cost, and more difficult oxidation, together with less production of nitrous fumes and useless secondary products. The operation is carried out by carefully retaining the apparatus used for the reactions at a lower temperature, and by adding gradually the sulpho-nitric mixture.

The benzene to be used for nitration is obtained by subjecting commercial benzene of a strength of 90 or 50 per cent. to fractional distillation, in order to separate the homologues; the product which passes over between 80.2° C. - 80.8° C. is regarded as chemically pure.

The sulpho-nitric mixture, which only attacks cast iron and iron slightly, is sent to the nitrating room in order to be poured into earthenware receptacles, either automatically by means of compressed air or by hand in earthenware jugs or cast iron acid resisting receptacles. The reaction is effected in nitrating apparatus made of iron or cast iron, equipped with stirrers, refrigerating coils and thermometers.

The acid mixture, which flows from a receptacle above, is allowed to fall slowly into the apparatus containing the necessary quantity of purified benzene. The mixture, kept continually stirred, is maintained first at 25° C. by a circulation of cold water on the exterior of the apparatus. During the last stage, in order to increase the reaction, the mixture is heated to about 50° C. In the mixture there is always an excess of benzene to prevent the formation of dinitrobenzene. If the reaction is properly conducted there is no evolution of nitrous gas. Nevertheless, the nitrating apparatus and the receptacles for acid are provided with exhaust shafts for any poisonous gases which may be set free, if the apparatus functions badly.

Although, as a rule, the nitrobenzene which is formed does not contain dinitrobenzene, it may, on the other hand, contain a little unchanged benzene.

When the heating is finished, the stirring is still kept up for about two hours. The liquid is then pumped into tanks arranged above. On settling, the acid mixture falls to the bottom, and the nitrobenzene floats to the top. The acid is decanted by taps and is driven by compressed air to the sulphuric acid room for regeneration.

As a matter of fact, apart from nitric compounds, this acid contains oxide of nitrogen and the remains of the nitric
ac. Freed from nitrous acid, it may be used for a new nitration, after concentration and the addition of sulphuric acid, or of manure for the dis-aggregation of phosphates.

The crude nitrobenzene is forced, under pressure, into a vat where it is washed and stirred, and then freed from traces of acid by means of a lye or a solution of carbonate of soda.

On standing, the nitrobenzene is deposited at the bottom; it is decanted and separated, by distillation in a current of steam, from unchanged benzene and other hydrocarbons. A second distillation gives nitrobenzene sufficiently pure for technical purposes, and, in particular, for the preparation of aniline. But for the perfumery industry this product must be subjected to distillation in vacuo. Formerly, especially pure essence of mirbane, required for high-class perfumery, was produced by distilling, in a current of steam, the sediment from sulphate of lead containing nitrated compounds, which form in the washing vats and in the residuary acid.

Of late the nitration of benzene has been carried out by a continuous process: the benzene and acid mixture are introduced in equal parts, but without any excess of benzene, such as is necessary in the preceding process, into an apparatus fitted with columns, or into vertical nitrating apparatus, divided up in the form of a labyrinth; it is equipped with a rapidly-moving stirrer, and arrangements for regulating the speed of arrival of the two fluids, and also a cold water circulation. The nitration is carried out by stages as the temperature is raised, and is only in the last columns that it is completed, or — if a sufficiently complete reaction is obtained immediately at the start by means of regulated cooling at an optimum temperature of 50° C. — during the onward passage of the material through the various chambers of the nitrating apparatus.

The resulting emulsion is composed of residuary acid, almost entirely freed of nitric acid, and nitrobenzene, practically free from benzene. A separator, placed at the extremity of the columns, separates the two bodies in a rapid and complete manner, so that the nitrobenzene and residuary acid flow off continually and simultaneously.

The further purification of nitrobenzene is carried out as described above. This automatic process also has the advantage of requiring completely closed apparatus, which must be of a relatively small size in comparison with the output, and also of reducing considerably the danger of explosion. These processes, however, have not been much used up to the present.

The process of nitrating vapours of benzene by means of oxides of nitrogen at 300° to 350° C., and of benzene by means of nitrate of soda and sulphuric acid at a strength of 90-96 per cent. at a temperature raised to 100° C., seem to be now completely given up.

The mono-nitro-derivatives of the homologues of benzene — nitrotoluenes and nitroxylenes — are obtained in a similar way, by nitration of toluene or of xylene in similar apparatus, but at lower temperatures, at 20° C. for toluene, and at 17° C. for xylene. For the rest, the proportions of the acids in the sulpho-nitric mixture are somewhat different (see also article "Di-nitrobenzene").

For use in the dye industry — but not in the case of further nitration in the explosives industry — the isomeres which are formed during nitration must also be separated, especially those of the nitrotoluenes, so that the separation may not take place with the formation of toluidines by reduction of the mixture.

Ortho- and para-nitrotoluenes are present in crude nitrotoluene up to 35 to 63 per cent.; but meta- is only found in the proportion of 2 per cent. The two former are distilled in a current of steam or in vacuo. The orthoisomere passes in the largest quantity. The residue of the distillation is cooled; it contains chiefly para-, which crystallises in lamellar prisms of the rhombic system. After being centrifuged rapidly the residuary mother-liquor contains chiefly ortho-. This residue mixed with the ortho-distilled at the beginning is rectified afresh in order to obtain the ortho- in a purer state.

Speaking generally, the five isomeres of nitroxylenes are not separated, but more frequently the xyldines, which are more important from the technical point of view, are isolated.

Uses.

Nitrobenzene, its homologues and derivatives are almost exclusively used in the chemical industry for aniline dyes and explosives; also, on account of its odour, nitrobenzene is used in small quantities, and in addition on a large scale, as a perfumery product in the manufacture of cheap soaps and other toilet articles, of boot polishes and of polishing materials. It is even used as a substitute for the natural
essence of bitter almond in confectionery and liqueurs. The designation of these products under such names as "mirbane oil" or "essence of bitter almond" results in persons who are ignorant of their poisonous properties using them without taking necessary precautions. Spinner has collected 160 cases of poisoning, of which 31 were fatal, in a period of thirty-five years, occurring equally in industry and in private life.

Nitrobenzene, its homologues and derivatives are subjected to a fresh nitration when they are required for the manufacture of highly nitrated explosives, and, in particular, of dinitrobenzene (see that article).

In the aniline dye industry they are used as they are, or more often after having been transformed into various derivatives. Nitrobenzene and paranitrotoluene are used directly and on a large scale for preparing dyes derived from triphenylmethane, especially fuchsin, by the nitrobenzene process, in which they act, at the same time, as raw material and oxidising agent (see article "Aniline"). In the preparation of dyes derived from anthracene, such as indanthrene, nitrobenzene is much used as a solvent, after which it is recovered by distillation. But the greatest parts of the nitrobenzene and its homologues are used as basic products in the preparation of the corresponding aromatic bases, which are obtained by reduction, for the manufacture of aniline, of benzidine and such homologues as toluidine, xylidine, anisidine, toldidine and dianisidine (see article "Aniline").

Similarly in the dye industry, nitration is carried further in order to prepare, by reduction, starting from the dinitro-derivatives, the corresponding diamines: meta-phenylenediamine and meta-xylxylenediamine, which are used chiefly in the manufacture of nitric colours and colours derived from sulphur.

Nitrobenzene is also used as a basic product in the preparation of meta-chloronitrobenzene, of meta-nitrobenzene sulphoneic acid and of metanilic acid. Nitrotoluene is used also to prepare para-nitrotoluene sulphoneic acid, which is an intermediate product in the manufacture of colours derived from stilbene.

Numerous other intermediate products which are regarded as derivatives of nitrobenzene and its homologues are not obtained by starting from these products, but by direct nitration of the corresponding derivatives of benzene and its homologues, such as ortho- or para-chloro-

---

**Nitrobenzene, meta-nitrobenzaldehyde, ortho- and para-nitrophenol, para-nitraniline, or chloronitrobenzene sulphonic acid, or indirectly by chemical transformation of other nitrated compounds, for example: the nitrophenols, by making potash lye act on chloronitrobenzenes; meta-nitraniline by the reduction of meta-dinitrobenzene by means of alkaline polysulphides; para-nitraniline by the action of ammonia on para-chloronitrobenzene.**

**Toxic Effect**

The paths of entry for nitrobenzene and its homologues are by the digestive and respiratory apparatus, and, owing to their great capacity for dissolving lipoids, by the skin.

Their toxic effect is exerted chiefly on the blood, in particular on the haemoglobin and on the central and peripheral nervous system. Whereas the injury to the blood is, as a rule, given the first place from both clinical and pathogenic points of view, the nervous symptoms, especially in serious or subacute cases, are much more pronounced and more violent than in cases of poisoning by aniline or other aromatic bases (Curschmann).

The effect on haemoglobin is to change it into methaemoglobin; and this gives rise to pronounced and characteristic cyanosis, that is to say, a bluish-grey coloration of the skin and mucous membranes, with a dark shade of the arterial blood.

The toxic effect on haemoglobin is strictly in proportion to the change undergone by the nitrobenzene in the body. But this reaction has not been obtained in vitro, or only to a very slight degree; hence it cannot be attributed to nitrobenzene itself.

Lethey was the first to put forward the view that nitrobenzene is reduced in the body into aniline, and that the poisoning is really caused by aniline; but this has been contradicted by Filehne and Erich Meyer, the latter of whom was the first to show that most of the nitrobenzene is changed into para-amidophenol and eliminated by the urine, in conjunction with glycuronic and sulphuric acids.

Small quantities of ortho-amidophenol are formed, in addition to para-amidophenol (Brat). The principal product of the change is thus the same as with aniline. However, a small quantity of unchanged nitrobenzene is eliminated partly by respiration and partly by the urine, where it can be detected by its characteristic odour and by chemical analysis. In experimental
poisoning, in addition to para-amido-phenol, there can be detected para-nitrophenol which also readily changes into para-amido-phenol. On the other hand, aniline has not been found, although Lehmann believes he found traces in the urine. It may, then, perhaps be concluded that the change from nitrobenzene into para-amido-phenol is made, in all probability at least in part, by transition through para-nitrophenol, which is able to give rise — like intermediate products of the reduction of the nitrated groups — to intermediate bodies having a considerable power of producing methaemoglobin (nitroso-phenol and chloronitrophenol).

According to the recent researches of Lipschitz on the disintegration of dinitrobenzene (see that article), it is very probable that the change occurs by transition through the intermediate production of β-phenohydroxylamine, which has a great power of producing methaemoglobin.

During this change, first, by a kind of process of poisoning, intermediate products are formed — perhaps, in principle, the same for all the nitro- and amido-derivatives which act upon haemoglobin — which attack the haemoglobin and reduce the oxyhaemoglobin.

Opinions on this point, as well as on the spectroscopy of the blood in nitrobenzene poisoning, are still very divergent. As a matter of fact, Starchow found the band of acid haematim, and Filehne, in his experiments on the dog, has described, as characteristic of nitro-derivatives, an absorption which is not very distinct, situated in the red part of the spectrum, which could only be detected in strong concentrations. This band is not identical with that of haematim and is found sometimes — during life — more to the right, and sometimes, more to the left; it did not disappear on reduction by means of ammonium sulphide, but only changed its position. This band has also been described by other authors (Roehl, Weissenstein); however, the most recent researches have Lipschitz and the certain presence of methaemoglobin spectroscopically, either in animals (Gibbs and Reichert), or in man (Erlich and Lindenthal; E. Meyer). Numerous observations made during occupational poisonings (Brat and others) have confirmed that the formation of methaemoglobin is the most important and decisive phenomenon in the development of the disease.

Besides this action, nitrobenzene has, as have all the toxic nitrated derivatives of the aromatic series, a destructive action on the red blood cells, which is much more marked than that of aniline and of the corresponding aromatic bases. This different intensity in the toxic action can be explained by the greater selective affinity of nitrobenzene for lipoids, and by a slower removal of the poison during metabolism; thus there is a possibility that the aromatic nitro-derivatives destroy the red blood cells first, and only then change the free haemoglobin into methaemoglobin, whilst the change caused by the aromatic bases must take place in the interior of the red cells (Brat, Curschmann). Perhaps, however, it is more likely that the formation of methaemoglobin takes place in both cases, first in the intact red cells; but that, in poisoning by the nitrated derivatives, there is in addition to that, and later, a great destruction of red cells with liberation of methaemoglobin (Engel). Hence, the action on the mass of blood is much more durable, since the haemoglobin, once liberated, is completely lost for regeneration. This injurious action on the red cells is seen in animals as well as in man, taking place more slowly and in a more sluggish manner than that exercised on the haemoglobin. Generally, and only after a few days, a diminution of the number of red blood cells is found, as well as alterations in their shape: poikilocytes, with numerous micro- and macrocytes, schistocytes, phantom cells and the appearance of Heinz's corpuscles. Methaemoglobinuria is also sometimes observed in serious cases. A little later regeneration forms appear: polychromasia, normoblasts and often a pronounced leucocytosis.

The direct action on the nervous system, which is considerably stronger than in anilism, is independent of blood changes and appears clearly in the experiments on animals (Filehne, Haldane, Makgil and Mavrogordato), especially with such animals as rabbits and mice, which offer great resistance to an action on the blood. These experiments seem to contradict the nervous symptoms stated as observed in man, which are attributed chiefly to blood lesions and anoxaemia.

The chief of these symptoms is the paralyzing action of nitrobenzene. It acts upon the sensitivity, motility and excitability of the reflexes, and on the centres of the medulla oblongata, with diminution in blood pressure, and, at first, quickening of the respiration, followed by paralysis.

Irritating action on the central nervous system is much less pro-
nounced, at least in the first stage of poisoning, than in the case of aniline. In animals, motor stimulation, cramps with opisthotonos, and direct muscle stimulation with stiffness and contraction of the muscles, are observed before the appearance and at the onset of general paralysis and immediately before death, especially in the case of serious poisonings, following rapid absorption and conditions favourable for strong doses (Filehne). In man this action seems to be less definite; and the cramps which appear in serious cases, during coma, appear to be associated with forms of asphyxia.

The sensorial and sensory parasthesias and hypoesthesias must be attributed to the involvement of the peripheral nerves. In spite of the presence in the urine of the same principal product of elimination, i.e. para- amidophenol, as is also found in anilism, nitrobenzene does not obviously originate the vesical lesions which are produced by anilin. In acute poisoning by nitrobenzene, death is due to paralysis of the respiratory centre.

The toxic and fatal dose for man is very variable and differs according to the method of administration, the conditions of absorption and re-absorption. With animals this dose naturally varies according to the different species: rabbit, 0.6-0.7 grm. per kg., if given by the stomach (Ziegler), and 0.5 per kg. if given by the skin, fatal in 52 hours; cat, 0.4 grm. per kg. if given by the skin, fatal in 9 hours (Dambieff); 0.5 mg. per litre of air is introduced for 6 hours; slight symptoms after 24 hours with recovery, and also after a longer period of exposure to a greater strength (0.6 mg.; K. B. Lehmann and his pupils).

Subcutaneous injections made in fifteen different places, of 0.6 grm. per kg. in the rabbit produce poisoning in one hour; but if the injection is made in one place, no symptoms appear after five hours (Filehne). It can, therefore, be accepted that when re-absorption is rapid and complete, the toxic and fatal dose is considerably smaller than the experiments on animals suggest. It is generally considered that women, especially during the menstrual period, and young persons are more susceptible than adult men to the action of nitrobenzene.

The fact that resistance to the poison is greater in persons of robust health than in persons of poor health and particularly in thin persons, may be due to the formation in the fatty tissues of a harmless deposit of the poison. The part played by this deposit finds a satisfactory explanation only in cases of acute poisoning. Febrile diseases, such as influenza, favour the appearance of acute symptoms of poisoning (Bachfeld). It is also certain that drinking alcohol, even in moderate quantity, increases considerably susceptibility to the toxic action of nitrobenzene and of other nitro- and amido-derivatives of the aromatic series, and may even favour the development of an acute form of poisoning (Mohr) (see also article "Aniline"). This characteristic action of alcohol appears to be due partly to the fact that it "mobilises" the poison suddenly out of the relatively harmless deposits present in the fatty tissues, and partly to the intensification of cellular respiration which accelerates the reduction of the poison into phenylhydroxylamine (Lipschitz), which in turn appears to intensify the poisonous action in the case of febrile diseases.

The toxic action of the homologues of nitrobenzene, up to the present, is not so well understood. It has only been studied experimentally in animals, for it seems that acute occupational poisonings have never yet been observed in man. The action on haemoglobin in particular seems to be lacking, perhaps on account of a different transformation of the products during metabolism. Thus, for example, ortho- nitrotoluene is eliminated in the dog chiefly as uronitrotoluene acid, with the ortho-nitrobenzylic alcohol combined with glycuronic acid, and as quite small quantities of ortho-nitrobenzoic acid. On the other hand, para-nitrotoluene is eliminated chiefly as para-nitrobenzoic acid and para- nitrohippuric acid, the first being combined with glycocoll (Jaffé). The oxidising process attacks first the methyl group, all the more easily as it is in the para position. The nitroso group of para-nitrotoluene is prevented by reason of the reduction of the nitrate group, and especially by the intermediate formation of the hydroxylamine group and by the entrance of a hydroxyl group coming from the nucleus.

The action of nitrotoluences on the nervous system is less definite than that of nitrobenzene. The ortho-isomer seems to be the most toxic, and causes, but only when it is absorbed by the skin, temporary phenomena, first irritation, then paralysis of the central nervous system (Dambieff), and finally death (Ziegler). When introduced by the digestive organs, the three isomers can scarcely be called poisonous, animals being able to sustain for a long time,
without serious disturbance, doses of 2-4 grm. of the ortho-isomere and even 5 grm. of the para. Nitrotoluene, being hardly volatile at all, has not led to poisoning by the respiratory paralysis during experiments on the inhalation of its vapours (Ziegler).

According to these experimental researches, it may be accepted that the nitrotoluenes are only slightly toxic compared with nitrobenzene.

Sources of Danger

The ease with which nitrobenzene and its homologues are absorbed by the skin explains the reason why the skin is the most important portal of entry for the poison in cases of acute occupational poisoning. In industry this occurs owing to the wearing of clothes badly soiled with splashes, and with condensation of vapours contained in the air, or impregnated by the product due to faults of working in the apparatus or accidents, or more commonly due to lack of cleanliness on the part of the workman, who does not change his working clothes sufficiently often. The inhalation of fumes of nitrobenzene given off from clothes is also a factor which must not be overlooked, although it is of much less importance in acute cases than in poisoning by aniline, because the fumes of nitrobenzene have a weak vapour pressure and are not easily conveyed by steam.

The digestive organs are only of importance in case of accident; several times workmen in the chemical industry have been the victims of serious acute poisoning, as they have swallowed in error large quantities of nitrobenzene, attracted by its agreeable odour and ignorant of its toxic properties.

Danger of poisoning from soiling by contact during technical operations is relatively small, because in big factories where it is made, especially in the aniline industry, and where the final product is utilised, completely closed apparatus only is used (even though this is not the case for solid dinitrobenzene), and also a sealed system of pipes for transportation. The manufacture and direct utilisation of the derivatives of nitrobenzene in the dye industry are much less important than aniline (see that article), except in the case of the production of the triphenylmethane dyes. Hence, cases of acute poisoning by nitrobenzene are much more rare than by aniline. But in the case of defects in working of the apparatus, or during cleaning or overhauling, especially during soldering with lead, danger of acute poisoning becomes greater either from soiled skin, or from the inhalation of vapours. On the other hand, the fumes coming from small leaks in the nitrating apparatus and from the distillation, or those given off during the flow of the acid of nitration or of the washing fluids, explain the higher incidence of chronic disorders among nitrobenzene workers than among aniline workers.

Statistics

Figures of cases of nitrobenzene poisoning are difficult to give, as in the reports of inspectors and in the statistics relating to compensation of industrial cases, these cases are generally shown as cases of poisoning by benzene and its nitro- and amido-derivatives (see that article).

Spinner, in 1905, collected 160 cases of poisoning, of which 31 were fatal, reported over a period of thirty-five years; Grandhomme collected 60 cases, with 23 deaths; Adam reported 15 cases, with 3 deaths, from ingestion of the poison; 6 cases, with 2 deaths, from inhalation; 2 with 1 death from skin absorption; and 5 in which suicide or abortion was intended, wherein there was a fatal result in a very high proportion. Of these 28 cases, 9 were of occupational origin.

Pathology

The classification of poisoning under the headings of acute, subacute and chronic is based less on the evolution of the poisoning than on the way it has developed; whether rapid absorption of the poison, followed by immediate symptoms of poisoning, or repeated absorption of quite small quantities, the clinical picture is only established on the aggregate of effects due to functional accumulation.

(1) The acute form. — Clinically, this is characterised, at least, in the early stages, by methaemoglobinæmia; herein there is a resemblance to the clinical picture of acute anilism. The skin is pale, of a bluish-grey colour, especially pronounced on the visible mucous membranes, upon the lips, the nose and the ears. This coloration may be distinguished from natural cyanosis, caused by a deficiency of oxygen, by the shade, tending more to the grey. The blood itself is of a dark, brownish colour, almost black, and shows with the spectroscope the absorption band of methaemoglobin (see above, Toxic Effect).

"Among nervous disorders, those due to the paralysing action of nitro-ben-
It is of a dark colour, due to products of transformation freed by oxidation from para-aminophenol, especially in the first days of intoxication. This colour deepens still more on the surface on exposure to air, just as in poisoning by aniline (see below Detection). The urine does not directly reduce a solution of copper sulphate, but only after preliminary boiling with hydrochloric acid, which separates the glycuronic acid combined with amidophenol and that can be detected by reduction and its lavo-

deratory property. The elimination may last as long as two weeks. Haemoglobin, as methaemoglobin, passed in the urine as such, can, in very severe cases, be detected from the first days, either by the spectroscope, or by chemical reaction, or even by the micro-
scope. Urobilin, urobiligen, and sometimes haematoporphyrin can be detected as a rule for a long time.

(2) Subacute and chronic forms. — These forms follow upon repeated absorption of small doses of the poison. They are much more common than the acute form, and, in the slighter cases, indicate their presence by pallor which is due to a slight anaemia and is usually accompanied by slightly subic-
teric coloration of the sclerotics. This pallor, which is characteristic for the most part of workers manipulating nitrobenzene, makes it possible to distinguish them readily from aniline workers. Anaemia is the leading feature of the clinical picture; as a rule, there is no methaemoglobinaemia, or, if it is present, it disappears rapidly after the cessation of work.

In cases of moderate anaemia, the reduction in the number of red blood cells and in the content of haemoglobin is slight, often much slighter than the pallor of the skin would have led one to suppose; the colorimetric index is normal or diminished, while the blood formula is hardly altered morphologically. In serious cases, examination of the blood shows changes similar to those met with in the acute form: forms of regeneration of the red blood cells are more or less definitely present; there is no marked leucocytosis; enlargement of the spleen exists, but it is not serious. Nervous disorders, with fatigue and headaches, loss of appetite, and, more rarely, feelings of sickness, are common, even in the slightest cases. Complete recovery requires, in serious cases, several weeks; the urine may possibly show, only in the first days, a slight dark shade and contain paramidophenol; but the presence of urobilin may often be detected and last a long time.

As in poisoning by the other aromatic nitro-derivatives, cutaneous affections may occur in the form of a pustulous eruption, nodules or moist eczema, with redness and swelling (Pohl).

It is not possible to describe the clinical picture of occupational poisoning by nitrotoluene, for particulars relating to poisoning in the case of man are wanting.

Detection

(1) In the air. — Pass at a moderate speed large quantities of air — at least 100 litres, or, better still, 1,000 — containing the fumes to be analysed through absorption tubes filled with absorbing substances, such as activated carbon. Extract the nitrobenzene contained in the absorption tubes with ether; repeat the extraction with small quantities of ether, or better still, in an extraction apparatus. Evaporate the ether; reduce the residue to aniline by means of powdered zinc and dilute hydrochloric acid. Set the aniline free from the aqueous solution of chlorohydrate of aniline by the addition of sodium or potassium lye until a feeble alkaline reaction is established. Distil the aniline in a small apparatus sufficiently to obtain 25 c.c. of liquid. When aniline is simultaneously present, the nitrobenzene should be isolated from the extract by longer distillation with steam in an acid solution, and the reduction should be carried out on the distillate: Aniline is easily detected in the distillate by the violet coloration which it gives with a solution of chloride of lime.

Quantitative estimation is done by gravimetry after conversion into tribromaniline by means of bromine water (see article "Aniline").

(2) In the urine. — Saponify the urine by making it boil with a weak solution of hydrochloric acid. Detect the principal product of elimination, i.e. the para-aminophenol, by means of the reaction of indophenol, or of nitration and combination with appropriate groups. These reactions are more sensitive when they are carried out with an ethereal extract of the distillate, obtained after saponification of urines rendered alkaline.

Test for para-nitrophentol. — Take up again the residue of the acid ethereal extract of the urine with weak hydrochloric acid. If the indophenol reaction is negative, reduce with powdered zinc. A positive reaction with para-amidophenol, which is the indophenol reaction, shows para-nitrophentol. This reaction is useful for making a differential diagnosis in poisoning with aniline. It does not, however, succeed in every case. In serious cases the presence of nitrobenzene in the urine is recognised by its characteristic odour. Distil the acid urine in steam, then reduce the distillate with powdered zinc and hydrochloric acid; aniline forms in a positive case.

Hygiene

First of all it is necessary to ensure that workers do not come in direct contact with, or become soiled by, the product, and, further, to avoid the formation and spread of toxic fumes. It is, therefore, necessary to provide against eventualities, and to use only closed apparatus for the manufacture of the product, for its subsequent use and transport. Transport, as well as the emptying of receptacles, should be effected through closed pipes, either by the use of compressed air or by aspiration. The displaced or aspirated air should be directed on its exit, either outside or into chimneys. Avoid the evolution of fumes containing nitrobenzene and nitrous gases by using for distillation or washing only nitrating apparatus furnished with exhaust flues reaching above the roof or connected with an exhaust system.

Nitration should be closely watched, and especially the maintenance of adequate temperatures, and stirring effected during violent reactions, in order to avoid the evolution of vapours and nitrous fumes, as well as the risk of explosion. When the work-
places are constructed, good ventilation and natural aeration should be provided. The workrooms should be high, provided with windows, skylights and other well-arranged openings for ventilation.

The introduction into the rooms of working platforms which reduce the height of the ceiling should be avoided as far as possible; where they exist, they should not impede the free circulation of air, either by too large a surface, or by being pushed up against the walls. In any case they should not be placed above the apparatus for nitrating and distillation. Natural aeration, especially during hot weather, and under certain circumstances, should be completed by an artificial system of ventilation.

The floor should be impermeable, if possible smooth and sloped towards drainage channels; it should not be made of asphalt, or mixtures of tar, because these absorb and accumulate nitrobenzene.

**Personal hygiene.** — Suitable working clothes should be provided, which should be changed often so that they do not become unduly impregnated with the toxic product; gloves are necessary and should be frequently changed and cleaned; instruction should be given to workmen on the toxic properties of the products manipulated, and on the necessity for changing working clothes when they have become much soiled; and also on the special danger which follows the taking of alcoholic drinks.

Douche baths should be installed, and also cloakrooms and dining rooms. Medical examination on commencing work, and suitable periodical examinations thereafter, fulfill the object of removing from work in good time all workmen showing signs of chronic poisoning, such, in particular, as icterus and anaemia.

**Legislation**

The measures relating to the employment of women and young workers in the manufacture of nitrobenzene are the same as those laid down for benzene, its homologues and their nitro- and amido-derivatives (see these articles).

Some detailed instructions on the equipping and working of these factories, as well as on the personal hygiene of workers employed in them, are contained in regulations laid down in Germany and Great Britain (see articles "Nitro- and Amido-Derivatives", "Aniline", etc.).

See also the same articles for information regarding compensation for injuries by nitrobenzene of occupational origin.

**Nitrocellulose**

**Chemical Composition and Properties**

Cellulose is the name given to the principal constituent of the cell walls of plants. In the manufacture of nitrocellulose, raw cotton for spinning is used or linters (short staple cotton left on the cotton plant after the long staples have been picked) and waste cotton from spinning and weaving. Chemically-prepared wood pulp, treated with bisulphite and bleached with chlorine, may be used instead of cotton.

Of all natural cellulose substances, cotton contains that which possesses the most stable chemical properties. The empirical formula of cellulose is \( (C_6H_{10}O_5)_n \), or according to other authorities \( C_{13}H_{22}O_10 \) or with doubling of the formula \( C_{26}H_44O_20 \). Treated with a mixture of nitric and sulphuric acids, it gives rise to mono-, di- and tri-nitrates according to the concentration of the acids, the duration of their action and the reaction temperature, the nitro group replacing the hydrogen atoms. Several nitratred forms are known, of which only two are extensively used: the combination with maximum nitration (chiefly for guncotton or hexa-nitrocellulose), the formula of which, according to Marshall, is approximately \( C_6H_4(NO_2)_6 \), with 14.14 per cent. of nitrogen soluble in acetone, acetic ether insoluble in alcohol, ether and nitro-glycerine and the less highly nitrated celluloses (pyroxylene) of which the approximate formula is, according to Marshall, \( C_6H_4(NO_2)_7 \), with 11.11 per cent. of nitrogen, soluble in a mixture of alcohol and ether, and used in the manufacture of collodium.
A mixture of mono- and di-nitrate of cellulose dissolved in a mixture of alcohol ether gives collodion, well known as a medicament and in the manufacture of celluloid, etc.

In deciding whether a nitrocellulose is to be regarded as a dangerous explosive, the important factor, apart from the nitrogen content, is the degree of humidity. Experiments have shown that soluble pyroxyline with 12.3 per cent. of nitrogen, with a humidity of 26 per cent., could only be exploded by means of complicated appliances, such as the application of fulminate of mercury with intercalation of an initial charge of picric acid. In practice soluble pyroxylines with less than 12 per cent. of hydrogen and a humidity of 30 per cent. may be regarded as non-explosive. When ignited they burn out quietly with a high flame. Diminution of the degree of humidity increases the danger of explosion, and the greatest caution is therefore required in drying nitrocelluloses.

**Production of Nitrocellulose**

The various kinds of raw material referred to above contain various impurities (fats, gums, etc.) which have to be eliminated before the nitration of the cellulose is proceeded with. The waste products from spinning and weaving are first of all sorted, carded and degreased. The linters require only carding. The other products are submitted to lixiviation (in a solution of caustic soda at 1 or 2 per cent.) in an autoclave (temperature 100-140° C.), which renders the cotton absorbent and removes from it any pectic matter as well as most of the hydrocellulose. This is followed by treatment with hypochlorides and drying. This treatment is specially utilised in the preparation of collodion used in celluloid factories.

Nitrification of disintegrated, purified and dried cotton is effected by immersion from eight to twelve hours in a mixture of concentrated nitric and sulphuric acid. The composition of the baths varies according to the degree of nitration it is desired to obtain and the method followed. The older method is to utilise containers, troughs or pots for the purpose, while the more modern process is effected in a centrifuge. In the first case the cotton, after being weighed, is plunged into troughs filled with the acid mixture and withdrawn after immersion lasting some minutes. It is compressed to remove the excess of acid, and it is then transferred to a stoneware pot (reaction pot) furnished with a cover.

When the nitration reaction has been effected the contents are poured into centrifugal machines which eliminate a certain quantity of the residual acids (acid centrifugalisation).

The toxic fumes given off during the reaction are removed by means of a chimney or led to a condensation chamber.

The soluble pyroxyline, having been centrifuged and discharged, is immediately immersed in large vats of cold water, the water being constantly changed. The acid is partially eliminated by diffusion in the water. The cotton is afterwards centrifuged once again, and finally undergoes washing in hot water.

The dipping process in centrifuges (Selvig process) permits of better hygienic conditions in the nitration rooms, for the successive operations of immersion, compression, reaction and acid centrifugalisation are effected in the same apparatus without necessitating discharge of the material. The apparatus, which is a centrifuge or hydro-extractor, revolves, after receiving the acid mixture, at a slow rate; the charge of cotton is gradually immersed and the cover closed down, and the apparatus is left to revolve for half an hour. Nitration is effected thus, and by increasing the speed the material can be dried by eliminating the excess acid.

After centrifuging, the cotton is discharged and transported to a stoneware bath known as a "hydraulic transporter", consisting of a sort of cupboard into which the cotton is introduced, being immediately immersed and carried away by a strong current of water.

Discharging of nitrocellulose from a Selvig and Lange centrifugal drier is, however, accompanied by risk due to sudden decomposition and ignition of the product.

In the Thompson process, in which the same container is used for these operations, the nitration acids are slowly replaced by water, which is brought about by the difference in density. The operation lasts from two and a quarter to two and a half hours, and the nitrocellulose leaves the apparatus after complete rinsing.

The guncotton is next purified by successive washing in boiling water, sometimes in slightly alkaline water in large wooden vats, as far as possible hermetically closed and with very cautious manipulation, as nitrocellulose containing traces of acid or unstable nitrated products decomposes readily. In this case rinsing in cold water follows.

Rendering the guncotton homogeneous is effected by reducing to pulp in pulping machines similar to those used in
papermaking or by suspension in water and shredding it in a cylinder furnished with blades and revolving at great speed. There follow further operations having for their object elimination of foreign matter from the guncotton (levigation, decantation, drying in centrifugal machines until the humidity of the guncotton is 25-30 per cent.). In this damp state the guncotton, which can be handled without danger, is compressed into small blocks and packed in wooden cases. The product obtained is pure white; if, however, it develops a yellowish tinge (decomposition of residual acids) it is a sign that there is a tendency to explosion. To accelerate stabilisation and bleaching, there is often added to the hot water in the final washings soda, ammonia, permanganate of potash, etc. Well-stabilised guncotton should be able to withstand heating for two hours at 132° C. in an amyl alcohol bath without decomposing or igniting.

Guncotton is very sensitive to frictional electricity. The drying is therefore usually carried out on metal slabs in frames which divert to earth any electricity which may be present. Any exceeding of the dry temperature of about 50 degrees is indicated by a thermometer which starts an electric alarm.

Manipulation of material with less than 20-30 per cent. humidity is to be avoided.

**Uses**

Nitrocellulose is chiefly used in colloidal solution for the preparation of smokeless powder (see article "Explosives"), of artificial silk (see that article), photographic films, cellulose varnishes and lacquers, etc. By treating oils with nitric acid to obtain substitutes (see article "Rubber or India-rubber Industry"), viscous semi-solid products are obtained, which, when mixed with nitro-cellulose, give a product known as "Velvirl" fairly similar to gutta-percha and India-rubber. Nitrocellulose used as raw material can be dissolved in a damp state. Consequently centrifugal drying is not required, the water being driven out by the alcohol (dehydration) (see also articles "Rubber or India-rubber Industry" and "Varnish and Lacquer Manufacture").

**Dangers**

The storing of large quantities of nitric acid always involves grave risk. When in a pure state and kept in a place that is free from damp, the large iron vats containing it are not attacked; but diluted acid dissolves iron and generates hydrogen which, in combination with the oxygen in the atmosphere, may form an explosive mixture, capable of igniting and bursting the iron receptacles. When the acid is contained in glass carboys with straw covers and these are broken, the acid reacts on the straw, as in fact on any organic substance whatsoever, causing ignition and liberation of nitrous fumes. The mixing of acids being dangerous on account of the liberation of nitrous fumes, it should be effected in closed apparatus. The greatest risk, however, occurs when nitrous fumes are liberated during action of nitric acid on organic and metallic substances (see article "Nitrous Fumes"). They also exert a local caustic action on the skin and mucous membrane. Finally, centrifugal driers, which in course of rotation suck in atmospheric moisture, may cause decomposition and explosion of nitrocellulose in the apparatus.

**Toxic Action**

According to Lehmann, the quantity of nitrous fumes sufficient to cause marked irritation of the respiratory passages would be 0.2 mg. per litre of air; 0.5 mg. could only be tolerated for a very short time. The acids used (particularly sulphuric acid) often contain small quantities of arsenic, which may be given off in the form of arseniuretted hydrogen (see that article) and inhaled during reaction on metals. These quantities of arsenic are generally, however, so small that no case of poisoning imputed to this cause has so far been reported. In one case, in which death was ascribed to the inhalation of nitrous fumes, traces of arsenic were discovered in certain organs of the victim (Holtzmann). The beard and whiskers assume a yellowish tinge as a result of the reaction of the acid on the capillary substance. Teeth are likewise discoloured and damaged by nitrous fumes.

Preparation and use of nitrocellulose involves exposure to the risk of fire and explosion, a risk which is present from the commencement to completion of the industrial processes. Danger of explosion occurs particularly during drying, now effected in safety chambers provided with a vacuum or by dehydration by means of alcohol, followed by drying. Handling and transport of dry nitrocellulose also entails grave risk for the workers. In the cleaning and emptying filters containing guncotton debris impregnated with acid. These facts are true of stabilised
nitrocellulose, the risk being very much greater for the less stable varieties, which tend to ignite and explode even without any apparent cause, merely owing to decomposition at an ordinary temperature. It is, therefore, indispensible that only stabilised qualities of nitrocellulose should be produced.

The phenomenon known as "firing" of guncotton causes, after a short but moderate liberation of acid, clouds of red fumes, and the only effective remedy against this is immediate removal of the staff.

The explosion of nitrated cotton liberates fumes, the toxicity of which may be compared to those of carbon monoxide.

**Statistics**

Cases of poisoning from nitrous gases are comparatively frequent; they were particularly frequent during the war, when explosives were manufactured in increased quantities. A section of the Trade Association in Germany, including Baden, Wurttemberg and the Rhenish Palatinate, with an average of 33,000 members working full time, made the following returns of industrial poisoning cases:

In cases of death from nitrous gases, the death followed mostly on the second day after the poisoning; in one case, however, death did not supervene until the eighth day.

According to comprehensive statistics prepared by Leymann, workers dealing with nitric acid are greatly troubled with corrosions of the skin, and a fairly high percentage of cases of diseases of the respiratory organs are met with amongst them.

**Pathology**

The pathology of nitrocellulose workers is connected with poisoning due to nitrous fumes, carbon monoxide, etc., and with poisoning due to other toxic substances already referred to above under Dangers.

**Hygiene**

Hygienic measures taken in the manufacture of guncotton are in general satisfactory, especially if the process of dipping in troughs is replaced by Selvig centrifugal machines, or even better by the Thompson system of double centrifuges. Oleum (fuming sulphuric acid) at 70 per cent. should be replaced by oleum at 20 per cent. Prevention of clouds of vapour in the shops, where washing in hot water is engaged in, must be effected. Suppression of these is possible when compulsory regulations are complied with. Further, nitrous fumes, in regard to which attempts are generally confined to more or less complete diffusion in the atmosphere, ought to be condensed. The wash basin placed at the exit of the Selvig centrifuges should be protected by a hood communicating with exhaust ventilation. The piping as well as the ventilators should be of stoneware (acid-resistant) and the fumes should be forced into condensation towers. As there is danger that the nitrous fumes are given off at the moment when the nitrated cotton leaves the double centrifuges (Thompson system), and even with a good exhaust installation, it is advisable to provide the workers with respiratory apparatus.

Liquids from centrifugal drying and from condensation of fumes should be withdrawn under an exhaust apparatus and filtered. This latter method is not however generally applied.

It is essential to prevent production of nitrous fumes by taking care that no foreign matters (water, oil) are mixed with the product in course of reaction. Every shock capable of producing a sparking discharge is to be avoided; friction and wearing away of the aluminium cover of the Thompson centrifuge should be guarded against, powdered aluminium being a powerful reducing agent. Precautions against fire should be taken by careful supervision of the plant and adequate maintenance of the heating and lighting system.

Effective measures should be taken to remove cotton dust from the workshops, where sorting and carding are carried out. When drying operations are effected in sections, as for example when using the Pétrie drying apparatus, there is ample production of cotton dust which no system of ventilation can cope with. If, by accident, liberation of acid fumes occurs, the workers must quit all workrooms facing the wind. The use of apparatus a feature of which is the production and maintenance of a partial vacuum in the reaction retorts and condensation batteries, throughout the duration
of the various operations, automatically prevents the diffusion of fumes in the atmosphere. Workers engaged at the ovens should be provided with respiratory apparatus containing oxygen. Instruction of the workers in the dangers to which they are exposed, and in the means of avoiding wrong practices, etc., should be insisted on. Medical examination of workers before engagement and periodically thereafter is essential. Persons suffering from respiratory troubles and especially asthmatic subjects are much more susceptible than others and ought consequently to be excluded from the nitration shops. All the provisions prescribed for explosive factories (see article "Explosives") to combat danger of fire and explosion are of course applicable to nitrocellulose factories (see also article "Celluloid").

LEGISLATION

The legislator treats nitrocellulose simply as an explosive and places it, as regards manufacture, conveyance, packing and storage, under the provisions applicable to explosive substances. For soluble pyroxyline these are often unnecessarily stringent requirements, since, as already indicated, soluble pyroxyline with less than 12 per cent. of hydrogen and a humidity of 30 per cent. is no longer to be regarded as an explosive.

Nitrogen

PROPERTIES

Nitrogen is a gas found free in the atmosphere (78-80 per cent. nitrogen, 22-20 per cent. oxygen). With other elements, it enters into the composition of ammoniates, nitrates, albuminoid matter, and forms the largest part of animal and vegetable tissues.

Nitrogen (symbol N) is a colourless, inodorous gas having a density of 0.97 (air=1). It is liquefied with difficulty; its critical temperature is —146° C. and its critical pressure 35 atmospheres. In the liquid state it is colourless with a specific gravity of 0.804 and boils at —194° C. It solidifies at —214° C. Only slightly soluble in water, it neither maintains combustion nor respiration.

Nitrogen is a very inert gas which only combines when heated with some metals (lithium, magnesium, silicon, etc.) yielding nitrides (sometimes only in the presence of catalysts).

Under the influence of the electric spark it combines with oxygen, forming nitrogen peroxide (NO₂) (reddish-brown fumes) and, with hydrogen, ammonia.

It is produced pure if ammonium nitrite or a mixture of sodium nitrite, ammonium sulphide, potassium chromate, and water are heated. Indirectly it can be obtained from liquid air by conversion of this into a gas in a rectifying apparatus; under these circumstances it is almost pure (99 per cent.), generally the industry using it produces it as required; this is also the case with ammonia, calcium cyanamide: for filling lamps and electric torches, etc.

Nitrogen is not toxic; but, as has been said, it neither supports combustion nor respiration.

COMPOUNDS OF NITROGEN

Among the five hydrogen compounds of nitrogen the most important are ammonia (see that article) and hydrazine (N₂H₄), prepared by the action of sodium hypochlorite on ammonia. Chloramine (NH₂Cl) is first obtained and, at low temperature and under a vacuum it distills, in the form of oily drops. By fractional distillation of the aqueous solution the hydrate of hydrazine (N₂H₄H₂O) is obtained — a very strong base, recalling soda-lye and acting like a caustic. But it is of no interest from the practical point of view for industrial hygiene.

Among the halogen compounds nitrogen chloride and iodide should be mentioned, and among the oxygen compounds the protoxide (N₂O) or laughing gas which has no irritant action; nitric oxide (NO), the trioxide or nitrogen anhydride (N₂O₃), the nitrogen dioxide (NO₂), the peroxide (N₂O₅), and nitric anhydride (N₂O₅).
Legislation

Regulations apply as in the case of nitric acid, ammonia, etc., the chemical industry, nitro-derivatives of benzene and its homologues, etc.

Nitroglycerine is to be treated as an industrial disease.

BIBLIOGRAPHY

Haldane, Banham and Savage, in British Medical Journal, 1 August 1925, London.

Nitroglycerine

(Trinitroglycerine)

Properties

Nitroglycerine, discovered in 1847 by Sobrero, who named it "pyroglycerine" or "glycerine fulminante", is a trinitrate of glycerine, the formula of which is:

\[ \text{CH}_3\text{O} \cdot \text{NO}_3 \]
\[ \text{CH}_2\text{O} \cdot \text{NO}_3 = \text{C}_3\text{H}_3 \cdot (\text{ON})_3 \]
\[ \text{CH}_3\text{O} \cdot \text{NO}_3 \]

In its pure state it is a dense oily almost colourless and inodorous liquid with a specific gravity of 1.66 at 15°C. Its taste is sweetish and burning. The technical product has a colour varying from clear yellow (white wine colour) to a brownish yellow. Nitroglycerine evaporates even at 50°C, and if it is gradually heated to 100°C it commences to decompose, giving off brown nitrous fumes (oxides of nitrogen). Below 13.5°C it solidifies (congeals); it is readily soluble in most organic solvents; it is on the other hand almost insoluble in water, carbon bisulphide and mineral oils.

Nitroglycerine itself is a good solvent, especially for some kinds of nitro-cellulose. It then forms stable colloids (gelatine).

When nitroglycerine contains no acid it does not decompose of itself; it is very stable and ignites with difficulty; it cannot even be lighted by contact with a piece of burning wood or even a gun-powder fuse. In small quantities, nitroglycerine burns slowly, making a crackling noise and with a greenish flame. There is danger of an explosion if it begins to boil while it is being heated.

Nitroglycerine explodes violently when heated to 250°C. with violent percussion or with energetic detonation. In accordance with its chemical composition, nitroglycerine is the most violent of all known explosives. When it is in a congealed condition it explodes more easily than when in a liquid state.

On explosion one litre gives 1.298 litres of gas, which, at the temperature of explosion, occupies 10.4 litres of space. Carbon dioxide, water, nitrogen and oxygen are formed as products of the explosion. This fact is of great importance so far as the use of nitroglycerine as an explosive is concerned, because in the fumes which form after an explosion no strongly toxic gases are found as is the case with other explosives (carbon monoxide, nitric oxide).

INDUSTRIAL OPERATIONS

Nitroglycerine is prepared from glycerine for dynamite manufacture, a product of very high concentration and the greatest purity. This condition is extremely important from the point of view of safety in manipulation.

The acid mixture is obtained by slowly adding sulphuric acid (96 per cent.) to nitric acid (98 per cent.) contained in iron receptacles, cooling and agitating strongly; for 100 parts by weight of nitroglycerine, 240-270 parts of nitric acid and 330-360 parts of sulphuric acid are needed. The best results seem to be obtained with a nitro-sulphuric mixture of 46 per cent. of the first and 54 per cent. of the latter.

Nitrification

This operation is considered one of the most dangerous in the chemical industry. In order to render it free from danger, the personnel must be perfectly conversant with the work and exercise meticulous care.

The nitro-sulphuric mixture in the desired quantity is received into an upper reservoir of the apparatus for nitrification of the glycerine. The apparatus made of lead is surrounded by a wooden envelope (not of iron because of the danger of sparks set up by violent contact, etc.); water circulates in between, as well as in the serpentine coils of lead applied against the internal wall of the boiler. The apparatus is closed and furnished with a duct serving for the escape of air and for the withdrawal of the intense fumes which are recovered in small condens-

The acids of nitrogen comprise hypo-
nitrous acid (H₂N₂O₃), nitrohydroxylic
acid (H₂N₂O₄), nitrous acid (HNO₂), nitric
acid (see that article), etc., and nitric
anhydride (HNO₃).

Various nitric salts are prepared by
dissolving the corresponding substance in
nitric acid. In this reaction nitrous fumes
are given off. When a mixture of nitric
and hydrochloric acids is used to dissolve
certain metals (gold, platinum) chlorine
is evolved.

\textit{Nitrate of barium} \[\text{Ba (NO₃)₂}\] is used for
producing a green colour in fireworks and
in the preparation of certain explosives; \textit{nitrate of stromatium} for red
colours; \textit{nitrate of ammonium} for explosives; \textit{nit-
trate of lead} is used in dyeing, in textile
printing, in the preparation of chrome
yellow and other lead compounds; in the
paste for matches (danger incurred from
nitric acid, nitrous fumes and lead); \textit{nit-
rate of iron} also is employed in dyeing
silk black, as is also \textit{nitrate of copper}.
It is well known that nitroglycerine to which \textit{nitrate of mercury}
is put, see the articles \textit{"Hatters Furriers Processes"} and \textit{"Haircutting"}.

\textit{Nitrate of sodium} is manufactured indus-
trially in large quantities for use in the
preparation of dazo compounds, with the
nitrate as the starting point and the addi-
tion of lead or iron. These latter act as
the reducing agent and when lead is used
the worker is exposed to the risk of lead
poisoning. Many such cases have been
reported in the course of manufacture of
nitrates in Russia. \textit{Nitrate of amyl}, the
vapour of which may cause palpitation
and congestion in the head, etc., has
caulsed many serious cases of intoxica-
tion (Egili-Rust).

\textit{Nitrate of ethyl} in 1921 also caused cases of
poisoning in a Bavarian chemical
works. The symptoms were as follows:
fainting, slow reaction of the pupils,
cyanosis, rapid heart action. On recover-
ing consciousness the patients showed
signs of irritability, spasmodic muscular
movements (in the limbs), faintness, etc.

The oxides of nitrogen are given off
when nitroglycerine, dynamite, etc., are
burnt or exploded in mines or confined
spaces. Thus, according to Haldane, nitro-
glycerine gives off 62 per cent. of carbon
dioxide and 31.6 per cent. of nitrogen;
when it burns in the presence of its own
gases 33.9 per cent. of carbon monoxide
and 48.5 nitric oxide which, in contact
with air immediately oxidises, forming
red fumes (nitrous fumes). Peroxide of
nitrogen is perhaps the most irritating of
all the oxides of nitrogen. The symptoms
come on some hours after the destructive
action on the mucous membrane of the
respiratory tract (see article \textit{"Nitrous Fumes"}); bronchitis and pneumonia are
frequent sequelae.

\textbf{TOXIC ACTION}

The experiments of O. Girndt and E.
Le Blanc on the action of the protoxide,
both in the case of animals and man,
showed that air containing 1.2 to 16 per
cent. (in animals from 0.5 to 80 per
cent.) had no effect on arterial pressure,
as had been admitted by Kestner.

Inhalation of the dioxide and per-
oxide has occasioned numerous acci-
dents in factories and laboratories
dipping metal articles, manufacture of
sulphuric acid, nitrate of mercury,
etc., with several fatalities (see article
\textit{"Nitrous Fumes"}).

In contact with air the nitric oxide is
quickly converted into the peroxide, so
that it is the latter gas which acts or,
at any rate, a mixture of the two.

Where pure, the nitric oxide is a co-
avourless easily liquefiable gas, which
dissolves in water (to the extent of one-
twentith of its volume) and combines
directly with oxygen to form the per-
oxide: it supports the combustion of
phosphorus, etc. Generally it contains
considerable quantities of the protoxide.
Davy tried to breathe nitric oxide
directly having been careful first to fill
his lungs with the protoxide to avoid
the oxidation of the nitric oxide. Davy
experienced a violent spasm of the
air passages and constriction in the glottis
and had to give up. In all probability, however,
partial oxidation at least of this gas
does take place in the lungs (Kohn-
Abrest).

Nitrogen has not, like oxygen, the
cpower of combining chemically with
the blood.

Hermann, who has described the ac-
tion of nitric oxide on the blood, ad-
mits that combination of the haemo-
globin with it does take place and that
the affinity between the two is so great
that it can displace the carbon mon-
oxide from its combination with
blood. The absorption spectrum of
NO-haemoglobin is not characteristic.
Ogier noted the ordinary spectrum of
oxyhaemoglobin, but the absorption
bands were very weak. After the ac-
tion of the sulphide this spectrum
resembled that of a specimen of oxy-
generated blood containing a very small
quantity of carbon monoxide. Kohn-
Abrest is of opinion that this cause of
ever is very rarely likely to occur in
testing.

At the same time the combination of
compounds of nitrogen with haemo-
globin has been recently studied (1926)
by Haldane, Banham, and Savage.

These authors are of opinion, that cer-
tain post-mortem findings, simulating
very closely those of carbon monoxide
poisoning, are due to the formation of
nitric oxide haemoglobin after death.
This opinion, which, however, does not
meet with acceptance by all writers,
especially not in Germany, deserves to
be given in full.
The findings in the case of a collier, whose death followed on stoking boiler furnaces, closely resembled those to be expected from carbon monoxide. But an analysis of all the facts of the case showed conclusively that the sole cause capable of imparting a red colour to the blood as well as of setting up other reactions — once the action of carbon monoxide was excluded was nitric oxide haemoglobin. This compound, discovered by Hermann in 1865, is formed when nitric oxide is brought into contact with reduced blood.

The colour of the blood changes at once from dark purple to the bright scarlet as shown also by blood saturated with oxygen or carbon monoxide.

A double-handed spectrum, similar on the whole to that of oxyhaemoglobin or CO-haemoglobin, appears at the same time. The bands are, however, much less sharply defined than those of oxyhaemoglobin, and somewhat less sharply than those of CO-haemoglobin. The NO-haemoglobin band in the yellow extends, also, to a slight distance on the red side of the D line. On great dilution with water the oxyhaemoglobin solution appears yellow in daylight, while CO-haemoglobin appears pink; this difference affords by far the simplest and most delicate means of detecting the presence of carbon monoxide in blood. NO-haemoglobin gives a tint which is pinker than that of oxyhaemoglobin, but not nearly so pink as that of CO-haemoglobin. The solution of NO-haemoglobin can be distinguished at once by boiling, since it gives a pink coagulum, while oxyhaemoglobin and CO-haemoglobin give a dull grey coagulum.

This difference is due to NO-haemochromogen, which is stable in the boiling water and of a red colour. In other respects, NO-haemoglobin gives similar reactions, including spectroscopic ones, to those given by CO-haemoglobin.

NO-haemoglobin and its products are very familiar. Haldane in 1901 showed that the red colour of raw salted meat is due to the presence of NO-haemoglobin, while the corresponding pink colour of cooked salt meat is due to NO-haemachromogen. The nitrite used in salting the meat becomes reduced in the meat to nitrite and in presence of the reduced haemoglobin, which is also there, the nitrite becomes further reduced and the resulting NO combines with the reduced haemoglobin to form NO-haemoglobin.

It had already been shown by Haldane, Makgill, and Mavrogordato that in animals which have been killed after receiving a dose of nitrite the blood becomes bright red after death in consequence of the formation of NO-haemoglobin; and the possibility of this being taken for CO-haemoglobin was pointed out at the time.

When nitrite is given to a living animal methaemoglobin is formed. Not only, however, is this the case, but a certain amount of NO-haemoglobin is also formed. The colour of the blood solution treated with nitrite is therefore reddish brown, in contrast to the dull brown of pure methaemoglobin. The contrast in both colour and spectroscopic appearance becomes much more evident on making the solution faintly acid by shaking it with expired air.

On reducing the methaemoglobin with ammonium hydrosulphide, the whole of the haemoglobin passes very gradually into NO-haemoglobin, or, on boiling the whole, passes rapidly into NO-haemachromogen, so that the coagulum is pink.

Nitrites poison an animal by depriving the haemoglobin of its oxygen-carrying power, just as CO does; but the animal has a cyanosed appearance, contrasting with the red colour in poisoning by CO.

The cyanosis is not due to the presence of reduced haemoglobin, but to that of methaemoglobin.

It is suspected that infected microorganisms producing nitrite from the body, such as, e.g., the influenza bacillus, may readily account for the presence of NO-haemoglobin post mortem.

From the medico-legal standpoint, therefore, the possible presence of NO-haemoglobin must now always be considered in cases of suspected CO poisoning. The distinction can be made with great ease by boiling a watery solution of the blood. If the red colour and other corresponding chemical reactions or spectroscopic appearances are due to NO-haemoglobin the coagulum will be pink.

According to Kohn-Abrest, very little information exists as to the effect of nitrogen protoxide on the blood.

However, extraction of this gas in the blood under a vacuum is not difficult and the amount of gas recovered from persons who have been asphyxiated by it is pretty considerable and consequently easy to recognise.

HYGIENE

See articles "Nitric Acid", "Ammonia", and "Chemical Trades".
The control of the temperature of reaction is carried out by means of thermometers placed in the vat at varying levels and connected up with automatic alarums. The bottom of the nitrating apparatus is provided with one or two large earthenware taps for rapid emptying, in case of danger, of the mass into a safety basin filled with water ("drowning" of nitroglycerine), which is below the apparatus and which has a capacity of about fifteen times the latter. An earthenware pipe, similarly provided with automatic closing apparatus, leads to the decanting apparatus. The glycerine is introduced into the acid mixture in several tiny jets, while stirring is effected by means of dried compressed air which bubbles through the reacting mass and maintains an even mixture. In general the temperature of the reaction is about 25°C. The course of the nitration is effected without danger when constant control is kept over the cooling arrangements. As a matter of fact, if a few drops of cooling liquid (generally a brine of magnesium chloride) were to penetrate into the mass and make it heat up rapidly, there would be danger of immediate decomposition and explosion of the nitroglycerine. This is why the brine circulates in the coils at low pressure, in order that it should not reach the mass, where it would cause an escape into the piping.

Maintenance of the apparatus and coils is controlled at least once daily and always in the evening. Finally, cylinders of compressed air should be kept in reserve or bottles containing nitrogen or concentrated carbon dioxide in case something goes wrong with the compressed air apparatus.

Decantation

When the operation is finished, nitroglycerine, the specific weight of which is less than that of the acid mixture, floats on the top of this and is separated by decantation. This apparatus is made out of a leaden vessel, with the bottom sloping towards the centre and supported by a wooden armature communicating above by means of a pipe with the vessel for washing. The tube in the centre of the bottom of the apparatus communicates with two or three taps and is provided with a glass window. One of the taps discharges the acid. The separating line of the two layers coincides almost with the tap placed in the centre of the side wall of the apparatus, which allows of the almost complete discharge of the nitroglycerine into a wooden reservoir lined with lead.

Secondary Decantation

The apparatus for secondary decantation is cylindrical in shape and has at the top a glass fixture with a tap and a glass window. It is made of lead and enclosed in a wooden box. The acid mixture remains for several days in this apparatus and the nitroglycerine, which is collected by mechanical means, rises gradually in the tube and is then discharged into the washing vessel.

Washing (Stabilisation)

The nitroglycerine which is contaminated by the acid mixture is delivered by a suitable pipe into receptacles of earthenware half filled with cold water, where it is agitated by bubbling compressed air through it. The nitroglycerine is then allowed to settle; the washing is repeated with water, and then with a very dilute solution of soda (stabilisation), until the washing waters no longer give an
acid reaction and the mass has a very slightly alkaline reaction. The washed nitroglycerine is transported in buckets of hardened rubber or of ebonite to the filters (wooden boxes covered with woollen cloth or felt, sometimes provided also with dried salt to keep back the emulsified water). After washing the nitroglycerine is stored or used immediately.

**Treatment of the Washing Waters**

The washing water still contains nitroglycerine and consequently cannot be run off easily. All the waters used in the operations pass into a single receptacle called the “labyrinth,” which is divided into several chambers by baffle plates, where the slowly flowing water, before escaping at the point opposite to that of entry, is forced to make a detour (up and down) and leaves the drops of nitroglycerine suspended in a state of emulsion. Before being run off, these waters are further passed across a filter made of several layers filled with peat. The last remains of the explosive substance are thus kept back. The peat from the filters is taken up from time to time and burnt with the greatest precautions.

**Denitration**

The acid from the secondary decantation (residual acid) contains not only 70-75 per cent. of sulphuric acid, 7-10 per cent. of nitric acid and 15-20 per cent. of water, but also various nitrous products and impurities of an explosive character (mono-, di- and trinitroglycerine). The sulphuric and nitric acids are recovered by denitration in towers 6 metres high with a diameter of about 1 metre, formed of six or seven Volvic stone rings and surrounded by closely adhering steel rings. The acid flows from above downwards over the filling matter (fragments of silica, glass or earthenware), while a current of steam at 350° C. and hot air at 400° C. passes through the tower from below upwards.

In this manner the organic products are destroyed, the nitric acid fumes escape at a temperature of about 110-120° C., and the sulphuric acid is collected at the base of the tower at about 150° C. The two regenerated products are either concentrated in special apparatus or used in other operations. The denitration is effected without danger if there is a complete separation of the nitroglycerine and the mixture, which can only be secured by providing sufficiently large apparatus for secondary decantation.

**Uses**

Formerly nitroglycerine was used in a very dilute alcoholic solution or in the form of a pastille in the treatment of chronic nephritis, for lowering the blood pressure in arteriosclerosis or for similar objects. Practically all the nitroglycerine made to-day is used as an explosive, in the manufacture of various types of dynamite, explosive gelatine, smokeless powder, etc. Serious accidents from the explosion of nitroglycerine have sometimes led to the prohibition of its manufacture. But the happy solution of Nobel has been able to eliminate the danger by mixing nitroglycerine with inert porous substances (diatomaceous earth) in order to obtain dynamite (see article “Explosives”).

To-day use is also made of cuprene, in the place of diatomaceous earth, as a stabilising agent for nitroglycerine. Freezing nitroglycerine has been suggested as a means for rendering it less sensitive, but this fact is generally contested; in some cases, it has been carried without danger dissolved in ethyl or methyl alcohol. It is re-precipitated with water when it is required for use.

**Poisonous Effect**

Nitroglycerine exercises its toxic action even through the uninjured skin, but it is the mucous membrane that is particularly susceptible to its absorption. On the skin, and especially on the palm and in the interdigital spaces of the hand, nitroglycerine produces eruptions characterised by great dryness and the formation of rhagades.

The workers show ulcers under the nails and at the extremities of the fingers, and these ulcers are very hard to heal (Erben). Susceptibility in regard to nitroglycerine is further increased by alcoholic drink; thus it is for this reason that excessive indulgence in alcohol brings on a state of excitation bordering on mania or confused mental agitation. In these circumstances, fatal cases have sometimes occurred.

The toxic action of nitroglycerine is characterised by headache accompanied by excitement, a feeling of heaviness in the frontal and occipital regions, insomnia with diarrhoea and vomiting in the night. Nitroglycerine
exerts toxic effects when absorbed internally in stronger doses: fainting, vertigo, burning in the oesophagus and stomach, colics, paralysis, slowing of the heart's action, diminution in the blood pressure, respiratory râles, cyanosis, coldness of the extremities and redness of the face have been observed. Apart from these nitroglycerine is a sexual stimulant; in some persons who are particularly sensitive inhalation of a small quantity of the vapour is sufficient to produce an effect.

Work with nitroglycerine leads to acclimatisation, which occurs more or less rapidly according to individual pre-disposition.

A break in the work interrupts this acclimatisation, which has to be re-acquired afresh. In order not to lose the effects of this action, American workers are in the habit of moistening their hat bands with nitroglycerine during any absence from the factory, but the efficacy of this measure seems to be very doubtful in comparison with the risks which it entails.

In the chronic form, intoxication by nitroglycerine shows itself in digestive troubles, tremors and neuralgia. J. Heitz (1924) examined twenty-six workmen and women of average age who were regularly employed for several months or years in the transport and mixing of nitroglycerine with other products or with the filling of cartridges. The commonest complaint was headache, prevalent on commencing work with nitroglycerine but which soon passed off, only to manifest itself again whenever the workman resumed work, even after a suspension of work for hours. The examination of blood pressure enabled Heitz to confirm the fact that it is always lowered when at work while normal in those not at work. The diastolic pressure is always markedly lower than the systolic. Alcoholic persons show increased pressure when not at work and a slight diminution during work, especially of the diastolic pressure.

Another source of danger is present in nitrous fumes, which, in the course of manufacture, are evolved or formed when nitroglycerine explosives are fired. When in small quantity, this gas produces tremor, congestion in the head, vomiting and headache; its presence in large quantities results in vertigo, cyanosis, excitation and loss of consciousness. Respiration resembles snoring, the skin of the hands is cold and the pulse feeble.

When consciousness returns the patient has a feeling of fatigue and headache, the pulse is intermittent. In the case of serious intoxication, the issue may be fatal.

In its liquid form nitroglycerine tends to explode spontaneously with great ease, especially if it contains traces of acid. It is particularly dangerous when it is frozen, because, if it explodes it is not completely destroyed and can set up successive decompositions. The freezing point can be lowered by mixing 25-30 parts of dinitroglycerine with 75-70 parts of trinitroglycerine, or 30 parts of dinitrochlorhydrine or nitroglycol with 70 parts of nitroglycerine. Sunlight exerts a violent effect on nitroglycerine and may cause explosions. In the same way sudden or excessive rises in temperature during nitration may result in explosion by immediate decomposition of the mass. This danger of decomposition is rare to-day and can generally be accounted for by faulty apparatus or inattention during the process of nitration.

SAFETY AND HYGIENE

The manufacture, as well as the manipulation, of nitroglycerine demands the most meticulous care and attention.

Since the reduction of the charge of glycerine to 100-150 kg., the number of factories undertaking manufacture has greatly increased.

To-day, nitration and decantation and washing are not carried out in the same workroom. In this way, if there is an explosion it is limited to a single site. The loss of a single small workroom thus affects production less seriously than formerly, when great expense was incurred.

The manufacturing rooms and storage rooms, etc., ought to be surrounded by an embankment of earth about 1 metre higher than the roofs of the neighbouring sheds. The circumference should be 10 metres at the base and 1 metre at the top. The slopes of this mound should be covered with vegetation to protect the neighbourhood from the debris resulting from the explosion and to reduce the horizontal pressure.

The distance between the sheds ought to be at least 15-20 metres, in order to prevent the propagation of fires or explosions. Access to the buildings through the embankments is made by means of passages with a bend in them or by tunnels walled or concreted; in order to prevent the propagation of explosions two sheds in
which this risk is present should never
be connected by means of tunnels. Care
should be taken, in the store-
rooms especially, in regard to light-
ing; all pieces of metal should be
earthy so as to prevent them becom-
ing charged with static electricity.
Up to the present the sheds have
been generally built of wood, to di-
minish the danger in case of explo-
sion, but this system affords no pro-
tection against the spreading of fires
or the fall of large pieces of debris.
As a matter of fact concrete build-
ings (with no siliceous stones) are to
be preferred, constructed in the form
of a vault open on one side and cover-
ed with an earthen roof.
The apparatus for the production of
nitroglycerine is placed at a very high
point in the workroom, so that, in the
successive operations the product is di-
rected towards the other apparatus,
all situated at a lower level.
When liquid nitroglycerine is being
prepared, or handled, the floor of the
workroom should be covered with
lead plates having raised edges, so
that the material can be collected if
any of the apparatus breaks. In
places where nitroglycerine cakes (dy-
namite) are kept, the floor should be
of closely fitted wood without any
cracks.
If nitroglycerine is accidentally spilt,
it should be mopped up immediately
with a sponge.
Nitroglycerine is fairly easily decom-
posed by an alcoholic solution of
caucus potash and this saponification
reaction is used to destroy and render
harmless where necessary small quan-
tities of nitroglycerine. For the same
reason, solutions of caustic soda are
used for washing the tables or floors on
which nitroglycerine has been spilt.
The piping for the circulation of
nitroglycerine is often gutter-shaped
with a movable cover and provided
with a pipe for the circulation of warm
water in order to avoid freezing in
winter, as that is always a source of
danger. There is a risk, however,
that if an explosion takes place in one
of the gutters it may spread along the
channels to all the rooms; hence it is
useful to detach a piece of the gutter
when nitroglycerine is not circulating.
It is, however, more prudent to trans-
port nitroglycerine in pails of hard-
ened rubber, or ebonite.
The glass in front of apertures
should be whitewashed, as curves in
the glass might act as lenses, and if
light were concentrated on the exp-
losive matter detonation might re-
sult.

For other means of safety see arti-
cle "Explosives".
The preparation and manipulation
of nitroglycerine demand most meti-
culous cleanliness if the workers are
to be protected against the risk of
sickness. All means of assuring
minute personal cleanliness should be
provided: working clothes, caps or head
coverings, etc. The workers should
wash the face, hands and nails and
pass as much of their time as possible
in the open air. All the workrooms
should be provided with a good system
of ventilation.
The treatment of headache due to
nitroglycerine belongs to the sphere of
the medical attendant in charge. It
should be remembered that very strong
black coffee, although not always
efficacious, is nevertheless to be rec-
commended. The medical man
should be called in at once, especially in
serious cases.

LEGISLATION

Statutory provision as to the manu-
facture and use of nitroglycerine is bound
up with legislation on explosives and
makes for diminution or avoidance of the
danger inherent in the irrational manipu-
lation of explosives.
Several countries have laid down spe-
cial requirements for the installation and
production of nitroglycerine explosives:
France, Germany, Great Britain, Italy,
etc.
Illness due to nitroglycerine entitles to
compensation in Finland and Switzerland.

Nitrous Fumes
(Oxides of Nitrogen)

French: Gaz nitreux. — German: Nitrose Gase. — Italian and Spanish: Gas nitrosti.

CHEMICAL PROPERTIES

Glowing red nitrous fumes — products of the low oxidation of nitrogen — consist of brown or brownish red gases decidedly heavier than air. A litre of protoxide of nitrogen weighs 1.34 grm. Fumes generally consist of a mixture of nitrogen peroxide (or hyponitric anhydride: N₂O₅) and the protoxide (N₂O₃) or dioxide of nitrogen (nitric oxide NO₂) which, however, on coming into contact with air, changes immediately into peroxide of nitrogen. Other compounds of oxygen and nitrogen which may be found in nitrous fumes are nitrous anhydride (N₂O₅) and nitric anhydride (N₂O₆); these are less stable than the two compounds mentioned above and, under certain conditions, become transformed into dioxide of nitrogen or into hyponitric acid and also into the peroxide which is the most stable compound of oxygen and nitrogen. Among the oxyacids which may also occur in nitrous fumes are nitric acid (HNO₃), nitric oxide (H₂N₂O₂), and hyponitrous acid (H₂N₂O₂). During certain processes, e.g. in cleaning metal, fumes of oxide of nitrogen arise from solutions containing chlorine and then form nitrosyl chloride.

Nitrous fumes come to be noticed by their reddish-brown colour and irritant action. The protoxide is, on the contrary, colourless; the lower oxides are pale.

SOURCES OF POISONING

As Chief Products

Risk occurs when the nitrogen of the air is oxidised by different processes, among which must be specially noted the oxidation of nitrogen in the electric display arc and the preparation of oxide of nitrogen according to the process of Haber, the starting point for synthetic ammonia.

Oxide of nitrogen obtained by these processes can be used in various ways. The gases freed by an intermediate process may be utilised immediately for the preparation of ammonium nitrate, which is used as a manure, and in the manufacture of explosives; or they are absorbed by water (following the principle of the counter current), the residuary gases being submitted to a fresh absorption; or else the gases are subjected to a cooling process, when the oxide of nitrogen, after being thus dehydrated, is liquefied by bringing it to a very low temperature by means of a refrigerating machine.

Some substance that nitrifies with difficulty is passed through the machine, generally as a cooling liquid (ethane machines are specially used). If the tubes are not quite airtight and if the nitrous fumes come in contact with organic liquids, reactions and even explosions occur, accompanied by liberation of large quantities of oxide of nitrogen. This danger, which has attracted attention owing to a series of small and large explosions, seems to be all the greater in that it is always underestimated by the technical staff, or that it cannot be avoided.

As By-Products

These by-products, which are always unpleasant, are constantly being formed when, in technical processes, nitric acid or mixtures of this acid with sulphuric acid are used and when the operation is accompanied by a strong reduction. It is the case, for example, in all branches of the large and small metal trades when it is necessary to remove oxides from sheets of polished metal (décapage or cleaning).

Oxides of nitrogen may also develop following a disturbance in a process or particular reactions; for example, when nitrination occurs at a high temperature, or in presence of easily oxidised impurities. These gases develop particularly when, in consequence of a break of the receptacles, nitric acid, or mixtures containing it, come in contact with metal or organic compounds. In these circumstances, large volumes of oxides of nitrogen are suddenly formed and it is dangerous to enter the work- places. Rescue work and, particularly, the salvage of materials are both dangerous.

Danger from the setting free of nitrous fumes exists in a large number of industrial operations, among which may be mentioned those where fuming nitric acid is manipulated, such as soaking, mixing, recovery, and transport; as well as in the chemical industry, for the preparation of arsenious acid, arseniate of soda; sulphuric, nitric, chronic and oxalic acids; ammonia and its combinations and salts; nitric acid, by distillation of nitre with sulphuric acid in iron cylinders; nitrate of barium, by dissolving sulphate of barium in nitric acid; nitrate of lead; acid nitrate of mercury; nitrate of silver; soda; explosives; fulminate of mercury; nitrates derived from bidentate and its homologues; chemical manures: celluloid; aniline colours; artificial silk; photographic films; and in the preparation of thorium and cerium. Danger
also arises from the action of: fuming nitric acid on organic substances, such as coal, wood, straw, and textiles; during the making of glass heads, glue, and artificial leathers by the process called "preparation by animal charcoal" (preparation par le noir); in the making of morocco leather; during the making of glass heads, glue, and metales; during the preparation of iron mordants, etc.; and during the construction of tunnels at high altitudes and during work near glaciers in winter.

Oxides of nitrogen are produced in all branches of the metal industry, particularly in cleaning articles of brass, when this material is in small pieces—work which generally falls to the lot of odd temporary workers, indolent and uncomplaining.

For these processes mixtures of nitric acid, kitchen salt and lamp black are used, prepared according to numerous tests and old recipes. When metals covered with oxide are dipped in such mixtures, complex combinations of very irritating fumes are set free, of which nitrosyl chloride is the prototype; such fumes vary much in composition from factory to factory.

Oxide of nitrogen is also a very disagreeable by-product in the first stages of the decomposition of celluloid, that is to say, of the spontaneous combustion of this nitro-cellulose combination. The decomposition takes place sometimes even in the absence of air, between 120 and 130° C., but it most often occurs about 140-150° C. It sets free an irritating, partly brownish-red smoke, smelling of camphor and containing a relatively large amount of oxides of nitrogen. This smoke, when mixed with air, may give rise to very violent secondary explosions, which generally no longer contain detectable oxides of nitrogen.

TOXICITY

Investigations have been made to determine the critical concentrations which cannot be endured for more than some seconds or one minute.

Like nearly all industrial gases, nitrous fumes are not generally pure and contain always their poisonous action in the pure state. Their action depends especially on their concentration and duration of action, although they are generally diluted in the air. Zangger is of opinion that, generally speaking, nothing is known regarding fatal dosage. According to Lehmann, the quantity of nitrous fumes sufficient to cause irritation of the respiratory passages is 0.2 mg. per litre of air. A dose of 0.3 to 0.4 mg. is absolutely dangerous. The higher oxides of nitrogen are probably more poisonous than those which approximate to "laughing gas", N₂O₃.

The investigations of Lehmann and Hasegawa have shown that for animals there is no difference between the action of nitrous fumes and those of other irritating gases. The poisonous dosage is estimated in terms of total nitric acid: 0.1 mg. of total nitric acid per litre of air is scarcely harmful at all; but 0.2 mg. causes quite a strong irritation and is injurious at the end of a certain period. A dose of 0.3 to 0.5 mg. can only be endured for a very short time. A dose of 0.5 mg. kills a cat in 4 hours, but a dose of 0.7 mg. can sometimes be endured for one hour or two. All doses above 0.9 mg. kill animals in one or two hours; a dose of 5.6 mg. has been borne by a cat for five minutes and killed another cat in 10 minutes.

Ronzani, when investigating chronic poisoning, found that a dose of 0.19 mg. was harmless. Lehmann has also recorded that a dose of 0.27 mg. during 7 to 18 days was not dangerous.
Haldane has reported that 0.05 per cent. of nitrous fumes inhaled for half an hour kills mice at the end of 24 hours. This strength has been confirmed by other experts.

From the clinical point of view, some fatal cases result from inhalation of fumes which do not seem very strong. In particular, old workmen have died after exposure to a toxic dose no stronger apparently than those to which they were habitually exposed.

Hudson claims there can be no question of varying degree of susceptibility to caustic vapours; he holds that apparent differences in susceptibility are due to the exposure-risk incorrectly assessed. Nitrous fumes are not of uniform composition. When they contain a high percentage of irritating products, the worker feels at once the effects and imagines he has absorbed large quantities of fumes. But, on the contrary, the most harmful products are not immediately irritating; they only make their presence felt after having penetrated the lungs and reacted with the tissues. It seems, however, that in the case of massive poisoning personal susceptibility can play a part. It is possible to become in some measure accustomed to inhaling nitrous fumes.

Workmen are very differently affected by the oxides of nitrogen. This has been particularly noticed by students during visits to works: some are extraordinarily sensitive, others much less so. Occasionally, especially among workpeople, persons are met with who have an amazing lack of susceptibility to nitrous fumes and boast about it.

Absorption takes place exclusively by inspired air, for oxides of nitrogen form gas, for on contact with water, or moist air, or the moisture of the mucous membranes or liquids of the body, it is converted into nitrous acid (NO$_2$H) and nitric acid (NO$_2$H$_3$). (Researches by Lehmann and Hasegawa, completing those of Lunge and Berl.) These are the acids which act. In the same way toxicological research upon nitrous fumes resolves itself into that of nitrates and nitrites.

Oxides of nitrogen have a local irritating and corrosive action upon the tissues and more especially on the respiratory and digestive mucous membranes. Any general narcotic effect is of quite secondary importance. It is particularly the action on the respiratory passages, extending even to the small bronchioles, which causes death, not directly, but indirectly, due to local phenomena with pulmonary oedema and cardiac weakness.

Most experts consider that the toxic action of nitrous fumes affects the respiratory passages, setting up laryngitis, bronchitis, and pulmonary oedema, rather than the blood, as is supposed by some other experts. The latter maintain that the nitrous vapours pass rapidly into the circulation, and that changes in the blood elements lead to death.

Nitrous fumes have, in addition, an action on the vaso-motor system, analogous to that of nitrates, acting by vaso-dilatation on the blood, making the red blood cells with transformation of oxyhaemoglobin into methaemoglobin, followed by lesions of spleen, kidneys and liver. Finally, in certain cases, as a result of extra- or post-vital reduction processes, nitrated haemoglobin is found in the blood of the victims, the reactions of which might lead to confusion with the haemoglobin in combination with oxygen and carbon (Heubner and Meier).

The practice of industry, however, creates such unique conditions as regards poisoning by nitrous fumes and oxides of nitrogen that it is quite difficult for the medical man who is not up in the subject to guard against
them. Thus, for example, oxides of nitrogen, like a large number of process by-products, are almost always at the commencement of feeble concentration and are hardly irritating. As a rule, in certain industries nitrous fumes are found mixed with air. A slow increase in the concentration of the fumes is scarcely felt, for persons become inured in a remarkable way to this gas, just as to the irritating action of sulphur-rettéd hydrogen. It is this tolerance, assisted by an anaesthetic and narcotic action, however slight, of nitrous fumes, which often very quickly mitigates the cough, but, by so doing, suppresses a symptom of great importance to an early diagnosis of poisoning.

Another difficulty, perhaps the greatest, depends upon the fact that this gas, although producing local irritation, does not always cause severe pains or a sensation of malaise, or any difficulty in respiration, as do most of the known gases, such, for example, as chlorine, fumes of bromine and hydrochloric acid. The local symptoms only become painful and threaten life several hours after exposure, often 10-12 hours and up to 24 hours; but these poisonings by nitrous fumes are all the more dangerous because their first effects often pass unnoticed, a very limited number of workmen, often only one, being exposed to the action of this gas and a long space of time lapsing between the absorption of the poison and the appearance of the first serious symptoms. This latency in poisoning has only been definitely studied in a series of war gases which cause symptoms of serious secondary poisoning after a similar latent period. This period is considerable with phosgene, shorter with diphosgene, and longer with chloropicrine. It is also seen after absorption of ammonia, chlorine and bromine, but does not exist with dichloroethlysulphate.

STATISTICS

The literature relating to nitrous fumes is almost inexhaustible.

The first record of pulmonary oedema caused by nitrous vapours seems to have been made in 1844 by Potl, who described two fatal cases in the burning of a factory where artificial leather was made by the action of nitrate of soda.

Thirty years ago, Duisberg had already drawn special attention to the danger generally presented by nitrous fumes. Since then numerous cases of acute and chronic poisonings by nitrous fumes have been reported, which are almost all classed under the heading "Acute and Chronic Poisonings".

Leymann (Concordia, 1906) pointed out that respiratory diseases, due partly to the action of nitrous fumes, are high in the nitric acid industry (11.8 per cent against 8.8 per cent, among ordinary workers).

In Germany the cases reported by factory inspectors are as follows: from 1914 to 1918, 13 cases of which 11 were fatal; in 1920, 4 cases of which 3 were fatal; in 1921, several cases of which 2 were fatal. Further, in the reports of factory inspectors, numerous cases have been reported, in Prussia particularly, but no figures are given.

On the other hand, a section of the Trade Association of the Chemical Industry in Germany, including the Free State of Baden, Wurttemberg and the Rhinish Palatinate, with an average of 300,000 active members, gives the following figures for cases of industrial poisoning by nitrous fumes:

Death from nitrous fumes occurs for the most part two days after the poisoning. In one case death only occurred at the end of the eighth day.

In Austria, from 1914 to 1918, 11 cases were reported of which 4 were fatal.

In France, Courtois-Suffit abstracted 9 cases in 1913, of which 6 were fatal, from medical literature from 1822 to 1906; 2 fatal cases occurred in a gunpowder factory in 1907. Slight affections are less rare.

On the other hand it has been observed that workmen, considering alcohol as an antidote, take an excessive quantity of it; from whence arises a frequency of tuberculosis. Statistics published from 1899 to 1904 show a mortality from tuberculosis twice as great in workshops where nitrous fumes were set free. Sanitary conditions have advanced since 1907, workshops having been improved and better ventilated. In one gunpowder factory in 27 years only 2 cases were reported of pulmonary congestion and some cases of bronchitis of very short duration and not serious.

In Great Britain the reported cases of poisoning by nitrous fumes are as follows:
Most of the cases were reported from nitric acid works or from nitration processes of chemical products or explosives.

In the Netherlands one fatal case was reported in 1917 and another in 1919.

In Switzerland the reported cases are analysed as follows:

In the United States, in her study on industrial poisonings in the explosives industry, Hamilton reported 1,389 cases of poisoning by nitrous fumes, of which 28 were fatal. The workers affected were employed in the following operations: the manufacture of gun-cotton, picric acid, nitrotoluene, nitrobenzene, nitronaphthalene, nitroglycerine, and in the handling of nitric acid required for these processes.

The nitration of cotton to make nitrocellulose and of phenol to make picric acid present the greatest dangers of poisoning by nitrous fumes; the nitration of glycerine the smallest danger. Between these two extremes are placed the making of nitric acid and the nitration of toluene, benzene, naphthalene, aniline, chlorobenzene and dimethylamine.

According to Hamilton, high industrial mortality caused by nitrous fumes set free in the making of nitrocellulose and picric acid is due to faults in technique.

Slight cases are very frequent at a warm temperature in a heavy atmosphere and do not attract attention. According to Hamilton, in one gun-cotton factory in 1916, during a very warm summer, out of 300 workmen employed, there were each day 20 slightly poisoned, but able to return to work the same day, or even the same night. In another factory with an effective list of 600 men, there were each month, from June to September, an average of 57 cases of poisoning by nitrous fumes.

In the summer of 1916, Irving reported some cases of poisoning in mines, and Czaplewski a considerable number of cases on board warships, when smokeless powder was fired in confined and insufficiently ventilated places.

**Symptoms**

Illness produced by the inhalation of nitrous fumes is always an acute happening. Although this gas may be disagreeable to breathe even in the smallest quantities, it is nevertheless respirable and more especially so when it is strongly concentrated (Curschmann).

If should however be stated that there is no connection between the quantity of nitrous fumes breathed and the seriousness of the affection.

On first inhalation there is a feeling of oppression more or less painful, rarely with thoracic pains, violent spasmodic cough in asphyxiating paroxysms, with a feeling of suffocation in serious cases, which resembles an attack of bronchial asthma.

Inflammation of the larynx has caused such serious symptoms that tracheotomy has been necessary in two cases out of seven.

Removal of the affected person to the open air, and administration of some

![Fig. 44. — Action of nitrous fumes on teeth.](image-url)
NITROUS FUMES

drops of chloroform in warm water, may ease or cure the spasm; and the individual, restored to health, is able to return to work at the end of a day or two if no bronchial or pulmonary lesion arise.

There is a less common form of poisoning which is so rapidly fatal that it does not cause any anatomical changes. In these cases (of Apfelbach and Hamilton, etc.) the poison acts directly and especially on the respiratory centre.

In serious cases the onset is identical; then the respiration becomes normal and all danger of poisoning seems to have disappeared. This apparent state of good health, which is quite pathognomonic, owing to pulmonary changes, and partly toxic, owing to the nervous system being affected; orthopnoea develops with a state of anxiety, and a spasmodic and fatiguing cough. Congestion of all branches of the respiratory tree rapidly sets in with pulmonary oedema accompanied by very abundant expectoration of liquid mucus of a yellow or yellowish-red colour. The pulse is increased, rapid and fleeting; blood tension is low, sometimes even to a dangerous degree, following on vaso-motor paralysis caused by dioxide of nitrogen.

The loss of water, which is serious, causes an increase in the viscosity of the blood; and this with other factors, such as cardiac weakness and pulmonary oedema, establishes in the days which follow a condition which leads to death.

Digestive troubles are also observed: keel is thirst, nausea, very violent colic accomplished by diarrhoea and vomiting.

The temperature is sometimes raised. The blood is brownish-black of a chocolate colour, and will not allow the serum to separate. The presence of methaemoglobin can be detected by the spectroscope. The urine contains albumen and serumglobulin.

The aspect of the sick person is characteristic in serious cases: anxious expression, pallor, bloodshot eyes, cyanosis of the lips, which rapidly develops, and cold extremities.

From the clinical point of view, certain symptoms may predominate and give to the disease a special aspect: thus a digestive, a nervous, and a pulmonary form may be described.

In serious, but not immediately fatal, cases, bronchitis or lobar pneumonia of a common type is often found, and may cause a fatal result at the end of five days and even of two weeks, especially when a latent pulmonary lesion previously existed.

Sometimes also relapses are seen occurring on the threshold of an apparent cure, in the first two or even three weeks after the attack. This development of a late pneumonia which may end fatally is very important from the medico-legal point of view.

Among the sequelae of poisoning by nitrous fumes chronic pulmonary lesions have been reported, also cardiac irregularity with sclerosis of the heart (Curschmann), an increase following a decrease of the heart's activity, an irregular pupil, paralysis of the eye muscles, nervous or trophic disturbances, secretory troubles, anaemia, and wasting.

Chronic poisoning caused by the absorption of small quantities of nitrous fumes is not common. According to Zangger, chronic poisoning by nitrous fumes can scarcely be distinguished from chronic catarrhal bronchitis and is classified under the head of bronchitis. Extensive statistical investigations have not yet been made at all establishments where nitrous fumes are used, but where they have been made the data risk loss of accuracy from the personal equation on the one hand, and rapid changes in personnel (labour turnover) on the other.

Workmen exposed to nitrous fumes suffer from a serious condition of the teeth (see articles "Nitric Acid", "Hair-Cutting Work"). When using copper as a mordant, for example, nitrous fumes cause among workmen a greenish coloration of the teeth with a metallic lustre (Teléky).

The mucous membrane does not escape the injurious effect of the fumes: inflammation and ulceration of the mucous membrane of the mouth, of the nostrils, and of the conjunctivae have been observed, even in workshops where only small quantities of the fumes are liberated.

According to certain experts, mild illnesses attributable to nitrous fumes are quite frequent, and a general weakening of the system attributable to pulmonary or blood changes ought even to be recognised.
Diagnosis

Diagnosis must depend largely on knowledge of the occupation of the sick person, previous history and the symptoms. The latent period is pathognomonic but this fact frequently also causes errors of diagnosis. A medical man cannot always know the relation of time existing between the work and the illness. Further, he forgets that this latent period, more or less long, is characteristic of poisoning among mankind, even though it would seem to be in opposition to experiments made upon animals.

Zangger has reported that in the small trades they always employ only one man on dangerous work and sometimes only for some hours a day, the worker in question being never either accustomed to or familiar with the danger. So we can understand that when these workmen fall ill it is only a question of a short time that the doctors do not ordinarily think of poisoning and see only a sick person who was taken ill at home, generally in the middle of the night; it happens in a number of cases that the man is living alone. Zangger relates this type of cases: "A workman does not answer when called in the morning. He breathes deeply and groans. He has coughed during the night and there is in the chamber vessel a certain quantity of a brownish-red liquid and froth." The doctor sent for later in the morning arrived when the workman was already dead. He diagnosed poisoning by carbon monoxide simply because the dead man was the day before a young man in perfect health. The police requested the opinion of a medico-legal expert, who made the following observations: absence of carbon monoxide in the blood; intense yellow coloration of the hands, the hairs of the nose, the nostrils and forehead (sign of handling nitric acid). The records and an enquiry into the conditions of work showed that this workman, who was employed in a small factory where incandescent mantles were made, had (on the previous day for the first time) the task of dipping all day large quantities of brass into nitric acid. He was not aware of the danger; the ventilation was very defective and at a certain stage in the operation such a large quantity of oxide of nitrogen was set free that the workman had to leave the place for a short time. The workman left the factory before the end of the day's work complaining of pains in the chest.

In other cases it is no use expecting to detect chemically the oxides of nitrogen. However, the liquid expectorated during the night gave with diphenylaminosulfonic acid a characteristic coloration of oxides of nitrogen. In other cases Zangger did not find this coloration. Very often this determination is of capital importance for the worker or the survivors. In fact, it is evidence of an outside influence independent of the will of the person and unavoidable, developed in an exceptional manner during work time. It is, as it is seen, the full explanation of the illness. But medical practitioners do not notify such cases on the ground that it concerns a poisoning.

What is at the root of such errors is the fact that individuals affected are generally still able to return to their homes and only fall sick during the night.

Another personal observation of Zangger, distinctly more complicated than the preceding, shows how oxides of nitrogen may be overlooked by various experts:

A doctor examines a workman who coughs and shivers a little. The patient looks ill and has pulmonary emphysema; the border of the lung is lower to the extent of the width of the hand than when the same doctor made a previous examination. The workman, who had returned home without feeling any particular trouble, said, however, that his illness was due "to ras" and, as he could only speak with difficulty, the doctor assumed it was a simple poisoning by illuminating gas, that is to say, by carbon monoxide.

The illness subsided, and on the fourth or fifth day he went to his parents' home, a railway journey of four to five hours. He had a note to the effect that he was "ill in consequence of the absorption of carbon monoxide during work." The doctor who visited him, trusting the opinion of the first, naturally accepted the diagnosis given in the note, when death occurred ten days after leaving work. The doctor who made the autopsy did not pay much attention to signs of bronchitis and to definite foci of slight broncho-pneumonia, while the chemist who examined the blood sent without other indications, and who did not know the date of this blood, claimed that he found carbon monoxide in one of the three tests made by means of a hand spectroscope.

In a general way no one would wish to undertake a revision of opinions given by five different experts, who all by means of perfectly independent methods had diagnosed carbon monoxide.

However, although carbon monoxide had been detected in one of the three tests, it was not proved that it came from the factory, since the patient had survived ten days. That rather showed a source of carbon monoxide existed near
the place where he had passed his last night, that is to say, at his parents' home.

These considerations led the medical expert to compare all the reports, and that enabled him to establish that at the onset the symptoms were not at all those of poisoning by carbon monoxide; that two absorption bands resistant to sulphuric acid in ammoniacal solution did not show carbon monoxide in the blood. A minute investigation showed that it was impossible that carbon monoxide had been absorbed during the last five days (this had also been noticed by the chemist). The worker in question worked in a large stereotype plate factory, where during the whole day he had to engrave by means of a mixture of nitric and sulphuric acids and of lampblack, without any arrangement for the removal of fumes. This working engraver was an old man; short-sighted and hunchbacked; he had then in doing his work breathed more fumes than a man holding himself straight and having good sight.

On the contrary, sometimes, but much more rarely, poisoning by nitrous fumes is diagnosed when it is not the case. That arises from nitrous fumes being much less known in their properties, possibilities and action, than the only, or nearly the only, poisonous gas which is discussed in clinics, viz. carbon monoxide.

Differential diagnosis is concerned with such as products which, although different from the chemical point of view, have a similar symptomatology, e.g. phosgene, carbon monoxide, ammonia, compounds of cyanogen, dimethylsulphide, the halogenes, acrolein, and with organic products containing nitro groups, as for example, nitroglycerine, mono- and di-nitrobenzene, picric acid, and nitrobenzene.

Detection

In the Air

The characteristic behaviour and estimation of nitrous fumes depend, in the main, on the presence of peroxide of nitrogen and nitric acid. A method devised by Robertson and Napper which gives good results for the estimation of small quantities of peroxide of nitrogen (0.05 per cent.) in the air requires a precise spectrosopic apparatus of delicate adjustment; it is not applicable to the investigations of industrial hygiene.

The classical process of absorption by means of ferrous sulphate is only of practical use for gaseous mixtures containing relatively large amounts of nitrous fumes. It is better to propose to use indirect, but more simple, processes. Among the various methods planned to this end, it is better to choose the ultra-sensitive colorimetric, e.g. for nitric acid and the nitrates, the reactions of diphenylamine, of potassium iodide with starch, of amidobenzoic acid, of metaphenyldiamine, or the formation of a dinitric salt under the influence of a mixture of nitric and hydrochloric acid; for nitric acid and nitrates can be detected colorimetrically the decolorisation of indigo, of diphenylamine, of phenol and sulphuric acid.

A certain number of these methods are applicable to both nitrous and nitric acids, especially those which are very sensitive, e.g. the reaction of ferrous sulphate, and of sulphate of metaphenyldiamine, which detect a mixture of acid and nitrates.

Lehmann's process consists in collecting the nitrous fumes and oxidising them with a solution of 3 per cent. of oxygenated water. After twenty-four hours' rest, the nitric acid formed is titrated with soda. The air for analysis can also be made to pass through a solution of iodide of potassium, when the iodine set free is titrated with hyposulphite of soda. The results are expressed in nitric acid. A cubic centimetre of decinormal solution of iodine is equivalent to 0.2 grm. of nitric acid.

Hébert and Heim have stated that the processes based on the estimation of nitric acid are inapplicable and they have suggested a very sensitive method, of which the limit of absolute sensitiveness is about 0.003 mg. of peroxide of nitrogen (nitrous fumes) per litre of air. The method of working is as follows: a fixed volume of the air for examination (generally 1 litre) is made to pass by aspiration into an absorption tube containing 10 cc. of a 5 per cent. solution of potash. The tube is emptied and rinsed carefully at the laboratory; the fluid which is collected is increased to 500 cc. in a graduated vessel and in a test tube 1 cc. of this homogeneous solution is mixed with 5 cc. of the sulphate of diphenylamine reagent (0.2 grm. per litre of pure and concentrated sulphuric acid).

The coloration obtained is compared with a scale prepared in the same way with increasing and known quantities of a standard solution of nitrate of potash. Knowing that 1 grm. of nitrate corresponds to 0.455 grm. hyponitric acid in weight, or 220 cc. in volume, it is possible to work out the proportion of peroxide of nitrogen, i.e. of nitrous vapours, present in the sample of air.

The reaction which is given by all oxidising agents can only be used in the certain absence of other gases or fumes, such as chlorine, bromine, iodine, hydrobromic acid, hydric acid and organic substances.

In the System

It is sometimes necessary to search for nitrous fumes chemically in the blood or the viscera. This investigation belongs to the domain of toxicology; but, in the opinion of Zangger, in many cases it is impossible.
Sometimes it is because the oxides of nitrogen become oxidised, undergo a change, or enter into reactions in the body. At other times these substances are separated and expelled by mucus, mucous secretions and by coughing, so effectively that oxide of nitrogen, or its derivatives, can no longer be detected in the body when serious symptoms occur. The investigation is only possible when the conditions are entirely favourable. In conclusion, testing for, and separation of, the oxides of nitrogen and the products of decomposition have remained impossible up to the present.

**THERAPEUTICS**

The serious danger and consequences of poisoning by nitrous fumes make it essential to discuss certain points of important practical therapy.

First and foremost there does not exist an antidote acting as a neutraliser on these fumes once they have penetrated into the respiratory passages. There never will be any antidote, for very soon after these fumes have entered into contact with the respiratory mucous membrane and have been absorbed therein, the chemical effect makes itself felt and causes disturbances. Therefore, all treatment based on the chemical action of an antidote will be a mistake. The inhalation of oxygen as soon as the absorption of fumes occurs and without waiting for serious symptoms is intended to counteract the impoverishment of the blood in oxygen. If some of the pulmonary tissue remains unaffected, the person may still be saved provided that oxygen is administered until all symptoms of acute poisoning have disappeared.

The cough which fatigues and damages the heart must be eased. Inhalations of fine sprays of water, weak alkalis, etc., cannot be used as a rule, for the workmen do not report sick and appear to be in comparatively good health. The serious symptoms are for the practitioner to deal with. Narcotics must not be used to calm the patient. For some time in industry chloroform (5 to 10 drops in water) was given, and certain managers and experts are still in favour of this treatment, although it is difficult to understand in what way it acts. Some experts, especially Germans, are of opinion that the use of chloroform is not without danger.

Treatment ought to deal particularly with the first serious symptoms which threaten to be fatal. Pulmonary oedema is regarded as the most important. Without entering into details as to the best treatment to adopt, it should nevertheless be said that, while colloidal treatment is still in its infancy, and that depending on chloride of lime or thiosulphate has partisans and opponents, the dynamo-osmotic treatment by means of a solution of glucose seems to be the most rational. When the pulse is still comparatively good, an immediate bleeding is recommended before the injection of glucose. The treatment carried out at the right moment has astonishing and lasting results (Zangger). The withdrawal of blood relieves the heart, the glucose exercises a favourable action on the viscosity of the blood and especially on the activity of the heart.

**HYGIENE**

In industrial processes where the liberation of nitrous fumes is inevitable, it is necessary as far as possible to carry off the poisonous fumes, condense them, destroy them or recover them. In the processes in which the fumes can be eliminated, the risk must be reduced to a minimum.

It has also been suggested to neutralise the nitrous fumes by liberating in the workroom an alkaline gas, such as ammonia, or to vapourise a 10 per cent. ammoniacal solution.

The use of "silica gel" (colloidal silica) has also been suggested as an absorbent for nitrous fumes.

In certain processes the use of hermetically-closed apparatus with exhaust draught insures efficient protection of workers. In other cases the apparatus is such that it is often difficult to carry out the necessary modifications.

Close attention must be given to the airtight condition of the apparatus and of all piping, and to the proper working of ventilators which must of course be made of material resistant to acids.

Some measures are similar to those laid down for sulphuric or nitric acid (see those articles).

The exclusion is called for of persons who have suffered or are suffering from respiratory diseases, and of persons predisposed to diseases of the respiratory passages and the circulation.

The education of the workpeople on the dangers to which they are exposed should be carried out by leaflets or posters, or better still by the works doctor on the occasion of his periodical visits. Posters have been prepared by the Governments of Germany, England, Netherlands, etc.

We give here the English poster published in 1916 (No. 358), and the Dutch poster published in 1919.
ENGLISH POSTER RELATING TO NITROUS FUMES
(Published in 1916, No. 358)

(1) Workers are warned of the danger of breathing brown acid fumes.

(2) Before repairing leaks, or entering, or staying in any part of a workroom heavily charged with fumes, breathing apparatus must always be put on.

(3) When these fumes are inhaled they may cause difficulty of breathing some hours after and serious illnesses.

(4) If these symptoms occur at home, send immediately a doctor and in the meanwhile remain in the open air as much as possible.

(5) If these symptoms occur at work, send immediately for the doctor. Whilst awaiting his arrival the correct treatment is as follows:
   make the patient lie down;
   keep him warm; and
   see that he has fresh air.

   If the face has a dusky colour:
   give oxygen.

   If he is not sick, give him to drink 5 teaspoonfuls of salt in about half a pint of tepid water and repeat the dose until it causes vomiting.

(6) Keep the breathing apparatus close at hand and in working order, for one never knows when it may be required.

DUTCH POSTER OF 1919

(To be posted in the workroom in accordance with section 69, subsection 2, of Labour Act, 1919.)

Advice to Workers who use nitric acid and the nitrates among other mordants for acting upon and cleaning metals:

NITRIC ACID IS A POISON!
BEWARE OF RED FUMES!
YOUR LUNGS ARE IN DANGER!

Red fumes are due to the action of nitric acid on metals and such substances as cotton, oil, petrol, wood, paper, ashes and earth. These brown fumes are extremely dangerous to certain persons. Inhalation even in small quantity may sometimes have an immediate effect; generally they cause serious affections of the lungs.

Danger of poisoning: Everywhere where nitric acid is exposed and in contact with no matter what material.

Symptoms of poisoning: Restlessness, nausea, pains in the throat and chest, gasping, cough, blue coloration of the face. If the nitric acid is breathed for a long time, there is expectoration of blood and yellow coloration of the face.

Prevention: You must avoid inhaling the red fumes. If nitric acid is upset, clear it away with plenty of water; avoid the use of sawdust or any other similar material. If the worker feels any discomfort after having inhaled these fumes, he must cease work as quickly as possible and go speedily to the doctor.

LEGISLATION

As regards the employment of women and children, see article "Gases and Fumes".

Special legislation has been laid down in Germany (Prussia) by the Ministerial Circular of 8 January 1900 concerning nitrous fumes and the measures of prevention for the use of nitric acid, and by the Industrial Association of the Chemical Industry, the rules of which on the prevention against injuries caused by gases and poisonous fumes have been in force since 1 January 1912 (see Part II, § 13, referring to the liberation of nitrous fumes). The Circular of 8 February 1911 of the Prussian Ministry of Commerce and Industry on the construction and management of workrooms for cleaning metals provides measures against the danger of nitrous fumes.

In France the Decree of 13 October 1913 on hair-cutting works (see that article); in Great Britain, in the United States, etc., the rules concerning hygiene and safety in the chemical industry, explosives, etc., wherever there is liberation of gas and poisonous fumes.

Notification of cases of poisoning by nitrous vapours is enforced in Western Australia, Bavaria, France, Missouri (toxic gases), the Netherlands and Poland; compensation is granted in Western Australia, Finland, Great Britain, the States of Minnesota and New York, Queensland, Switzerland and Venezuela.

BIBLIOGRAPHY

Prof. Zangger (Zurich).
Noises

French: Bruits. — German: Lärm. —
Italian: Rumori. — Spanish: Ruidos.

The influence of noises on the health of workers is one of the most important problems of industrial pathology, for it concerns nearly every modern industry. As a matter of fact, there are few industries to which the introduction of machinery has not brought, in addition to radical changes in methods of work, more or less serious disadvantages from noise and vibration. The study of industrial noises is of comparatively recent date, and the increasing interest which it arouses is accounted for partly by the increase in industrial noises, and partly by a better realisation of their harmful effect, and of the waste of energy which they cause.

**Definition**

Noises consist of a more or less rapid succession of sounds, irregular in periodicity and in intensity. Sound properly so called is, on the contrary, uniform, steady, and without variations in its constituent parts. It is an accepted fact that all noises may be referred to pure musical sounds; for they are similarly constituted with regard to intensity, pitch and tone.

**The Character of Industrial Noises**

In industry there are met with:

1. Musical sounds properly so called, e.g. in industries where sonorous metals are beaten, as when copper boilers and other copper ware articles are wrought. However, more or less pure sounds rarely occur alone.

2. Noises properly so called.

3. Vibrations of varying intensity, affecting the ground and the bodies of workers, due to the vibration of machinery. Although these vibrations are sometimes accompanied by the production of fairly loud noises, these noises cannot as a rule be regarded as excessive. Besides, it is often hard to decide at what point noise ceases and vibration begins. The decisive factor is the number of sound waves per second, and it is difficult to decide if it is the ear by itself, or the whole body which detects the sound or vibration.

**Origin of Noises: The Noisy Trades**

Noise in industry is due to the running of machinery and to actions effected by machines; to vibration and din caused by parts of machines that are not well equilibrated; to transmission gear, such as defective driving belts or bad running; to such tools as hammers and saws; and to the manipulation and transport of material.

Peyser classifies the noisy trades as follows:

**Metallurgical trades.**—Smelting and casting, especially settling and removing sand by means of pneumatic hammers; mechanical stamping by steam hammers; rolling, beating and drawing metals; and forge work. But the noisiest work of all is riveting, either by hand or mechanically. In this latter case the hammer may be rigid or movable, and either held in the hand or fixed on a rest. Automatic riveting may be carried out by means of compressed air, steam, or electric power. A different technique, wherein hydraulic pressure takes the place of the blow, is noiseless. The unpleasant conditions that accompany riveting vary according to the method employed, depending on the workman's position, and on augmentation of noise by resonance; according as the work is carried on in the open air or not, in workshops or even inside boilers, reservoirs, and gasometers that are being riveted. The mechanical cleaning of boilers by means of pneumatic picks, delivering 6,000 blows a minute, is also very trying work. The cutting, milling, planing, boring, and drilling of metals, all of which make discordant sounds, must also be classed among noisy operations. The polishing of metals and soldering operations, especially with the electric arc, make a shrill whistling noise; the gas blow-pipe makes more rasping sounds.

These various operations belong to all metal-work industries, but more particularly to the following: copper works, sheet-iron mills, tin-plate works, nail factories, shoe factories, scythes, locks and manipulating old iron for breaking up machinery, boiler works, and ship-breaking yards.

The Bureau of Standards, Washington, in 1926 studied the transmission and absorption of sound by metals used in construction, using a sonorous source acting in frequencies allied to the four average frequencies, all varying: 250, corresponding to most male and female voices; 1,000, corresponding to the highest pitched soprano voice; 2,000 and 3,000 corresponding as near as possible to the top limit of musical sounds. The materials tested were panels of the dry wall treatment, with or without wooden frames, covered with a more or less smooth varnish.

According to the frequency of the sound, the amount of energy trans-
spinning. The noisiest operation is that lose their power of absorption in proportion as the frequency increases. The less absorbent substances, however, corresponds frequency 297.

of a sound incident at a frequency of 2,190, and 33 per cent, of a sound of 25 millimetres, absorbs 04 per cent. thus, for instance, felt, under a thickness
deal with the frequency of the sound; given out by the source, varying with so many ten-millionths of the energy 100,
same
mitted by the sound through the same panel may vary from 1 to 100, between so many thousandths and so many ten-millionths of the energy given out by the source, varying with the nature of the panel.

The absorption of sound in the case of the same substance varies a great deal with the frequency of the sound; thus, for instance, felt, under a thickness of 25 millimetres, absorbs 94 per cent. of a sound incident at a frequency of 2,190, and 33 per cent. of a sound of frequency 297. In the case of some substances the maximum absorption corresponds to average frequencies. The less absorbent substances, however, lose their power of absorption in proportion as the frequency increases.

Textile industries.— Weaving and spinning. The noisiest operation is that carried on by the "beetlers" — workmen who, in the weaving shops and the shops where the preparation and stamping of patterns on the fabric takes place, keep beating the rolls of material with heavy mallets of metal or wood.

In flax spinning the noisiest operations are those of preparation and spinning; mechanical combing and carding are less noisy; bleaching of cotton is also very noisy. In the garment-making industries the sewing machine is an extremely noisy factor.

Felt industry.— The mechanical processes of pulling out and scraping the hair, and also hair clipping, are noisy.

Transport industries. — Especially railways: workers in the workshops, mechanics, stokers, and engine-drivers are all exposed to the din and whistling of the trains, and also to noises from oil engines (Mazout), from which the hum of the combustion is far louder than from coal-driven engines.

Building trade.— Noisy operations are stone-breaking, construction of tunnels, breaking down walls and foundations by use of pneumatic picks, and work on building stone with stone saws.

Other noisy industries are: the manufacture of cement, of earthenware, of refractory goods, of porcelain, and of emery wheels; the wood industry, including sawing, smoothing and planing; flour mills, chemical industries: extraction of oil by pressure; manufacture of India-rubber goods; multigraphing processes, especially those connected with rapid printing presses; telephone work, from the cracking noises in the instrument; telegraphy, from the noise caused by the apparatus and the operators; gunpowder and armament industry: while testing firearms, manufacturing rifles, and testing shooting ranges, without including lesions which occur in the army and navy to officers, non-commissioned officers and men.

Apart from these various sources of noise must be noted, in all industries and in every place, dull noise and vibration of the ground and walls, due to machinery in rapid motion, such as dynamos, motors, and driving belts; and, above all, worn cog wheels. Increase in these noises is due partly to the development of machinery, and also to the fact that modern concrete buildings are first-rate conductors of sound.

Danger of ear trouble is by no means the same for all these occupations, and differences may exist in the same groups. Coppersmiths do not develop deafness to the same extent as boiler makers (Villaret). A case is quoted of a boiler maker's hearing improving when he left his old trade and became a blacksmith (Peyser).

It must also be recalled that there are, too often, inaccuracies and mistakes when designating the occupation pursued. All the workmen employed, say, in copper works, iron works, or a big ship-building yard are not exposed to an equal degree to the noises peculiar to the industry. The differences may amount to a slight effect, or to double, ten-fold, or a hundred-fold effect, and this may go on for years. Besides, in some workshops the noise may be deafening in some places, but quite bearable elsewhere, e.g. in stamping out metal and in factories for stamped metal boxes. The degree of noise so varies according to the machinery that in workshops which are essentially vibrating and noisy, there may be a matter of fact, corners which are tolerably quiet. In boiler making, for instance, those who are most exposed to noise are the young apprentices who help the riveters by holding up rivets from inside the boilers, whilst they are being hammered home. The same applies to the young boys, boiler-scrapers, who go inside boilers in works and on ships to remove the scale.

It is also necessary to mention shops and modern offices; the latter are specially noisy; this is due to several causes; the cost of modern buildings, which makes it necessary to economise as far as possible in space; and new methods of organisation which tend to create a modern central office instead of an office for each department. The number of office machines goes on increasing; there are machines for
typing, calculating, binding, classifying, multiplying copies, and addressing. As in the case of factories, modern buildings are hard and fireproof, and are constructed of concrete in such a way that they do not absorb sounds, which is accentuated by the fact that there are rarely any curtains, hangings, or carpets to deaden the sound. Then again offices may be situated in noisy streets, quiet one day and busy the next. In summer there is the additional complication offered by open windows.

THE EFFECT OF NOISES

The mechanism by which noises are appreciated is still a matter of discussion. According to Helmholz's theory, the organ of Corti vibrates in unison like a resonator; the elements of the inner ear are attuned to various pitches, the low sounds being perceived by the parts of the cochlea that are further from the base than the high sounds by the parts that are nearest to the base. According to Ewald's theory, which is called the telephone theory, the basilar membrane of the inner ear vibrates throughout its structure at every sound. According to Bonnier's hydro-dynamic theory, the whole of the fluid of the cochlea is set in motion and comes into contact with the sensorial epithelium. The baresthetic theory of Marage attributes the perception of sound to variations of pressure in the endolymph.

Noises act by intensity, pitch, and tone. The most intense are the most injurious. The expressions often used are: "dull noise", "slight noise", "great noise" only give a vague description; but it is comparatively easy to determine experimentally the relative intensity of industrial noises which are regular and more or less continuous by comparing them with other noises of constant intensity. It is known that the sensitivity of the ear varies with the pitch of the sound (Helmholz, Zwaardemaker, Eschat, Vaquier). The normal sensitivity reaches from 256 double vibration (60') to 6,144 d. v. (60'). At higher and lower limits the sensitivity rapidly diminishes. Some experts consider the pitch to be the important element. At all events it is a fact that sounds of high pitch, shrill and very shrill, but not necessarily very loud, produce more lesions than the low deep or the high din in boiler-making works is more injurious than the roaring in cotton spinning mills; the reports of small calibre artillery and machine guns is more injurious than the booms of big guns (Cheatle). The pitch is more difficult to estimate than the intensity; but it may be estimated by comparison with sounds of a known pitch.

Tone in combination with pitch gives to certain noises the particularly disagreeable character which distinguishes them, such as the rasping and rattling sound of flints or the grating of saws or files. When the tone is one of such a painful nature it is very important, owing to the injurious influence it exerts on people of nervous temperament. Tone may easily be distinguished with considerable accuracy. It is tone which makes it possible to pick out different machines in motion without seeing them.

To these fundamental characteristics of noises must be added other harmful factors. First there is the time that the sounds last — the exposure to noises; the noises that last the longest are the most harmful, and in the noisy trades the workmen who suffer most are those who have been exposed to the noise for the longest time.

Rhythm is also an important factor in the harmful nature of an industrial noise. Noises that vary in intensity and are uncertain and irregular as to the moment of their occurrence are more harmful than constant, humming sounds to which one may learn to get accustomed. The suddenness with which some short loud noises burst out at longish intervals has a very disagreeable effect on the nervous system. Sounds, otherwise of the same variety, are much more important to the ear when they are sudden, intermittent, periodical, or more or less irregular.

Account must also be taken of resonance and the reflection of noise. Resonance may vary according to the position of the workmen in relation to the noise. Work within closed walls is more injurious than work in the open air. Thus hammering inside a boiler, the resonance of enclosed workshops where engines are built, or firing from warships or in enclosed rifle ranges are all very dangerous.

Apart from the resonance, it is necessary to ascertain whether vibrations are mingled with the actual noise. As a matter of fact, many factors contribute to the injuries caused by noises and vibration, and, what is more, they often act concurrently. All the trades in which workers are most exposed to lesions of the middle ear or of the nasopharynx, and constitute in themselves a risk to the integrity of the hearing, are more harmful if the noises are on an equality. Some experts, however, consider that such lesions of the middle
ear as suppurations and sclerosis, by preventing the passage of the deep-toned waves to the internal ear, act as a protection; thus Rodger and Got who, in speaking of the deafness that attacks artillermen, consider that those who have healthy ears suffer the most. Among other personal factors must be noted the part played by fatigue. Whereas noise may be tolerated, or even completely ignored, by those in good health, lowered physical or nervous health makes it impossible to bear up against the irritation and resulting fatigue caused by continuous loud noises. The age of the sufferer must be taken into consideration with the increase of lesions from arteriosclerosis. And this is said to occur chiefly in occupations which involve laborious physical work, such as men who carry heavy loads, blacksmiths, and stokers. The part played by intercurrent diseases, especially by syphilis, which intensify the sensibility of the central and auditory neurones, is important.

Among predisposing factors the effect of dust must also be mentioned; opening and carding rooms in flax spinning; locomotive mechanics; the effect of such poisonous substances as mercury carbon bisulphide, and especially lead; irritant poisonous substances as mercury carbon acid vapours, smoke, poisonous gases which show a predilection for the bony framework from which they are subjected being considered as excessive.

Obviously, in comparison to the effect of tremors when noise predominates, transmission through the frame assumes still greater importance when the vibrations and tremors constitute the chief factor. The hearing is then rapidly and seriously affected; the weighty body of the workman in contact with the vibrating ground, and particularly the bony framework from the feet to the head, constitute favourable conductors for the transmission of tremors (Peyser).

It is probable that in practice the two kinds of transmission play parts varying in importance with each particular case.

**PATHOLOGY**

Injuries due to noises and vibrations are of two kinds: (i) the effect on the ear, and (ii) the effect on the nervous system.

The symptomatology of auditory affections is considered elsewhere (see article "Occupational Diseases: Ear, Nose and Throat"). It is sufficient to say that they are due to a chronic degenerative neuritis of the cochlea (Peyser) and that they are serious in proportion to the length of time a workman has worked at a noisy occupation (Layet).

Nervous affections, the symptoms of which are also dealt with elsewhere (see article "Occupational Diseases: Nervous System"), are due essentially to functional disorders of the central nervous system, caused by mechanical lesions from noises and vibrations. Some sounds are fundamentally disagreeable and fatiguing; others, occurring frequently at irregular intervals,
with an unpleasant intensity, pitch and tone, require constant adjustment of the nervous system of the worker; this is wearing and leads to a waste of energy. The attention is distracted; hence arises necessity for concentration.

The effect of noises is not as well known as that of light, heat, or ventilation; all the more so as very few accurate facts are available on amelioration brought about by "anti-noise" apparatus, and that it is sometimes difficult to determine if it is the ear alone or the whole body which vibrates. It follows that the ill-effects caused by sound are not easily distinguished from nervous exhaustion resulting from direct vibration.

It is of value to bear in mind that, from the economical point of view, noise, even though of slight intensity, causes a marked diminution in capacity for work, and a diminution of output which may fall as low as to 40 per cent. of the normal, and an increase in labour turnover; whence follows a diminution of production.

**Propylaxis**

Propylactic measures would be greatly facilitated if the mechanism of hearing and the theory which corresponds most nearly to reality were exactly understood. However that may be, the measures that may be taken may be divided into two categories, measures applicable to the workman and measures applicable to work.

**Measures Applicable to the Workman**

First and foremost, proper means must be taken to protect the hearing. The best is still the ear tampon of compressed wool moistened or steeped in some greasy substance, such as vaseline, glycerine, or plasticine. It is necessary to remove such tampons from time to time to allow of ventilation and to let out the warm air from the ear. Numerous ear protectors (obturators plugs) have been made, but the metal kinds, which may break and allow fragments to penetrate into the interior of the ear, should be avoided. Protective helmets are only a last resource, for use in special circumstances where it is not possible to do without them. Men dislike wearing them, for they interfere with the usual methods of work or are uncomfortable on account of their weight or pressure; they prevent the clear reception of orders, and, by diminishing the perception of unusual noises or the warning shouts of comrades, constitute an extra cause of danger.

Another recommendation given to workmen is to open the mouth or to hold a cork (sic) between the teeth.

The protection of workmen is further assured by the use of substances which isolate the vibrations, by wearing boots with soft soles, and by using straw mats, felt braid, and special chairs with springs, like the one recommended by Gilbreth. But all these methods for eliminating vibrations vary according to particular cases. Thus, in hammering operations the use of benches with springs, for supporting the material which is being hammered, does much to reduce the vibrations experienced by the workman at each blow.

These prophylactic means must however be completed by the following measures:

(a) Medical examination on engagement, which enables a selection to be made and the elimination of workmen affected by diseases of the auditory apparatus, such as otosclerosis, lesions of the middle and internal ear, and insufficient patency of the tubes; or predisposed to these diseases by such lesions of adjoining parts as respiratory affections; or afflicted constitutionally with anaemia or neurasthenia; or of the adenoid type. In this way those particularly predisposed can be excluded from the most harmful workshops.

(b) Periodical medical inspection of workmen in noisy occupations. It might even be required to make this compulsory and give more particular attention to the detection of troubles at their beginning. Hence, the employment of workmen not used to noisy work; change of occupations; withdrawal from noisy occupations and the prohibition of the employment of workmen not used to noisy work. A useful measure consists in regulations for rest pauses. In some very noisy work it is recommended that the work be interrupted every fifteen to thirty minutes by a short interval.

(c) Medical treatment, making it possible to deal with affections at their very beginning.

(d) Measures relating to scientific organisation of work: changes of shifts in noisy work; change of occupations which is sometimes difficult to realise, or simply change of process in the same occupation; the prohibition of the employment of workmen not used to noisy work. A useful measure consists in regulations for rest pauses. In some very noisy work it is recommended that the work be interrupted every fifteen to thirty minutes by a short interval.
enable an effective fight to be put up against the aggravation of incurable deafness. The performance of some kinds of work in the open air is also a very important measure.

**Measures Applicable to Work**

These are the only rational efforts, for whereas the preceding ones aim at diminishing the harmful effect of noises, these aim at the suppression or diminution of noises and vibrations. They can only be arranged after careful examination of the surrounding conditions, and aim at protection against noises by isolating or deadening them. First of all, it is advisable only to allow noisy works to be set up in neighbourhoods where they will not be a nuisance, so that work can be carried on in the open air or with open windows. The same considerations should lead to the choice, for the situation of offices, of quiet streets or at the top of high buildings. Again, it would be advisable to prohibit noisy work in buildings of several floors.

Walls, ceilings and especially floors can be covered with anti-noise materials which diminish the production of vibrations from the ground. With this object, there may be used felts made of leather, hair, asbestos, or wood pulp, which can be made fireproof in some cases by silicate of soda or india-rubber, while, for the floors particularly, linoleum, or numerous special compounds now on the market, as "Acoustic", "Cellothex", or "Akoustolith" and special plasters are used.

Vibrations from machines may be deadened by arranging them on bases of special materials or on special foundations, independent of the floor used by the personnel, or enclosing them in special rooms closed by stout iron doors. The same considerations in offices and business premises lead to placing typists and other machine operators in separate rooms.

Careful control of businesses should permit: diminution in the number of noisy machines in each room, but chiefly elimination of noise and vibration, and of the causes which increase them, such as wear and tear of machines, lack of care and of repairs, clogging, improper use of unsuitable partitions, insufficiency of natural ventilation; in offices, the elimination of doors which grate or slam; the selection of machines and tools which are silent or provided with arrangements for reducing noises, such as silencers for internal-combustion engines; the substitution of pressure for impact, whenever that is possible; the elimination, properly so called, of harmful noises. It is necessary in this case to determine the origin of the noise, its intensity, its pitch and rhythm, and the local circumstances which increase the vibrations by which it is accompanied. The analysis of industrial noises can be carried out in various ways. Gradensigo in his well-known investigations used the following: tuning fork, Marbe's rings of lamp black, the phonograph, Edison's dictaphone, and the electric oscillograph. This last method, which is the most delicate and most complex, proved to him clearly that noises are made up of vibrations belonging to two and three and more groups, composed of numerous kinds irregular in periodicity and intensity.

It should be noted that noise is sometimes the best antidote to noise; that it is sometimes a good thing to place near machines making a moderate continuous noise, engines which periodically make a loud bang ing noise, as this breaks the monotony. In order to protect those in offices against neighbouring vibrations which are troublesome because it is impossible not to hear them, a recommendation has been made to adopt the plan of making an electric motor revolve fairly rapidly on a box of varying resonance, which reproduces variations agreeable to the ear, and interferes with the injurious vibrations, annulling their effects on the auditory centres.

The prevention of noises would be greatly helped if permissible noises could be standardised and if apparatus were used which enabled anyone to determine at once the strength of the noises observed. Some have been constructed, e.g. Low's audiometer which enables the noises to be measured.

Prophylactic measures should be further completed by propaganda and instruction of workmen on the dangers from noises.

In November 1927 a Commission was appointed in Germany to study, and conduct a campaign against, deafness due to noises in industry. A propaganda leaflet was also published by the Ministry of Labour in conjunction with the German Industrial Hygiene Society.

**Legislation**

Legislation can bring efficient help in the fight against noises, first of all by recognising officially noisy industries as dangerous trades, and then extending the benefits of compensation to industrial diseases caused by the noises. At the
present time Russia alone compensates deafness of industrial origin.

According to Peyser, the metal and textile industries, railways, and telephone services should be regarded as noisy trades.

The elimination of noises cannot but be profitable to all concerned: to the workers, because it improves their health and their enthusiasm, diminishes absences and lessens friction between employers and employed; and to the employers because it increases output and diminishes the cost of production.

Occupational Diseases

Historical Review

French: Maladies professionnelles: Histo-
tique. — German: Gewerbeerkrankheiten: Geschichtse. — Italian: Malattie profes-
sionali (Storia delle). — Spanish: Enfer-
medades profesionales (Historia de las).

A brief summary of some few pages devoted to a historical review of occupa-
tional diseases in the civilised countries is not without interest. From the earliest
times it has been recognised that certain occupations constituted a more or less
serious risk for those engaged in them. Yet it has required the lapse of many years
— of centuries even — before the data assembled in regard thereto could be
systematically classified and studied by competent experts on the subject.

EGYPTIAN PERIOD

Very few details are known relative to the tragic conditions of workers in
ancient Egypt. The peasants — from whom taxes in kind and work could be
exact to the uttermost — were bound to the soil, which belonged to the Pha-
rahs. Their lot was so hard that when a famine occurred to aggravate
conditions the peasants revolted (2360 B.C.). Yet though thereafter the
peasants possessed the right to become hereditary tenants of the soil and
were free to cultivate it as they pleased, their conditions cannot have been
very happy if the evidence of the scribe who, in a long and well-known
address, warns young men against entering the occupation of agriculture
is to be believed (Papyrus Anastasi V).

The lot of the city workers has been thus crudely described as opposed to
that of the peasants:
I have never seen a blacksmith acting
as ambassador or a foundry worker sent
on a mission, but what I have seen is the
metal worker at his work: he is grilled
at the mouth of the furnace. The mason,
exposed to all weathers and all risks,
builds without clothing. His arms are
worn out with work, his food is mixed
up with dirt and rubbish; he bites his
nails, for he has no other food. The
barber breaks his arms to fill his stomach.
The weaver engaged in domestic work is
worse off in the house than the women:
doubled up with his knees drawn up to
his stomach, he cannot breathe. The laun-
dryman on the quays is the neighbour of
crocodiles. The dyeworker stinks of fish
spawn; his eyes are tired, his hand works
unceasingly and as he spends his time in
cutting up rags he has a horror of clothing.
(Papyrus Selier II.)

Stone and metal engravings, wall
paintings, all bear witness to the gangs
of forced labour dragging colossal
statues of kings and overlords. The
execution, moreover, of those gigantic
masterpieces of architecture which are
to-day the admiration of the world
gives some idea of the cruel sacrifices
demanded of the free citizens of the
Egyptian Empire.

When it is considered that the
temples and obelisks which defy the
passage of centuries were constructed
in a few months, that the blocks of
granite extracted from distant quarries
had to be dragged to the Nile moored
to immense rafts, that these obelisks
over 50 metres high and weighing
about 2,000 tons were sometimes
seven months only after extraction
(the time necessary for detach ing the
block from the quarry has been
estimated at two months, construction
of scaffolding one month, planing,
polishing and engraving the stone four
months), one may admire such "scientific management", but one can but
pity the countless slaves, criminals,
debtors, prisoners of war, workers
and peasants compelled to provide the
forced labour to which they were
subjected by brutal force in order to
complete these titanic constructions.

GREEK AND ROMAN PERIOD

Aristotle speaks of the diseases of
runners and prescribes a diet for
gladiators. Plato had already noted
that the artisan’s body is deformed by
the exercise of his profession. Pliny
refers to the dangers incurred in handling sulphur and zinc, and his *Natural History* speaks of masks made of transparent bladders used by the workers engaged in preparing vermillion in order to protect themselves against the metallic dust. Hippocrates (370 B.C.) was the first to recognise the toxic properties of lead, and reports a very serious attack of colic affecting a lead miner. He considered the most ordinary occupations as the true sources of disease. He was also the first to advise gymnastics, physical exercises, baths, massage and diet for the treatment of diseases and the maintenance of health.

Further allusions to occupational afflictions may be found in the writings of ancient authorities. Pliny, for instance, speaks of respiratory troubles, spitting of blood and hernia of runners. Martial refers to lesions of the eyes of sulphur workers, of callouses noticed as affecting horsemen. Juvenal reports eye lesions amongst forge workers and varicose veins amongst augurs which are ascribed to the standing position necessitated by the work of examining the entrails. Lucretius describes the tragic existence of the workers in mines and quarries: slaves worked in the Laurion mines (discovered in A.D. 483) for ten hours in galleries having a maximum height of 1 metre and a width of 60 to 90 cms., the air being stagnant and contaminated with smoke from the lamps; in the mines of Spain, Egypt 1 and of Syracuse

Pliny, Celsus and Galen refer to diseases peculiar to miners, tanners, fuller, bearers of burdens, chemists, etc. Galen has also described accurately the pathology of lead poisoning. Nicander (200 B.C.) established a connection between lead and pallor, stomach-ache and constipation noted amongst his patients. Avicenna mentions painter's colic, while Dioscorides and Aetius attribute this symptom to contact with litharge, and the latter also refers to wrestlers' diseases. Another doctor, Herodicus, held that workers should be advised to take sufficient nourishment.

1 It was in the valley of Ouady Maggharn about the year 5300 B.C. that the copper industry first arose, spreading later to the Sinai peninsula: women and children from the conquered countries and prisoners of war were the first — and during the whole duration of the Egyptian Empire the only — miners and workers engaged in them, being exposed to all imaginable suffering and goaded by the weapons of the soldiers.
(Lautumiae) they were exposed to the most serious diseases and the most atrociously trying work. He recalls the work of women and children at the entrance to the mines and outside the works. Lucien, in his Dream, also refers to deformities caused in men by trades and occupations. Ovid, Plutarch and others recall the sufferings of workers; but none proposed means of ameliorating them.

Much later (A.D. 643) an edict issued by Rotari made it compulsory for employers engaged in the construction or repairing of houses to compensate injuries to masons resulting from occupational accidents.

THE PREDECESSORS OF RAMAZZINI

In the Middle Ages there appeared already certain orders emitted by health officials in regard to certain industries, but these were intended rather for the protection of the inhabitants than for the workmen involved. In the fifteenth century a certain amount of interest in occupational diseases commenced to make its appearance.

Certain works on the diseases of men of letters are known, but mention should here be made of the pamphlet written by Ulrich Ellembog in 1743, to which Koelsch has just recently drawn attention (1927). This pamphlet on toxic fumes and vapours, Von den giftigen Besen Tempfen und Reuchen, was written as a sort of warning by the author, who had had the opportunity of noticing a certain number of occupational injuries amongst goldsmiths, especially poisoning, and who therefore judged it advisable to draw up a note as to the best means of their prevention. He insists on the toxic action of carbon monoxide (coal smoke) of lead, mercury and other metals, especially of their fumes, of aqua forte (nitric acid), antimony, etc., and he proposes numerous recommendations as to hygienic preventive measures. This note, which was first circulated in manuscript form, was only printed for the first time in 1524 (Koelsch). It is a remarkable fact that the pamphlet in question was not mentioned by medical

![Fig. 46. — Theophrastus of Hohenheim, known as "Paracelsus". (From an edn. of his works published in 1553.)](image-url)
writers of the time interested in industrial hygiene, but the reason is probably to be found in the fact that the publication remained unknown outside the circle of persons for whom it was originally intended.

It was, however, not until the sixteenth century that research on the subject is seen to have its rise. Paracelsus (1493-1541), a Swiss doctor and chemist, was the first to treat the subject in his book De Morbis Metallicis, where he publishes the results of observations made among Tyrolean miners. He investigates therein diseases of smelters and smelter workers due to inhalation of fumes and exhalations from the metals. Agricola published in 1556 a richly illustrated book entitled De Re Metallica.

In the seventeenth century Martin Pansa, a physician of Annaberg in Saxony, wrote on disorders incidental to miners and smelters (1614). Mathesis, Libavius and Ursinus were other writers who dealt with the subject about 1600-1650. Yet no really clear explanation of the nature and origin of the poisoning in its general form existed. Many and varied forms of illness were described and imputed by these authors in turn to lead, quicksilver, arsenic, cobalt and cadmium. Citois wrote on an epidemic of painters' colic or "Poitou colic" in 1639.

In 1656 Samuel Stockhausen, for twelve years doctor at Goslar in Brunswick, and entrusted by the Duke of Brunswick with the medical supervision and treatment of the metal workers in the Brunswick Luneburg mines, published a work based on his practical experience there and giving a lucid account of the so far very indubitably and vaguely characterised causes of disease. This work is entitled Huttenkatze or "Disorders caused by Smelter Fumes", with an appendix relating to asthmatic affections of metal workers. The book is written in Latin, but the appendix—dedicated to those mining officials who could not read Latin—is in German, showing the author's desire to render his treatise of practical utility. He made a close study of symptoms, made lengthy observations on the fumes and emanations from the different metals, and even underwent personal experiment in his efforts to determine accurately the causes of the disorders produced and earned the designation of "the miners' and foundry workers' friend" bestowed on him by a contemporary.

Loehniss again refers to the respiratory diseases of miners in 1690. Diemerbroeck, after carrying out post-mortem examinations of miners, states that in making a section of the lungs he had the impression of cutting a sandy mass.

In England the first documents dealing with the nature and results of occupation in dangerous processes are to be found in the Transactions of the Royal Society of England. They are of a theoretic and reflective character and touch on manufacturing and mining in Europe (white lead, silvering of mirrors by mercury, lead and coal mining). They appeared from 1665 onwards.

B. RAMAZZINI (1633-1714)

The seventeenth century provides some works relating to the diseases of courtiers, magistrates, men of letters, soldiers and seamen. Occupational diseases properly so called occupy but a very restricted space in clinical descriptions. Certain authors, however, describe isolated cases of mercury or lead poisoning in various occupations, but despite the growing interest being shown in certain branches of the subject of occupational disease about this time, it was not until 1700 that a comprehensive volume covering the whole field and at the same time embodying all past knowledge and vastly extending and completing it was published. This volume was the work of Bernardino Ramazzini, the father of industrial medicine, whom a modern authority has aptly described as "the benevolent and learned Italian physician of the seventeenth century, in touch with every available source of information of his own and preceding ages."

His Life and Work

Ramazzini was born at Carpi near Modena on 4 October 1633. He studied philosophy and medicine at Parma University, where he qualified in medicine on 21 February 1659 "cum signo laudis". After further medical study at Rome, he engaged in general practice in the provinces of Bologne, Canino and Marta, near Viterbo, and thereafter returned to Carpi, where he pursued classical and medical studies and practised as a doctor. In 1671 he went to Modena, and on the restoration of the University there, he was appointed Professor of Medicine, and was invited to pronounce the opening oration. He held two medical chairs there until 1688, when at his request one was assigned to a colleague. He worked in Modena for thirty years, eighteen of which were spent at the University, and it was while there that he prepared the greater part of the work which has made him so famous.
His fame as a student, professor, and writer spread throughout Italy and Europe, and many eminent foreign and Italian scientists visited him at Modena, and he was in correspondence with all the great scientists of his day. He gained distinctions from numerous learned societies. The Venetian Senate called him to the Chair of Practical Medicine at Padua; he accepted the call in 1700 and delivered an inaugural address before the University staff and an international audience on the progress of medicine in the seventeenth century as compared with the sixteenth century.

He won distinction at Padua as at Modena, and in 1706 was made a member of the Berlin Academy of Science and of the Academy of Science at Rome. His health suffered from the change to Padua; he developed arteriosclerosis in 1703 and gradually lost his sight. In 1710 he wished to resign, but he says his resignation was not accepted, and he continued to teach despite his sufferings till 1714, when he died of apoplexy on the way to the University. He is buried in Padua, in the church of St. Mary of the Armenians (now Saint Francis of Sales). His tomb bore no inscription — "sine titulo" — so that his exact resting-place is unknown. It is probable that it was displaced when the church was restored. A statue was erected to his memory at Carpi.

Besides his masterpiece, Ramazzini wrote on varied scientific subjects, showing singular scientific ability, and writing almost always in Latin. He was a literary man, a physicist, geologist, as well as a doctor and above all a hygienist, "Longe praestansus est praeses quam curare" being a maxim cited in his medical works. He was convinced of the necessity for the hygienist to extend his studies from the human organism to that of animals, despite the criticisms of his contemporaries, who found it indecorous for a doctor to study the maladies of animals. He engaged in important epidemiological and epizootic studies, the results of which were published in 1714, and his epidemiological research excels all previous work of this kind, his study containing observations useful even at the present time. He also studied the subsoil of Modena, and carried out research for determining the temperature of the subsoil and devoted himself to the study of meteorological conditions.

In his investigations into health and hygiene he covered not only craftsmen and manual workers, but also wrote on the diseases of intellectual workers ("De Litteratorum Morbis") and the health of nuns ("De virginitum sacrarum valetudini tuenda") and of princes ("De principum valetudini tuenda"). The latter work containing reflexions of moral and educative value as well as hygienic precepts. His claims to fame rest, however, not on these works, despite their merit, but on the "De Morbis Artificum Distriba" — "Disserantiones on the Diseases of Craftsmen", the first edition of which was published in 1700 and contained forty chapters. A second edition followed in 1713, to which the author added twelve chapters. In his preface Ramazzini says with justification that he has broken ground so far untouched by his predecessors, and that he has realised to the full the ultimate importance which the subject he unfolds was to assume in future. To the famous question "What is your occupation?", he was the first to realise the importance of the causative connection between occupation and disease, stating that the medical man, even when aware of his patient's profession, seldom attributes sufficient importance to it. He considered it to be the duty of medical science to engage in a specialised study of industrial conditions, in order that the worker might be permitted to gain his living without receiving bodily injury. Several critics and practitioners, "constitute a source of evil for those who follow them, and the unhappy workers, meeting with the worst of diseases where they have obtained sustenance for themselves and their families, die cursing their thankless calling."

Such were the ideas that led Ramazzini to devote his attention to occupational disease, and, having set himself the task, he was untingr in his efforts to accumulate data by means of study and observation. He wrote to well-known experts in various countries for information based on their experience, and he studied conditions at first hand in the homes and workshops of the craftsmen, which he characterised as "the only schools where any satisfactory knowledge of these matters can be obtained". He was even ridiculed for exposing his life to danger in the course of his investigations. His book deals with practically all trades and professions known in his day — metalliferous workers, gilders, chemists, glass-workers, potters, painters, dyers, tanners, bakers, millers, stonemasons, lead and silk workers, barbers, surgeons, nurses, porters, exponents, workers in the tobacco and salt industries, rag merchants, razor and lancet sharpeners, sailors, scholars, watch and trinket makers, soap-makers, and so on.

Ramazzini speaks of the "dismal calamities" inflicted on goldsmiths engaged in gliding silver and brass work by corrosive metal with mercury afterwards driven off by heat. Ramazzini's description of the pottery processes does not differ greatly from the conditions obtaining at present in this industry. He tells how the potters used to brown the clay by beating it with a piece of wood hung from the ceiling, and how the potters used to brown the clay by beating it with a piece of wood hung from the ceiling, but also wrote on the diseases of intellectual workers ("De Litteratorum Morbis") and the health of nuns ("De virginitum sacrarum valetudini tuenda") and of princes ("De principum valetudini tuenda"). The latter work containing reflexions of moral and educative value as well as hygienic precepts. His claims to fame rest, however, not on these works, despite their merit, but on the "De Morbis Artificum Distriba" — "Disserantiones on the Diseases of Craftsmen", the first edition of which was published in 1700 and contained forty chapters. A second edition followed in 1713, to which the author added twelve chapters. In his preface Ramazzini says with justification that he has broken ground so far untouched by his predecessors, and that he has
He distinguishes clearly between the different trades of the pottery trade, and the evil effects peculiar to each process; likewise, when dealing with the painter's trade, he seeks to isolate thenoxious effects produced by the various mineral colours, and he ascribes the melancholia frequently recorded as characteristic of the trade, when dealing with the processes in the pottery trade, and the evil effects peculiar to each process; like-workers in the early processes of this industry, for instance, making of catgut — and in imputing fever and illness to linewashed walls, and would probably have been greatly astonished at the present legisla-tive requirements in this direction. He notes with justice that the hatcheling of flax appears to he more unhealthy than the hatcheling of hemp. He makes an interesting reference, which strikes quite a modern note, to the additional fatigue suffered by bakers owing to their being obliged to work at night. He gives an accurate description of the unpleasant nature of the dust inhaled by silk spin-ners in the early processes of this industry — chiefly combing out of silk cakes, which retain part of the bodies of the silk worms mixed with them, and which, being dried in the sun, are drawn out by the workers into threads with small combs. Respiratory troubles experienced by these workers he attributes to the particles of the dead silk worms mixed up in them, and which, after being retained part of the bodies of the silk worms, mixed with them, and which after being put in the mouth repeatedly, cause considerable respiratory troubles, which are made worse by the presence of water and acid in the mouth, and which, if not removed quickly, are apt to cause the development of chronic diseases.

Ramazzini recognised that the principal causes of the numerous ailments which affect workers are twofold — the first and most extensive cause being the injurious qualities of the products handled, and the second the violent movements and unnatural postures demanded. He thus at that early date distinguished the two principal factors of ill-health as they are known and recognised to-day, saving, perhaps, the addition in the second case of excess of work and bad objective conditions.

Many of his precepts are so remarkably modern that they might well come under the designation of welfare recommendations to-day. For example he underscores the need for ventilation and unsuitable temperatures, and urges that workers in dusty trades should, in default of any known exhaust system, work in spacious rooms with their backs to the draught, and should wash their faces and rinse their mouths frequently with water and acid and quit work in such trades immediately they become threatened with lung trouble. He counsels rest intervals in work of pro-longed duration, and dwells much on the need for exercise and change of posture, being thoroughly convinced of the importance of faulty posture in producing ill-health in many trades. He observes that the excellent provision of baths for the people in Roman times had fallen into disuse, urging strongly the need for cleanliness and the institution of baths, massage, and regular exercise as essential to the maintenance of health and fitness.

He fully realised the importance of post-mortem examination as an aid to determining the cause of disease, and complains that owing to the ignorant superstition of his time he was often denied permission to proceed to an autopsy. His chief abilities were an exactness and accuracy of observation which enabled him, in spite of the lack of knowledge of anatomy, physiology, chemistry and bacteriology of his time, to arrive at surprisingly accurate conclusions.

It was not his intention, he stated, to offer a complete treatise on occupational diseases, nor to provide a long series of remedies for these, but merely to bring to the notice of practising physicians certain facts serving to guide them to a more successful treatment of those who toll.

Yet despite this modest assertion, his work, far exceeding the fulfilment of the practical aim referred to, has become the basis of the extensive literature which now exists on the subject of industrial hygiene.

**The Eighteenth Century**

Unfortunately, Ramazzini's work remained without practical import during this period, the political and social state of the various European countries preventing him from profiting by his instructions. His name fell into obscurity for about fifty years, for, according to Devoto, it was Adam Smith who in 1760 again drew attention to his treatise. However, the deleterious effects which attended the rapid expansion of industry caused the medical profession to turn to the study of Ramazzini. Twenty editions and many translations of his book appeared, of which we may cite: in England: translation by R. James (1745, 1746, 1750); in France: translation by Fourcroy (1711 and 1777); in Germany: *Opera Omnia* (Leipzig, published by Gleditsch, 1705 and 1718), and translation by Ackermann (published by Verlag Franzen and Grosse, 1780 and 1789), and Ilmenau (Verlag Voigt, 1829); in Italy, translations by Chiari (1745) and
The various authors who wrote on occupational diseases about this time, however, for the most part copied and paraphrased chapters of Ramazzini’s work. This is true of a volume published by Hecquet in 1740, of a Dictionary of Health which appeared in 1780 based on Hecquet’s work, of a Dictionary of Medicine published in 1772, and of a thesis on the Maladies of Craftsmen written by Dr. Skragge, of Upsala, in 1764, and to some extent also of Dr. Buchan’s references to workers’ diseases in his Domestic Medicine (1775), though the latter adds certain interesting original matter regarding a suitable diet for sailors, and the advisability of specially constructed tables for tailors and other sedentary workers, to correct faulty posture, and pleads for workers’ gardens and for greater facility for exercise.

In the course of the second half of the seventeenth century there appeared several works relative to occupational diseases and their treatment by the following authors: Isemann, Baker, Huxham, Zeller, Combaluzier, Tronchin, Gardane, Desbois de Rochefort and Poitevin.

Gardane’s book may be considered as the complement of Stockhausen’s. In 1740 Hecquet published Medicine, Surgery and Pharmaceutical Chemistry for the Poor. In 1775 Percival Pott was the first to study chimney sweeps’ cancer, and this subject received further development at the hands of Simmons, Aldis, Earle and Cooper. Robert Willan, an early dermatologist, dealt with bakers’, shoemakers’ and grocers’ itch and skin diseases of metal workers (1798). The Pocket Dictionary of Health (Paris, 1768) devotes several articles to occupational diseases; the Memoirs of the Academy of Medicine of France of 1779 contain remarks relative to accidents affecting workers handling tallow and animal hair.

In Italy J. P. Frank in 1779 called for measures of protection for women before and after childbirth, and expressed the desire to see women liberated from work for the three months preceding childbirth. Pietro Verri instituted in Milan in 1776 the “Societa Patriotica”, which inspired a movement in favour of agricultural workers suffering from pellagra. There was opened at Legnano in 1784-1787 a clinic for workers suffering from this disease. The same society interested itself likewise in tuberculosis affecting white lead workers, wool and silk workers, etc. The poet Parini suggested the creation of a Social Academy for Agriculture.

Scopoli had already studied injuries due to mercury and Mongiardini (1808) and Ravenna (1812) had described lesions of slate workers at Chiavari (Genoa). Towards 1870 there was founded at Manchester a Literary and Philosophical Society, which later counted amongst its members Percival Pott, Thackrah, Gaskell, and men like Owen, devoting their energies to the protection of women and children employed in factories and workshops.

In 1782 there was instituted in Germany, the “Annals of State Medicine” (Annalen für Staatsarzneikunde), which also constituted a valuable contribution to the subject.

THE NINETEENTH CENTURY

In the nineteenth century, with the rise of industrialism on the one hand and the concomitant development of biological and medical sciences on the other, the knowledge of occupational diseases achieved rapid development. The ravages made amongst the English working classes at the end of the eighteenth and beginning of the nineteenth centuries by the inauguration of the industrial system are well known and had for their consequence an enormous increase in disease. In 1761, according to Roscher, 50 per cent. of the English population died under the age of twenty. In certain industrial centres in 1833 the average age of the labouring classes was only twenty-two compared with forty-four amongst the upper classes, and later the death rate in the labouring districts reached 36 per thousand per annum as compared with 22 per thousand and for the country as a whole (Kober and Hayhurst). The dawn of the nineteenth century witnessed the first attempts at improving these appalling conditions. There commenced in Great Britain, and spread to the chief Continental countries, a gradual movement towards legislative regulation of industry — the limitation of number of hours worked, protection of women and children, and institution of factory inspectors. In 1844 there was legalised in Great Britain the appointment of regular “certifying surgeons” entrusted with the task of certifying the ages of children commencing factory work.

An increasing number of trades were brought within the scope of the
Factory Acts, and reports on conditions and causes of diseases in these trades were published. The report of the Medical Officer of the Privy Council in Great Britain for 1861-1862, for instance, contained such material, and dated from 1857 the removal of dust by mechanical means was first exacted by law in Great Britain, while 1805 marked the first demand for compulsory notification of certain industrial diseases in the same country, to mention but a few of the measures which marked legislative progress as regards prevention of industrial diseases at this time.

Though on account of her early industrial development Great Britain was the first country to institute factory laws, other countries later in adopting the enforcement of such laws were in a position to make more rapid progress. In addition to investigation and knowledge of industrial diseases, since they were able to profit by the English experience from the outset in establishing their inspection services and to have at their disposal scientific data in regard to medical, technical and chemical problems.

Concurrent with the growth of legislative measures dealing with the prevention of occupational diseases there occurred, concomitantly as the result of the revived interest being taken in the subject, a great expansion in the literature bearing on it and certain writers commenced to specialise in the study of these diseases.

C. Turner Thackrah. — In 1831 Charles Turner Thackrah published his book The Effects of Certain Trades and Habits of Living on Life and Longevity, based for the most part on his experience in the manufacturing district of Leeds, in which his practice was situated. As one might suppose, in view of the different periods in which they lived, there is an immense difference between the spirit in which Ramazzini and Thackrah dealt with the subject treated by them. Thackrah was a perfect anatomist and very conversant with methods of clinical diagnosis. His classification of the trades could hardly have been improved and the equity of his judgment alone prevented him from denouncing the employers for the deplorable industrial conditions which he describes (for instance, in the textile industry). He died of tuberculosis at the early age of thirty-seven. His premature death probably retarded by about half a century the progress of industrial medicine and surgery in Great Britain, as well as the improvement of industrial conditions. The second edition of his book appeared in 1839 (for further particulars see article by Legge in the Journal of Industrial Hygiene, 1920, No. 12, p. 593).

Thomas Bateman (1835), a pupil of Willan, pursued his master’s dermatological investigations still further.

European progress in public health was greatly stimulated by a report entitled The Sanitary Condition of the Labouring Population, published in England in 1838. An enquiry was effected in 1839 by J. Murray amongst rag sorters and rag merchants in Edinburgh. Allen studied conditions amongst petrol workers (kerosene) in 1861, and Leach those affecting cotton workers in 1864.

In France the movement likewise experienced wide development. In 1806 a dermatologist named J.J. Alibert published a report on the skin from the aspect of the exercise of various trades. In 1807 a prefect of police in Paris drew up a report addressed to the Minister of the Interior containing data relative to the tragic conditions of workers.

The year 1821 is a noteworthy date in the literature of industrial hygiene for it marked the foundation of the...
French periodical Les Annales d'Hygiène, which did more for the promotion of industrial hygiene in general than any other publication. Chevalier (1793-1879), a distinguished pharmacist and chemist, was an early contributor, and provided valuable contributions relative to the effects of lead, copper, chrome, arsenic, phosphorus, iodine, fuchsin and bromine, as well as to the skin disorders caused by these. Patissier re-edited Ramuzzini in 1822 and made some additions on the subject of skin diseases. He published for the first time mortality and morbidity statistics. In France exhaustive investigation was made into working conditions of wage earners by the "Académie des Sciences Morales et Politiques" in 1839, which gave an impetus to factory legislation. Tanquerel de Planches published (1839) an important book on lead workers' diseases. Villermé published in 1840 his work entitled L'Etat physique et moral des ouvriers, which also contains numerous occupational statistics relating to mortality and morbidity. Cadet Gassicourt expressed the idea of utilising these as the foundations of a rational system of vocational guidance. Thouvenin wrote on skin diseases in the woollen industry in 1846. In 1848 the "Académie des Sciences Morales et Politiques de France" instituted an enquiry into the physical, intellectual and moral condition of workers, with special reference to the effect of various occupations on the health and character of the working-class population.

Between 1825 and 1850 the Socialists (Fourier, Blanqui, and Prudhon) achieved effective action in regard to the study of occupational diseases. In the second half of the nineteenth century Halle de Arcet, Villerme and Parent-du-Chalet engaged in useful research relative to occupational dermatitis. Mahier and Chevalier in 1852 studied affections of the skin amongst mother-of-pearl workers. Desayre published in 1856 in the Annales d'Hygiène publique a long work on occupational diseases. In 1861 there appeared articles on antiline and nitrobenzol by Letheby, Oliviere and Bergeon. Maxime Vernois contributed in 1862 a striking article to the Annales d'Hygiène publique dealing with workers' hands, and about the same time research into diseases of workers handling skins was engaged in by Baugrand, Becourt and Chevalier studied the effect of bi-chromate of potassium on the skin, Chavret that of handling fuchsin, and Picard the skin diseases of spinners. Jorden wrote in 1863 on steel workers' diseases, and Delpech in the same year treated diseases of workers in the rubber industry with reference to carbon bisulphide poisoning. Thelimer wrote in 1864 on skin affections of laboratory workers. Giraudon, Gibeau, Maout-Gervais and Devergie published monographs on skin diseases, whilst Bazin was the author of Lecons théoriques et chimiques sur les affections cutanées artificielles, dealing with many categories of industrial workers. Delpech published in 1869 and 1876, in collaboration with Hilairet, the result of investigations into diseases of chrome workers, whilst the latter year also witnessed the appearance of Dr. Layet's Hygiène des Professions et Industries. An important contribution by Napier to the Manuel d'Hygiène industrielle dates from 1882 and that of Poincaré from 1886.

In German-speaking countries contributions to the literature at the beginning of the nineteenth century were much less numerous. Nevertheless, the Viennese School of Dermatology was founded in 1840 by Hebrau, and his pupils Kaposi and Neumann engaged in fruitful research. Cless, in 1842, wrote on bakers' diseases. In 1847 E. von Bibra and L. Geist published a study on the diseases of match makers and in particular on phosphorus neureisis. Breilisle studied the skin diseases of workers manipulating human and animal hair (anthrax) and advocated sterilisation of the hair. Halfort in 1845 published his Entstehung, Verlauf und Behandlung der Krankheiten der Künstler und Gewerbetreibenden, devoted to pathology and prophylaxis, and dealing with toxic gases, dusts, injurious effects of faulty posture, fatigue and abnormal temperatures. Schirmer (1856) dealt with lignite workers, Hoeisbeck (1858) with printers, and Keller with mirror workers.

The town of Hanover and, in Denmark, the town of Copenhagen, provided (1861) some striking statistical data relative to skin affections amongst bakers. In 1861 Kussmaul published a monograph on constitutional mercurialism.

In 1865 Eulenberg published Die Lehre von den Schädlichen und giftigen Gasen. Kuntz, in 1868, published the result of a study of diseases affecting workers in the sugar industry. In the same year Dankwerth wrote on petroleum eczema and Hoppe on the maladies of barbers and tobacco workers. The Industrial Code of the North German Union laid down that "every manufacturer must, at his own cost, establish and maintain all necessary
appliances for safeguarding his employees against dangers to health and life". These measures were extended to form the Code of 1891 and became the basis of the present factory legislation in Germany. In Germany the Factory Acts are general in character and local authorities have power to interpret them as circumstances demand. In 1870 Hirt published an extensive treatise on occupational diseases entitled Die Krankheiten der Arbeiter, which was reprinted in 1882, and in 1876 Eulenberg published a work entitled Handbuch der Gewerbehygiene. Ordtmann in 1877 drew attention to smallpox occurring amongst rug sorters, and Max Pettenkofer, the founder of experimental hygiene and editor of the Handbuch der Hygiene, induced Max Gruber, 1881, and Ogata, 1882, to undertake, with the aid of respiration apparatus, investigations on the action of sulphuric acid and carbon monoxide. In 1882 Popper published in Stuttgart his Lehrbuch der Arbeiterkrankheiten und Gewerbehygiene.

Since 1884 quantitative studies of upwards of thirty-five gases based on animal experiments and observation in industry, where possible with human control experiments, have been carried out by K. L. Lehmann of Wurzburg, assisted by his pupils.

Albrecht in 1896 published his Handbuch der praktischen Gewerbehygiene, and in 1898 Sommerfeld published the first volume of his Handbuch der Gewerbekrankheiten. In 1897 there appeared an important volume on industrial hygiene edited by Weyl, forming the eighth volume of a large treatise on health, and two years later R. Laudenheimer published a study on carbon bisulphide poisoning amongst workers in the rubber industry. In 1906 there appeared an important work Handbuch der Arbeiterkrankheiten edited by German authorities under the direction of Weyl.

In Italy the movement developed in similar fashion. Puccinotti (1837) drew attention to the tragic lot of workers occupied in foreign factories. Later there appeared collaborative publications dealing with occupational pathology and hygiene, amongst which may be mentioned those of Boeri, Contini (1881), Mantigazza (1881), Sanarelli and Trambusti (1895), Revelli (1898), not to mention numerous articles disseminated throughout the technical press.

In the United States, as elsewhere, the rise of machine production was accompanied by exploitation of child labour and enormous wastage of human effort and human life. Attention was first bestowed on the gravity of the social problems arising therefrom about 1856, and thereafter investigation committees were appointed and legislation introduced. The growth of factory legislation was fairly rapid from 1850 onwards, but prior to 1877 no legislation in regard to factory inspection existed in the United States.

The first American contributions to the literature on industrial hygiene date approximately from the prize dissertation published in response to an appeal by the New York Medical Society in 1837 entitled On the Influence of Trades, Professions and Occupations. In 1869 Walker published a monograph entitled Occupation of the People, and from 1880 to 1890 twenty-two American contributions were made to the literature. From 1890 onwards there has been a great increase in the number of contributions made to this subject.

In Australia an enquiry was instituted in New South Wales in 1893 into the incidence of lead poisoning amongst miners in the Broken Hill mines.

THE TWENTIETH CENTURY

As regards progress effected since 1900, it is preferable to consider separa-
ately the advance made in each of the leading industrial countries, as everywhere a great impetus was given owing to the increasingly scientific character of the methods pursued. Germany and Great Britain stand first amongst the European countries as regards regulation of unhealthy trades. Progress along the lines of drafting special rules affecting whole classes of workers is becoming more general. The statistical data provided by the German Accident and Sickness Assurance Associations have proved of great value in furthering investigation and research. In the United States large-scale investigations into special diseases, aided by statistical investigation, have contributed greatly to progress.

The European Contribution to Industrial Medicine

The profound significance of industrial health and the urgent necessity for adequately protecting the health and safety of the workers were forced on the public attention during the war of 1914-1918 by the scarcity of labour. Thus, for example, in Great Britain there resulted the appointment of the Health of Munition Workers Committee, the work of which has since been supplemented by Home Office investigations into industrial fatigue (Industrial Fatigue Research Board). As the result of the findings of this Committee an Act was passed in 1916 to secure the welfare of workers in factories and workshops, thus opening up a new phase in activity for the promotion of industrial hygiene. This tendency to promote industrial welfare in some measure actuated by efforts to abolish industrial unrest and secure contentment is in strong contrast to the position in the United States, where progress during the same period has rather been along strictly medical lines, having for its fundamental object diseases prevention.

In 1902 a very important work, prepared by medical experts under the editorship of Sir Thomas Oliver, was published under the title of Dangerous Trades, and in 1908 Sir Thomas Oliver published the first edition of his Diseases of Occupation, revised in 1916. In this year also there appeared a second edition of Weyl's Treaty of Industrial Hygiene. In 1909 there was published a Treatise on Occupational Diseases and Accidents by Greer.

Credit is due to Sir Thomas Legge for having, with the aid of factory inspectors and certifying surgeons, made very important contributions to a great number of problems on industrial medicine. In 1912 he published, in collaboration with Sir Kenneth Goadby, an important study entitled Lead Poisoning and Lead Absorption. He also made valuable contributions to Kober and Hanson's Diseases of Occupation and Vocational Hygiene and translated into English Rambousek's book Industrial Poisoning from Fumes, Gases and Poisons in Manufacturing Processes.

Leonard E. Hill investigated compressed-air illness in 1912 as well as the general evils of bad atmospheric conditions, and made highly important contributions to the science of ventilation and lighting of workshops, as well as the relation of food values to occupation. Haldane has done notable work in the study of atmospheric conditions and dust inhalation and also in regard to miners' health and compressed-air work. The studies made by him are very remarkable and represent one of the most valuable contributions made on the subject. Dr. Collis has gained distinction by his studies on physiological and pathological effects in regard to the action of dust in the production of lung disease (1910), in regard to housing in its relation to factory life, as a factor in tuberculosis causation (1914) and by studies on industrial pneumoconiosis (Milroy lectures, 1915), occupational injuries (1915) and welfare work in factories (1919). Research into occupational cancer mortality has been carried out by Green- wood, who has also devoted himself to the consideration of industrial accidents, fatigue and welfare work, etc. In 1921 Collis and Greenwood published The Health of the Industrial Worker, giving a satisfactory account from the standpoint of industrial hygiene of the profound changes in civilised life in the past century and as a result of the rising development of modern industry. In 1923 Hope, Hanna and Stalybrass published an excellent work entitled Industrial Hygiene and Medicine.

In France mention should be made of the studies effected by the Ministry of Industry and Commerce, one in 1901, Poissons industriels, and the other in 1908, Maladies professionnelles, in the preparation of which various experts participated (Leroy des Burres, Courtois de Ruffit, Brémond, Heintz, Dufraisse, J. Josias, Thoinot). Thoinot, in collaboration with Brouardel, made repeated contributions to the study of occupational diseases on the occasion of seeking a solution of problems in forensic medicine raised in regard to
industrial poisoning. In 1908 there appeared an important treatise on industrial hygiene, the result of joint collaboration on the part of Leclerc de Pulligny and Boulin, the second edition of which was issued in 1927. There should likewise be mentioned the works of Breton on lead poisoning due to white lead and on occupational diseases, Brouardel and Gilbert (1912) on industrial poisoning, Hém de Balzac and Hébert (1912) on various problems of industrial hygiene, Bargeron (1919) on hygienic construction of factories, Agasse-Lafont, Martin (Lyons), etc. There should not be omitted mention of the works of Freres and Langlois, who dealt with numerous aspects of hygiene and industrial physiology. The movement in favour of the study of occupational diseases has greatly developed since the war, and mention should be made of the foundation in 1925 of an association called the "Société d'hygiène publique, industrielle et sociale" (Society of Public, Industrial and Social Hygiene) which devotes a part of its activity to the study of problems of industrial pathology, likewise the Paris Institute of Industrial Hygiene and the creation of an Institute for Occupational Diseases attached to the Faculty of Medicine in Lyons University, together with the foundation in 1929 of a periodical entitled La Médecine du Travail (Industrial Medicine), edited by Professor E. Martin.

In Belgium the movement received a new impetus in 1895 thanks to D. Gilbert, who has since then been Chief Medical Factory Inspector in that country. This service, as well as the numerous factory surgeons throughout the country, constantly render valuable service in the various spheres of industrial hygiene and pathology. Even a brief survey of the work undertaken in Belgium would not be complete without reference to the works of Malvoz (Liège) and of Herman (Mons), particularly in regard to the campaign against ankylostomiasis.

Several general studies on occupa-

![Fig. 49. — Clinic for Occupational Diseases of Milan. (Its construction was decided on by the Municipal Council on 20 November 1902. It was opened on 20 March 1910.)](image)
and in addition of several other experts, contributes regularly to progress in the field of industrial medicine. The treatise on "Occupational Diseases" by Heijermans appeared in 1908 and a new edition was issued in 1928 in two volumes. The Society for Medicine and Surgery of Occupational Diseases and Accidents publishes a monthly review. A service for occupational selection and industrial pathology attached to the Faculty of Medicine has just been created by the University Council in Brussels.

In Germany a monumental volume on occupational diseases, the work of a number of recognised experts under the direction of Weyl, was published in 1908. In 1914, 1917 and 1921 there appeared the second edition of Weyl's treatise, published by Gärtsch. Dr. Lehmann's treatise Lehrbuch der Arbeits- und Gewerbekygiene appeared in 1919 and is remarkable for the precision of its data based on the vast personal experience of the author. He has studied the toxic effects of a great number of metal fumes by dosing animals and has determined the channels and extent of absorption of poisons; he has formulated new scientific theories relative to the toxicity of many industrial poisons, chiefly those of an organic nature.

Interesting work has been effected by the Federal Health Office represented by such experts as Wolffhugel, Renk, Wutzdorf, Rost, Engel and a certain number of factory inspectors: Joelsch, Muller, Bochfeld, Curschmann, etc., as well as many other doctors in industry (Müller, Bochfeld, Curschmann), etc. Mention should likewise be made of the extensive treatise on social hygiene (1926-1928), the work of Schlossmann, Gottstein and Teleky, one volume of which is devoted to occupational hygiene; the treatise of Syrup (Handbuch des Arbeiterschutzes und der Betriebssicherheit, 1927) and the work of Sommerfeld (Atlas der Gewerblichen Gesundheitspflege, 1926).

Special courses of occupational diseases are held in ore- than in Germany universities. Apart from the numerous publications devoted to the subject, much propaganda work is done by the Association for Industrial Hygiene (Frankfort-on-Main).

Austria has not failed to furnish a contribution to the subject in question. It suffices to recall the work of Ramhosek (1908), besides the publications of Brezina, Sternberg and H. von Schroetter.

In Czechoslovakia, Loewy published his treatise in 1924. Mention should also be made of the important institution designated under the title of "Masarykova Akademie Prace", one section of which deals with industrial physiology and psychotechnics. In 1928 there was instituted an association dealing with questions of social medicine and hygiene. A chair of industrial medicine was instituted in 1929.

For Hungary reference should be made to the research effected in regard to lead poisoning, especially in the pottery industry by Chyzer, as well as to the works of Friedrich, etc.

In Greece Catsaras, as the result of detailed research, has proposed new methods of decompression for divers, and Savas has furnished contributions in the field of industrial medicine.

In Poland many experts have devoted their time to industrial medicine. Amongst others may be mentioned the names of Zielinski, Karaffa-Korbut, etc. A periodical entitled Higijena Pracy devoted to industrial hygiene has been published since May 1928.

In Portugal there appeared in 1924 a treatise on industrial hygiene edited by Corbo d'Andrade, who published also in 1927 the Quesitos de Higienie Social.

In Switzerland the works of Schuler, O. Roth, Zangger and Vogt, etc., are well known to experts.

In Italy progress has likewise been made in regard to industrial hygiene. Amongst the general and special works on the subject, there should be cited those of Giglioli (1902), Pieraccini (1906), Allevi (1907), Anna (1909), Loriga (1910), Carozzi (1914), Ranelletti (1923), Ferraruzini (1929). The very important contributions to the subject made by institutes directed by Devoto, A. Monti, C. Biondi, L. Ferramenni and their collaborators are also well known, the movement having begun at Pavia at the instigation of L. Devoto.

The first industrial clinic was founded in Italy in 1910 by the town of Milan. It comprises consulting rooms, wards for patients affected with industrial diseases, laboratories, library, museum, courses of medical instruction, propaganda, publications and enquiries, etc. It constitutes a highly important centre of industrial hygiene and pathology. A second industrial clinic was founded in Naples in 1919 and new chairs of industrial medicine have been created at Turin (1929), Parma (1930), etc. Polyclinics for workers have been organised at Rome, Genoa, Turin, etc.

In Italy the movement found expression likewise in the organisation of periodical national congresses devoted
to industrial diseases (Palermo, 1907; Florence, 1909; Turin, 1911; Rome, 1913; Florence, 1922; Venice, 1924; Parma, 1927; Naples, 1929), congresses in which technical experts and scientists have actively participated. Special medical reviews devoted to the subject also exist: Il Ramazzini (1907-1915), Il Lavoro, now entitled La Medicina del Lavoro, founded by Devoto in 1901.

In Spain, the Barcelona local authorities in 1929 created a chair of industrial medicine and intend to organise a clinic for industrial diseases and accidents. A course of industrial medicine is given at the Institute for Occupational Rehabilitation at Madrid, which also publishes the periodicals Medicina del Trabajo y Higiene Industrial.

In Russia pre-war research was chiefly connected with the petrol industry (Berthenson), but since then Russian scientists and technical experts have become increasingly interested in questions of industrial hygiene and pathology. There should be cited the works of Kaploun, Lachtenkoff, Kagan, Vigdortschik and Wassilewsky devoted to occupational health. Numerous institutions for the study of occupational diseases have been founded, notably at Leningrad, Kharkov and Moscow. There should likewise be mentioned a periodical review devoted to industrial hygiene.

The American Contribution to Industrial Medicine

In the United States the number of publications relative to industrial hygiene has greatly increased, especially during the last few years.

The National Committee on Child Labour was incorporated in 1906, and resulted in the formation of the Children's Bureau in 1911. This organisation, amongst other aims, seeks to promote child welfare and to investigate dangerous occupations with a view to exclusion of children from these. In 1884 a Bureau of Labour was set up in the Department of the Interior, and in 1915 a Division of Industrial Hygiene and Sanitation was created with an Office of Field Investigation into Occupational Diseases. The Public Health Service and the Service of Mines have done excellent work in the sphere of scientific investigation into a number of dangerous occupations and processes. The first publication, issued in 1914, dealt with trachoma amongst steel workers, and was followed by articles on a wide range of subjects. Recently much good work has been done under Professor Winslow in regard to the study of factory ventilation and industrial dust hazards. The post-war programme covers:

1. continuing and extending health service in industry with a view to precise determination of the health hazards and of the best means for preventing them;
2. securing adequate reports of disease prevalence in industry and of sanitary conditions in industrial establishments and communities;
3. national development of adequate systems of medical and surgical supervision of employees in places of employment;
4. establishment, in co-operation with the Department of Labour, of minimum standards of industrial hygiene and prevention of occupational diseases; and
5. improvement of sanitation in industrial communities.

In 1910 and 1912 conferences on industrial diseases were held at the instigation of the American Medical Association for Labour Legislation. In 1915 a Section of Industrial Hygiene was organised in the American Public Health Association.

As regards training in industrial hygiene, most medical schools and colleges have courses in hygiene and public health, a certain number of lectures being generally devoted to industrial hygiene and dangerous occupations.

Much useful research has been done in the various medical schools throughout the country, into such subjects as: packers' itch, health hazards of the pearl button industry, strength tests in industry, TNT poisoning, hours of work as related to output and the health of the workers.

Harvard Medical School was the first in the world to confer a degree in industrial hygiene (session of 1918-1919), and its staff has made many contributions to the subject. It is also responsible for the publication of the Journal of Industrial Hygiene. Several States possess a Division of Industrial Hygiene. That of Ohio provides courses in industrial medicine and surgery. The first clinic for occupational diseases was opened at New York in 1910. Others have been instituted in Chicago (1911), Boston (1910), etc. A great deal of research has been done in these clinics, comprising enquiries into such subjects as: compressed air illness, brass poisoning, lead poisoning, pulmonary diseases of potters and cement workers, etc.

The Bureau of Statistics of the Department of Labour has published, in the series entitled "Industrial Accidents and Industrial Hygiene", some highly interesting reports, amongst which should be mentioned: Lead Poisoning in Potteries, Tile Works, and Porcelain Enamelled Sanitary Ware Factories; Danger in Use of Lead in Painting of Buildings (report of British Departmental Committee); Lead
Poisoning in the Manufacture of Storage Batteries; Lead Poisoning in the Smelting and Reclamation of Lead; Deaths from Lead Poisoning; Hygiene of the Painter's Trade; Dangers to Workers from Dust and Fumes, and Methods of Protection; Industrial Poisons Used in the Rubber Industry; Industrial Poisons Used or Produced in the Manufacture of Explosives; Industrial Poisoning in Making Coal-Tar Dyes and Dye Intermediates; Effect of the Air Hammer on the Hands of Stone-Cutters; Anthrax; Carbon Monoxide Poisoning; The Problem of Dust Phthisis in the Granite Stone Industry; Phosphorus Necrosis in the Manufacture of Fireworks and in the Preparation of Phosphorus; Hygiene of Printing Trades; Health Survey of the Printing Trades, 1922-1925; Mortality from Respiratory Diseases in the Dusty Trades; Causes of Death by Occupation; etc.

In June 1910 the first National Conference on Industrial Diseases (held at Chicago) was called by the American Association for Labour Legislation. The President, in his opening address, stated: "This is a warfare in which science, labour, business enterprise, and Government must all unite." A Committee of Enquiry appointed by the Conference estimated the economic loss to the country through sickness due to preventable causes to amount to $350,000,000. An informal Committee of Industrial Hygiene Experts formed in 1910 was in 1914 absorbed by the American Association for Labour Legislation. Much valuable work has been effected by special commissions and by official and private investigations in relation to the study and prevention of occupational disease. Mention may here be made of that of Illinois in 1911, of Ohio (Hayhurst) in 1915, etc.

In 1911 a series of annual Safety Congresses. In October 1912, Lew R. Palmer suggested the creation of a permanent association to be designated the National Council for Industrial Safety; it was instituted in 1913, with a section on hygiene. A Committee appointed by this organisation is now investigating the prevention and control of occupational skin diseases.

Section 4 of the Fifteenth Congress on Hygiene and Demography, held at Washington in 1913, was devoted to occupational hygiene, and stimulated a profound interest in the subject. The sixty-four contributions by distinguished experts served to lay the foundations for a scientific literature on industrial medicine in America, and in the following years many useful volumes on the subject were published.

In 1917 a conference was called at Washington by Mr. Gompers, of the American Federation of Labour, to discuss recommendations for promoting health and efficiency amongst industrial workers. For this conference reports were prepared on such subjects as: industrial fighting, dust hazards and general welfare. In 1917 the Council on National Defence organised a sub-section on industrial medicine: 1919 saw the inauguration of the Journal of Industrial Hygiene and The Nation's Health, two excellent periodicals devoted to industrial hygiene, medicine and surgery. The American Public Health Association participated in the proceedings of the Washington Conference.

The American Medical Association of Industrial Physicians and Surgeons was formed in 1916 with the object of stimulating scientific study and research in industrial medicine, advancing the adoption of health services in industry, and raising the standard of physicians in industrial practice. Much good work in pursuit of these aims already stands to its credit. In the State of New York there exist the Workers' Health Bureau and the New York State Society of Industrial Medicine, the official organ of which is The Industrial Doctor.

In 1925 Alice Hamilton published an interesting volume entitled Industrial Poisons in the United States. J. C. Aub, L.T. Fairhall, A.S. Minot and P. Reznikoff in 1926 published an important study on lead poisoning, and finally in 1927 Yandell Henderson and H. W. Haggard issued a publication dealing with toxic gases.

Though it is hardly over twenty-five years since serious attention was first bestowed on problems of industrial hygiene in America, good progress has been effected and has borne fruit, as proved by reduced mortality rates in certain trades. Dr. Fiske, in his striking report (1923) on the problem of the economic loss and waste in industry, to be attributed to lowered health conditions, sickness and accidents, reckons 42 per cent. of such illness to be preventable, and is led to expect from adequately applied preventive measures a life extension for workers of fifteen years. Since 1900 a probable extension of five years has, he states, been achieved, and the former estimated loss per worker of thirteen working days per annum may, he considers, be now computed approximately at seven days.

In Brazil a treatise on forensic medicine relative to industrial accidents and occupational diseases was published in 1926, the work of Afranio Peixoto, Flaminio Favero, and Leonidio Ribeiro, of the Medical Faculties of Rio de Janeiro and Sao Paolo.

In Canada there is an Industrial Clinic under the direction of Pedley.

Other Countries

In South Africa gold and diamond mining has attracted the attention of experts on industrial hygiene by reason of the different health problems involved. Very important organisations, such as the South African Institute for Medical Research and the Miners Phthisis Bureau, etc., as well as a
number of scientists (Mavrogordato, Orenstein, Ireland, Irvine, Watkins-Pitchford, etc.) have studied questions relating to detection, diagnosis, clinical and radiological work and the prevention of silicosis.

In Japan a very important movement is in progress, in which experts in the various fields of industrial pathology have participated. An Institute for Industrial Research, situated at Kurasaki, is directed by Teruoka (see fig. 50). This institute was founded in 1921, thanks to the generosity of Mr. Magosaburō Oohara, President of the Kurasaki Cotton Mill Company. Its aim is to study human industry from the medical and psychological point of view.

It suffices to recall, in fact, the enquiry instituted in regard to the occupational risks to which workers were exposed in the construction of the Sydney Tunnel (1902), that conducted in regard to the incidence of pneumoconiosis and pulmonary tuberculosis in mines (1904), the investigations at Bendigo (Victoria, 1906) and the enquiry into the incidence of pneumoconiosis and lead poisoning amongst workers in the Broken Hill mines (1914), etc. In 1921 the American authority Lanza, in collaboration with Robertson, organised a Central Office of Preventive Medicine, and in 1921 also there was created a Division of Industrial Hygiene under the direction of Dr. Robertson, who, on

Fig. 50. — The Oohara Institute for Industrial Science at Kurasaki (Bitchu, Japan).

taking into consideration other social problems. The institute comprises five sections: industrial physiology, industrial psychology, biometry, nutrition, social hygiene. The results of the activities of the institute are published in a quarterly periodical (in Japanese) as well as in a Japanese handbook on social hygiene, which appears also in other languages.

Since its inauguration in 1901, the Commonwealth Government in Australia has never lost sight of problems of industrial hygiene and pathology. His decease, was succeeded by Dr. Keith Moore. The first official general conference, the aim of which was to discuss and to propose to the Government measures of occupational and social hygiene for workers, was held in 1922, a second in 1924, and a third in 1927. The very important decisions adopted are to be found in the reports published by the Division of Industrial Hygiene, which has also issued a whole series of reports containing the results of very interesting enquiries. There should also be mentioned act-
ivities in the same sphere engaged in by the Hygiene Departments of New South Wales and Victoria, etc. A Royal Commission on Health, set up in 1906, also dealt with industrial hygiene and pathology, and suggested a whole series of practical measures for adoption. There should finally be recalled the scientific contributions of Badham, of New South Wales, Armit, of Sydney, Chapman, Smith and Walter Summons, who have published striking contributions to the problem of tuberculosis amongst the Bendigo miners, with special insistence on the anti-dust campaign, and on the need for adequate ventilation in mines.

MUSEUMS OF INDUSTRIAL HYGIENE

Several cities and towns possess Industrial Safety and Hygiene Museums which show by means of plans and photographs, methods of occupational disease and accident prevention, arrange for lectures, and publish pamphlets and propaganda tracts. There may be mentioned in this connection the industrial museums or exhibitions of industrial hygiene and safety in Amsterdam (opened in 1883), Milan (1894), Munich (1900), Berlin-Charlottenburg (1903), New York (1907), Budapest (1908), Vienna (1909), Lausanne and Turin (1911), and London (1927), the latter organised by the Home Office. Special collections dealing with particular problems (hygiene, miners' safety, for instance) have been organised at Mons, Gelsenkirchen, etc., and a collection forms part of the important Hygiene Museum in Dresden.

NATIONAL AND INTERNATIONAL PROTECTION OF WORKERS

The practical knowledge of occupational diseases in the various countries is aided by the organisation of medical inspection in industry, compulsory notification of occupational diseases and their compensation. These legislative measures, by providing scientific data, contribute to the improvement of knowledge of occupational pathology. The data thus collected are valuable not only to the countries possessing such schemes, but also to other countries.

The question of international protection of workers was raised for the first time in 1887, at the Congress of the International Association for Labour Legislation, which demanded protection of workers in unhealthy trades. The first International Conference, however, was not held till 1890, in Berlin. In 1896 the International Conference called by the Parisian trade unions in Paris raised the question of the principle of compulsory protection: provision in the workrooms of apparatus for protecting the health of workers, prohibition of certain processes and of the use of certain raw materials particularly harmful to the health of workers. In 1897 there was held in Zurich the International Congress for the Protection of Workers.

The International Association for Labour Legislation (Basle) was founded after the International Congress of Paris in 1906. The enjoyment of occupational diseases and accidents has been one of the various aims pursued by means of publications in French, English and German of studies on certain questions, and on the occasion of its biennial meetings it has engaged in the study of numerous problems of occupational hygiene. Prizes have been offered for the solution of problems of industrial hygiene. Thanks to the activities of this international organisation, it was made possible for authorities on the subject to draw up a list of this industrial poisons.

Action on an international scale has likewise expressed itself in the organisation of international congresses on occupational diseases (Milan, 1906; Brussels, 1910; Vienna, 1914; Lyons, 1929; Geneva, 1931).

It is advisable to recall to mind the fact that there was founded as the outcome of the Milan Congress in 1906 the Permanent International Committee for the Study of Industrial Medicine. Composed of distinguished experts from all countries, it has dealt with questions of industrial pathology, and has organised international congresses, etc. Its activity was suspended during the war, but as soon as the conditions were again favourable its members reconstituted, and resumed organisation of congresses in the form of meetings, the first post-war congress being that held at Lyons in 1929.

The international activity of the International Association for Labour Legislation, which had its headquarters in Basle, is at present carried on by the International Labour Office by means of its Hygiene Service and its Advisory Committee on Industrial Hygiene, which numbers amongst its members distinguished experts from many countries (see publications of the International Labour Office).

At present there is a widespread movement in favour of creation in the universities of laboratories for the development of research into industrial hygiene for doctors and factory inspectors, as well as the creation of private organisations with the same object.

Gradually the nations are coming to realise the truth underlying the words of Ramazzini: "It is but a poor profit which is achieved by the destruction of health."

BIBLIOGRAPHY

Cf. the quarterly publication of the INTERNATIONAL LABOUR OFFICE: Bibliography of Industrial Hygiene, No. 12, Dec. 1925, pp. 33-40, and No. 8, June 1929, in which are given a list of works relative to industrial hygiene and pathology.
Definition and Compensation

At the Seventh Session of the International Labour Conference (Geneva, 1925) the question of compensation for occupational diseases figured on the agenda. On this occasion the International Labour Office placed before the Conference a document comprising data relative to compensation in those countries which had issued measures dealing with this type of insurance. Since 1925 legislation in regard thereto has developed rapidly, and its beneficial effects have extended increasingly, with the result that at the present time the task of resuming the problem of compensation at its present state of progress cannot be dealt with within the bounds of a single article. For this reason the Office intends to revise and bring up to date a new edition (1931) of the study undertaken in 1925.

In the present article attention will therefore be confined to a brief summary of the most important points raised by this problem, whilst for details in regard thereto the reader is referred to the study prepared by the International Labour Office.

DEFINITIONS

According to Weyl, there should be included under the designation "occupational diseases" not only those diseases generally caused by the personal activity of the worker, but any frequent manifestation of symptoms affecting a given occupational class. This definition resembles that of Van den Borght, who declares that "occupational diseases are the consequence of long continued action of harmful effects in the exercise of a calling, and that they arise exclusively or with particular frequency amongst the workers in a given industry". Gilbert is of opinion that there should be considered as occupational diseases "those diseases which appear in any given calling with an incidence exceeding the normal, as well as those obviously due to occupational risk".

According to another group of experts, an occupational disease is a disease "related to the exercise of certain callings, in which it originates, and by reason of this it is to be regarded as an occupational risk" (Jouanny), or, again, it is "a continuous and enduring condition arising from a cause likewise continuing and enduring" (Bourgeois), etc.

Paulet has introduced into the definition a further very important element, that is to say, "the far-reaching consequences of fatigue and ill-health caused by the occupation".

The Committee for the Study of Occupational Diseases established in 1902 in Italy defines as occupational diseases "those diseases caused directly and exclusively by the exercise of an occupation, or those diseases which are the inevitable consequence of a given industry", and under Swiss legislation occupational diseases are defined as "all diseases exclusively or essentially due to the action of substances quoted in the list" forming an annex to the law on accident compensation.

Certain definitions even refer to "diatheses", although it is obvious that many disease forms of occupational origin cannot be compared to a diathesis.

Certain of these definitions are open to criticism. For instance, in regard to duration (definitions of Bourgeois and Van den Borght), it is not indispensable that the exercise of a calling should be of "long duration" before the worker develops an occupational disease. On the contrary in certain occupations, young apprentices and temporary workers are most often affected, and in these instances it is the "occasional" rather than the "habitual" exercise of the calling which at times suffices to give rise to the most serious accidents. As regards the "exclusive" element (Italian and Swiss definitions), there are certain affections where occupational etiology does not enter into the question and the trained medical man must always, in making a diagnosis, take into account conditions and predisposition to disease peculiar to the individual. More generally speaking, it is at times very difficult to differentiate with "certainty" and mathematical "accuracy" the rôle played by various causes which have exercised an effect on the system, and to assign to a given disease an origin either "exclusively" or "partially" occupational. Similarly, there cannot be accepted the conception of the disease being the far-reaching consequence of an unhealthy occupation (Paulet). Such is not the case with an infection having a very short period of incubation, or with poisoning, which progresses in a very short lapse of time (poisoning due to theocarbonic acid or benzine, lead colic amongst white lead workers, etc.).

It is likewise difficult to understand how even a trained medical man can
accurately determine the harmful action of one of the substances enumerated in the list (Swiss definition) when the disease or the lesion is due to two or several substances simultaneously present in the workplace. The frequency of these "mixed poisonings" is much greater than is imagined, especially in the modern chemical industry.

The occupational disease, and notably chronic poisoning, occurs by attacks of short duration followed by periods, which are at times fairly long, of at least apparent normal physiological equilibrium. The conception of "slow" poisoning is therefore too narrow, for there are cases in which the absorption of the poison occurs in a relatively short time, yet not so short that they can be considered as accidents in the legal sense of the word.

The conception, which is acceptable in theory, of "absorption", "impregnation", "poisoning", corresponding to three phases of the toxic action of a substance, represents in practice a subtle process which runs the risk of depriving the victim of legal compensation for occupational disease. It is with a view to safeguarding the principle of this right to compensation that for some time back authorities have bestowed a very wide interpretation on the definition of accident, especially in regard to its elements of "suddenness" and "violence" (see below).

The diseases which are of interest for experts in industrial medicine are those affecting exclusively the workers, or again those which, on account of economic and social conditions in which the workers live, show a special tendency to break out amongst them.

The first constitute occupational diseases or "technopathies", the second are "industrial diseases" or ordinary diseases which in certain special conditions assume particular importance.

According to Biondi, those diseases which are the consequence of unfavourable conditions intimately connected with ordinary industrial routine due to multiple and repeated effect but spread over a period of time, may be designated as occupational diseases.

On the other hand, accidents and diseases due to an accident are the consequence of unfavourable causes residing in abnormal, unusual happenings in the course of work, which is interrupted thereby. It is, that is to say, an event of sudden occurrence, occupying a brief space of time, and the manner of occurrence of which cannot be foreseen.

Martin has also provided a definition of "occupational disease" and "industrial disease". The latter, which is common to all workers, is not related to a certain occupation. Its etiology, the circumstances of its occurrence, etc., are conditioned principally by individual factors and indirectly by the work. The occupational disease, on the other hand, exclusively affects certain classes of workers. It is created, so to speak, entirely by a given occupation or by the conditions under which such occupation is effected.

Gilbert, however, when acting as Reporter to the Committee on Occupational Diseases at the Seventh Session of the International Labour Conference (1925), stated that "it is well known that no truly satisfactory definition of occupational disease exists, nor any criteria capable of determining in every case and with accuracy the etiological diagnosis of the disease symptoms encountered."

Finally, certain legislative authorities, belonging chiefly to the United States, consider that they have adequately satisfied the demands for compensation by replacing in the definition the word "accident" by the word "injury". This larger formula, it is true, covers the whole individual pathology, yet it necessitates a number of essential precautions for the exclusion of abuses. If account be taken, however, of the practical results already acquired over a long period (ten years, for instance, in California), it must be admitted that the system in question offers great advantages. Certain countries, notably New South Wales, have even gone so far as to substitute this system for the list previously adopted by them. It is therefore necessary to devote the closest attention to the movement in question with a view to the ultimate attainment of conclusions to be drawn therefrom.

Notification

Legal compensation for occupational diseases of necessity implies notification of diseases entitling the worker to compensation, which is generally effected by a simple and practical system. France, Germany, Great Britain, and certain of the United States provide highly interesting statistics (see section of this article "Statistics") relative to diseases compensated.

Notification also exists in those countries which, up till a few years ago, had no system of insurance for
industrial diseases, in the Netherlands, for instance. It is similarly instituted in those countries which possess systems of compensation for certain diseases not yet included in the list adopted by them.

Declaration implies in these cases collection of data which enable a fairly accurate estimation to be obtained of the incidence of the disease in question in certain industries or groups of industries, with a view to the preparation of adequate legislation relative to prevention and compensation.

It must, however, be frankly admitted that for a long time back authorities on industrial medicine have been unanimous in their opinion that compulsory notification of occupational diseases does not provide accurate information as to the occupational risk to which the workers are exposed, unless it is carried out by all doctors and with all possible care. Unfortunately, the long-existent practice in certain countries (in the Netherlands, for instance, where a doctor's fee is paid for every case notified) does not confirm this hope, and notification can only be effective where it forms one element in a system of insurance.

At the First International Labour Conference (1919), the Committee on Unhealthy Trades considered it advisable to formulate a resolution, ultimately passed by the Conference, expressing the hope that occupational diseases should in every case be notified by the medical profession.

Amongst those countries where notification is compulsory, may be cited: Argentina, Austria, Brazil, France, Germany, Great Britain, Italy, Netherlands, Poland, and several of the United States, etc.

The diseases compulsorily notifiable vary in different countries. In Great Britain, for instance, they include the following diseases: lead poisoning; poisoning by carbon disulphide, aniline, benzine, phosphorus, arsenic, mercury; anthrax; toxic jaundice; epitheliomatosous ulcerations and ulcerations due to chrome and chromates. In France the Decree of 16 November 1929 contains a long list of diseases of occupational nature which must be notified. The list drawn up by the legislative authorities of the Netherlands (Decree of 4 October 1920) is also very detailed.

In the various articles of this *Encyclopædia* there has been quoted as completely as possible the list of countries which require medical authorities to provide notification of the disease in question in each particular case.

## Statistics

By way of example, tables I to V provide some statistics for Belgium, Germany, Ohio (U.S.A.), France and Great Britain.

In 1927 and 1928 the following cases were likewise notified in France: hydrocarbides, 19; aniline and its derivatives, 4; carbon disulphide, 6; chlorine and its organic compounds, 19; hydrocyanic acid,
OCCUPATIONAL DISEASES — 392 —

DEFINITION AND

In table VI are given cases of occupational diseases compensated in Great Britain: The figures relate to cases compensated for the first time in each year in question.

In Switzerland from 1922 to 1927 the following cases of poisoning received compensation (the figures in parentheses denote fatal cases): lead and its compounds, 255 (11); mercury, its salts and amalgams, 54; phosphorus and its compounds, 5; arsenic and its compounds, 4; chrome and chromates, 4; carbon monoxide, phosgen, 26; nitrous gas, 13; cyanogen and its derivatives, 4; sulphuretted hydrogen, 10; mineral acids, 56; alkalis, 8; halogens and organic derivatives, 23 (1); benzine, its homologues and organic derivatives, 92 (4); tar pitch, etc., 4; aliphatic

There were also compensated cases of chronic skin disease due to the following substances: lead and its compounds, 6; arsenic and its compounds, 3; chrome and chromates, 26; cyanogen and its derivatives, 15; sulphuretted hydrogen, 2; mineral acids, 84; alkalis, 112; halogens and their organic derivatives, 80; benzine, its homologues and aromatic derivatives, 107; tar, pitch, etc., 35; aliphatic series, 45; various, 251 (of these 40 were due to alkaloids, 80 to turpentine, and 62 to mixed products).

Compensation

It may be said that at the present time public opinion is unanimous in its demand for a solution of the problem of compensating occupational diseases in a reasonable and conciliatory spirit rather than on an abstract legal
basis or within the strict sense of a legal definition.

At the outset this question was stated thus, in accordance with common law: the worker who is a victim of an occupational disease had to furnish the legal authority with proof of negligence or guilt on the part of his employer, and of the occupational origin of his injury. However, to avoid loss of time and money, the possibility of an adverse decision, and at times even the loss of his employment, the worker was often induced, unless he was totally incapacitated, to renounce all claim to the compensation to which he was entitled.

The principle of occupational risk being now universally recognised, the victim of an industrial accident is assured of really effective protection, yet it must be admitted that this protection is not as extensive and as general in the case of the victim of occupational disease.

There are yet, at the present time, however, many countries in which no compensation is granted to a healthy worker, or no indemnity paid to the dependants, in the case of his health being destroyed by an industrial poison in a few months or years, or in the case of loss of life, even where the employer neglects to adopt the most elementary precautions or omits to observe the regulations. Further, such an occurrence is even possible in countries which possess a system of compensation whenever their list does not comprise the toxic product in question, or whenever such product is used, produced or liberated in course of an industrial operation not mentioned in the said list.

</table>
The worker is, in numerous unhealthy trades, continuously in "imminent danger", even when he takes the most thorough precautions with a view to protecting himself against the injurious effect of poison or infection insidiously hidden in the product manipulated. It has already been shown (see article "Blood and Industrial Poisonings") that while some light has penetrated the obscure depths which still screen from view the exact mechanism of the receptivity of the body to industrial poisonings, there is still much ground to be covered before scientific effort succeeds in dispelling this obscurity. None the less, until such time elapses, it is neither logical nor equitable to refuse any compensation to those workers who are victims of occupational injury for the sole reason that the cause of the latter is not included in a list the form of which is usually unduly restricted.

It is somewhat difficult to understand from the medical point of view the necessity for differentiating between the occupational accident and the occupational disease, since the etiology — work — is in each case the same, and the resultant injury is also the same: incapacity or death, whether the disease form be of a medical or surgical nature. In both cases it is a question of an attack on the health of the individual. Without, however, insisting further on this point, it seems that it would be truly illogical to conceive of a difference between a case of accidental poisoning due to sudden liberation of toxic fumes or gas and a case of slow poisoning due to the same industrial gas. Similarly, it would be illogical to provide compensation in the case of injury caused by a toxic substance enumerated in a list whilst no compensation is provided for cases due to a substance not comprised in the list and affecting a worker employed in the same workshop as another whose accident (disease) entitles him to insurance benefits!

In the case of a whole series of injuries in regard to which the occupational origin could be proved by medical examination of the cases in question, there is hesitation in admitting the claim primo jure, a point of view which leaves out of account the fact that very often the worker is unable to defend himself against poisonous or harmful fumes and dust where no effective method of eliminating them is provided unless he gives up his work entirely. Likewise, the fact is often overlooked that in many cases colourless and inodorous fumes which escape from pipes and apparatus may poison the worker without his being at all aware of their presence, even from the very outset of their action, which takes effect even with minimal doses.

Appeal is also made to the worker's carelessness and his neglect in regard to personal cleanliness, facts likely to favour the development of occupational disease or to increase the danger of poisoning. These facts must be recognised, yet, on the other hand, how many cases of occupational poisoning can be quoted as having occurred amongst individuals who exercised care, paid attention to bodily cleanliness, and were aware of the danger inherent in the substances manipulated? To go even further, how many experts, and even employers, have suffered from the effects of substances handled in ignorance, at times, as to the composition of these, and, at times, as to their harmful or toxic properties?

Modern industry employs increasingly products furnished by organic chemistry, and introduced into industrial practice without any previous study having been made in regard to their physiological action. There have besides been met with cases of poisoning caused by unexpected reactions having no connection whatsoever with the industrial operations in question (liberation, for instance, of phosphorus in the form of phosphoric acid), even the watering with hot water of residual heaps of molten ore containing phosphorus. It is only by means of long and extensive daily practice that it is possible to acquire accurate knowledge of the toxic action of products at first considered inoffensive or only slightly toxic.

Legislative authorities have always been faced with the difficulty of defining the object of insurance, given the necessity for specifying the substance by distinguishing as far as possible between that due to occupational disease and that due to causes of ordinary disease.

Jurisprudence, ordinary practice and theory have all sought to endow occupational disease with a special character differentiated from accident by certain characteristics which Peri summarises as follows:

Origin. — So far from constituting an exceptional occurrence, the disease is the consequence of routine work.

Nature and moment. — It may be foreseen by very reason of the work in question: it is fatal in the sense that it depends on the repetition of the same work, setting up an action which is constantly and imperceptibly manifesting itself rather than in one single occurrence.
Pathogenesis. — It is generally slow and insidious in origin, and difficult to determine.

Evolution. — It develops slowly, and may remain unnoticed until the outbreak of symptoms which are at times of sudden appearance.

Methods of work. — The methods of work determine the incidence in a given industrial centre, the anomalies of evolution, the gravity of the forms presented, the characteristics of the symptoms, the development of these symptoms, and the progress of a common disease.

Individual susceptibility. — The pathological cause does not evoke amongst certain workers noteworthy effects; amongst others it sets up very grave injuries.

Death. — Death is the result of a constant series of accidents, the repetition of which is bound to lead to this issue, since each of them diminishes the force of resistance of the system, with the result that each new accident is more serious than the former.

If the question be regarded exclusively from the point of view of "compensation", it must be recognised that the diagnosis is essentially medico-legal, since it is a question of estimating the medical character of the injury with the particular object of presenting a legal report (Biondi). Yet a medico-legal definition in each particular case presents great difficulty. In fact, though it may be easy to specify that a given cause of injury may, by multiple and repeated action connected with the normal progress of the work, cause a given lesion, it may happen, on the other hand, that the doctor is not in a position to prove that this lesion really depends on this particular cause of injury which has exerted its effect at a more or less distant date. To avoid repetition, there shall be examined briefly the question of compensation for infectious and parasitical diseases, since consideration of this question provides opportunity for analysing certain elements of the definition of accident in regard to which there has been, and still is, much discussion.

The question of assimilating these diseases to accidents or occupational diseases for the purposes of insurance is still highly uncertain and confused. In certain countries the legislative authorities have inscribed some infections in their list of occupational diseases (Switzerland, Great Britain, etc.), yet later — as, for example, in Switzerland — the medical authorities refused to designate them as industrial accidents. In Italy infectious diseases are also regarded as accidents (this is the case in regard to anthrax, in virtue of section 14 of the Act on insurance for occupational diseases). Ankylostomiasis, on the other hand, figures in the list annexed to this Act.

The question, which is of little consequence theoretically, affects in practice general or local infections due to specific germs, but, as regards infections, as in the case of other disease forms, a clear schematic differentiation between these and accidents is not possible. There exist too many transition forms on the border line between disease and accident which complicate the problem.

It appears that at the present moment it would be much simpler to include these diseases in the list of those entitling the victim to compensation, rather than engaging in discussion as to whether in each particular case the conditions required by the law on accidents are fulfilled. However, in many countries preference still tends towards following the system which was adopted at the time when the law existed only in regard to accidents, and infectious or parasitical diseases are compensated by an extensive interpretation, at times even a slightly forced interpretation, of the definition of an accident. It is chiefly the terms "sudden" and "violent" in the definition which have been made the subject of discussion by medical and legal authorities. At the present time the opinion has been generally accepted that the words "violent action" should not exclusively and essentially designate "a lesion of mechanical origin."

The difficulty of interpretation has been chiefly in regard to the term "violent". Yet agreement has now been reached in regard to the fact that "violence" in the question under discussion refers not only to the intensity but also to the potential unfavourable effect of the agent, but not to the lapse of time during which this agent exercises its effect on the system. Further, the term "violence" describes not only an unfavourable cause of mechanical origin but also a body or phenomena acting by reason of their very nature in an intense manner because of some inherent energy which manifests itself and which is capable of exercising an effect on the system attacked in an intense fashion. The action of solar radiation may in consequence be "violent" and likewise the action of a current of cold air or, again, that of a toxic substance when the harmful force liberated is sufficiently intense to cause death or disease, even when such action only exercises its effect during a very short time.
It has been fairly easy to extend this conception to cover forces of a biological order such as infections and parasites. In fact, these agents possess the capacity of setting up phenomena of a special character and notably a morbid condition. The disease agents introduced into the body constitute forces which by multiplication become causes of injury to the system.

The conception of "violence" in this case is identical with that of "virulence" especially when this capacity for harm is exercised by a small number of germs which have penetrated the body on one or several occasions but within a short lapse of time. The mechanism of entry into the body must be left out of consideration (traumatic lesion or otherwise, digestive or respiratory passage), for it is here a question of a violent occurrence represented by pathogenic germs capable of exerting "violent action" after having penetrated into the body.

There must be recalled in this connection the violent action on the system of certain toxic products. In this case it must be admitted that the only criterion should be the nature of the substances which have penetrated into the system, without requiring that such penetration is brought about by means of violent lesions.

As regards the other aspect of the question, that of duration of the action, it is hardly necessary to recall the lengthy discussion which has been going on with a view to determining the length of period designated by the expression "suddenness" in regard to this action. The idea of a sudden or instantaneous action has been abandoned, and use is now chiefly made, in accordance with the Italian interpretation (Carneluti, Borri), of the words "rapidity", "concentrated cause", remembering that the harmful action may exert its effect also by repeated contact during a short lapse of time and not necessarily on one single occasion. It may indeed be asked whether such a short lapse of time is to be calculated in minutes or hours or days. It is nevertheless true that in regard thereto it is necessary to adopt a practical attitude and that the limit in question is well indicated by the very conditions under which the harmful action exercises its effect. The length of a shift already provides a limit in time to the action of the harmful effect and in consequence concentrates the risk as regards time. Diez, who has made a careful study of this problem, enquires whether it would not be advisable to adopt a chronological unit as a standard of measurement of occupational activity, and a unit of measure of the pathological action representing a cause of damage to the system.

Finally, where the worker has been exposed during the course of a day's work, either uninterrupted or broken by short enforced rest periods, to a harmful cause which has given rise to disease phenomena without any subsequent repetition or renewal of such harmful agent in the course of successive periods of work, it may be admitted that in these circumstances the conditions of intensity required by the words "violent action" in the definition of an accident are complied with.

Any infectious or parasitical disease may, however, occur as the consequence of a single inoculation of germs or during a short period of contact between the individual and the source of infection. It is certainly difficult to determine exactly when the individual exposed to contagion has contracted the disease, or "during how long" he was exposed to contagion, except in the case of obvious localisation of infection. It is the occurrence in the course of work which must be insisted on rather than the "violent cause", since in practice many forms of infection occurring amongst workers are most usually of occupational origin: anthrax (hides and skins, hair); glanders (stableboys, veterinary surgeons, etc.); the possibility and probability of infection once admitted, any other considerations become superfluous.

The principle that the cyto-microbial struggle being engaged in within the body by the disease agent, once it has entered into contact with the tissues, may be considered as a violent lesion has been accepted in regard to tuberculosis. When the Koch bacillus enters a healthy body in limited number it there sets up a benign affection which may remain in a latent state even permanently. It is only when the germ invades the body in massive doses that the disease breaks out. Yet amongst individuals affected by a form of the bacillus in a latent state, the outbreak of tuberculosis occurs when the virulence of the disease agent has been increased, or when new germs penetrate into the system and are superimposed on those already there; re-infection breaks out and is manifested by the characteristic symptomology. The assistance of a traumatic cause acting on any part of the body is not an
essential element to the outbreak of a bacillary lesion. From the medico-legal point of view it would be, as stated above, necessary to prove that the violent cause (tuberculosis bacilli) has set up the disease form encountered "in the course of work". This proof is sometimes difficult to effect, for the infection of a worker by tuberculosis may equally occur outside working hours. Yet this difficulty should not discourage efforts to determine conditions providing a basis entitling workers to compensation. Carnelutti is of opinion that it is necessary to overcome a current instinctive attitude of repugnance which leads to traumatic lesions only being considered as accidents exclusive of those habitually designated as "diseases". In order that adequate compensation should be provided it is therefore essential to prove that the "generic" risk to which every man is exposed may become, as for example in the case of tuberculosis, a "specific" risk.

Peri, who has made a very thorough study of this question, is of opinion that all forms of tuberculosis amongst workers engaged in industrial processes during which the work exposes an effect capable of reducing means of organic resistance and indirectly favouring the entrance of the tuberculosis bacillus, do not come within the number of lesions covered by the definition of industrial accident, but they may, however, be included thereunder when there is a presumption, if not a certainty, that the tubercular bacillus has penetrated into the body during work in "massive doses".

If Gilbert's definition is accepted, tuberculosis becomes occupational in origin when found to occur with particular frequency amongst certain categories of workers. It is then a question, according to Peri, of workers occupied at work in the course of which a traumatic action exerts slow but constant effect on a certain part of the thorax: boatmen on the Rhône (Pernoud); alabaster workers (Pieraccini); persons engaged in nursing tubercular patients or handling the linen of such patients rich in infectious germs: nurses (Devoto); nursing sisters, nurses (Peri); laundry workers (Landouy); rag-pickers (Brouardel), etc. In other cases tuberculosis meets with a centre more favourable to its development by reason of lesions of another nature set up by causes of slow effect. The risk here is generic, and tuberculosis represents a lesion directly superimposed, not during work, but on a centre rendered susceptible by the effect of the occupation.

This is so, for instance, amongst workers engaged in confined and overcrowded workshops where light is insufficient and often artificial, or where the nature of the work demands the use of coal stoves: tailors, dressmakers, seamstresses, ironers and embroidery-workers, etc. (Romme, Allaria, Magrini); in overheated places with abundance of dust and atmosphere vitiated, for example, by tobacco smoke: postal and telegraph employees (Brouardel, Hericourt); hairdressers, clerks, waiters, etc.; in places with a high humidity rate: workers in spinning-rooms, laundry-workers, miners (Monti); in places with very high or low temperatures: metallurgical workers, glass-workers, workers in the cold storage industry; in places where toxic gases or fumes are given off: chemists, etc.; in places were dusty vegetable origins are present: coal, flour (Koelsch, Courmont), tobacco (Peri, Stephani), textiles (Durozier), sugar-refiners (Bernheim); or animal (silk, wool, horn, tortoise shell (Hirt); or mineral (stoncutters, grinders, polishers, etc.); in professions where the worker is obliged to assume a posture which limits thoracic expansion: shoemakers, watchmakers, bookbinders, etc.; finally, in occupations where the outbreak of tuberculosis is favoured by occupational poisoning: workers handling lead, arsenic, mercury, copper, zinc, etc.

Systems of Compensation

With a view to solving the problem of compensation, legislative authorities have in the different countries had recourse to systems which are based on three general principles:

(a) Admission that all diseases may be of occupational origin and their total assimilation to diseases (system of universal insurance for disease and invalidity);

(b) Admission that occupational diseases represent an occupational risk and compensation for these on the same basis as that of industrial accidents;

(c) Compensation in accordance with special legislation.

(d) The first of these principles without doubt presents many advantages. It has been seen that besides occupational diseases ("technopathies") there exist "industrial" diseases finding in the occupation their primary motive; that very often there is no demarcation line between the occupational disease and the ordinary disease; that it is often difficult to prove that the disease has been actually caused by the occupational activity of the victim.
though it is possible to determine in many cases just to what degree its development has been aided. The system of disease insurance eliminates the necessity of etiological diagnosis, and hence the necessity for establishing a medico-legal basis for estimation of the injury (incapacity for work). It eliminates likewise other difficulties; discrimination in complex cases, enquiry into the influence of the former state of health of the individual, his heredity, his manner of living, his lack of cleanliness or even his carelessness; it does away with the difficulty of distributing responsibility amongst various employers; it provides insurance for a larger number of workers, and compensates a whole series of slight illnesses of a somewhat evanescent nature which exist on the borderline of occupational pathology, but which in practice represent a highly important cause of absence and a starting point for many occupational diseases.

On the other hand the system of disease insurance has been open to several criticisms: first, compensation for occupational diseases in accordance with this system imposes on industry in general a burden for compensation which properly belongs to but a few of them; disease insurance leads to appeal for financial assistance to the workers and often also to the State; that is to say, to the whole social community, the most important part of which is represented by the working classes, with the result that the burden rests on a group which is already the victim of occupational disease properly to be considered as a risk inherent in industry, and which ought not to be borne even partially by the workers. Yet that is not all. The injury of occupational origin from judicial motives, both from the medical and human standpoint, ought to be compensated on a more generous scale than ordinary illness or invalidity. In certain countries, however, the insurance scheme in question only provides the victim with a maximum period of one year). No invalidity benefit is taken into consideration unless the disease lasts over twenty-six weeks and causes incapacity amounting to over two-thirds. This system requires a long waiting period and in the case of death only provides payment of a subsidy towards funeral expenses, and no allowance is granted to dependants.

With a view to eliminating certain of these disadvantages, several authorities have studied a system of compensation coming within the scope of sickness insurance with a special scheme in favour of workers in unhealthy trades who are victims of occasional diseases. In this case the burden of compensation is placed on a group of industries in which workers are employed who are exposed to similar risk and whose employers are obliged to pay a higher premium proportional to the gravity of the risk involved. In this way the employer is stimulated to improve healthy conditions in his industry with a view to obtaining entrance into a lower category from the point of view of risk than that in which he is actually classified (Carozzi, Sand, etc.).

(b) Legislative authorities were led to recognise the necessity for affording occupational disease a special place within the scope of their social insurance schemes; but on the one hand, since they possessed no definition permitting them to describe "occupational disease", and on the other hand they were faced with the difficulty of establishing an equitable system of compensation, a solution was sought by avoidance of the obstacle in refraining from formulating any definition, and restriction to the framing of a list of those occupational diseases which are on the intention to compensate, such list being annexed to the law on compensation. Hence arose the system of the list and recognition of a presumption in favour of the worker affected by an occupational disease inscribed on the list. In this way it was possible to obviate the necessity for a case by case method which in most cases it was impossible to furnish.

In certain countries for reasons of convenience, legislative authorities proceeded to extend the law on accidents to cover occupational diseases thus defined. In others, on the contrary, preference was given to a system which consisted in defining accident in such a way as to cover at the same time occupational disease.

The situation created in regard to infectious or parasitical diseases of occupational origin has already been referred to above. Nevertheless, under this system the very important part of the burden of compensation inevitably rests on the shoulders of the victim. In fact many occupational diseases which are on the borderline of ordinary disease forms thus receive no compensation or only receive it under a system of general sickness insurance. It is therefore only right that the injuries caused should be compensated in as wide and rapid a manner as possible in these cases without any argument as to their occupational origin.

Attention must now be bestowed on the form to be given to the list in question — already the subject of a certain amount of discussion and criticism.

Three different conceptions at least emerge.

The first is confined to inclusion of a series of diseases or lesions affecting workers without any reference to the clinical picture or to the various occupations involved. In the first column of the list certain diseases are enumerated, as for instance lead poisoning, mercury poisoning, etc., and their sequelae; in the second column there is a note to the effect that the injuries in question affect any worker engaged on any work involving the manufacture or use of lead, its compounds or alloys; "of mercury, its amalgams, salts, etc."

The second conception consists in enumerating in the first column certain symptoms of the disease legally entitled to compensation (for instance, of lead or mercury poisoning), and in the second
COMPENSATION — 309 — OCCUPATIONAL DISEASES

column corresponding point by point to these is detailed a list of the industries or operations likely to give rise to the said diseases. For instance, the French system of legislation provides compensation for paralysis, rheumatism, colic, cachexia, etc., due to the poisoning when such symptoms are found amongst workers engaged, for example, in metallurgy and refining of lead, tinning, manufacture of salts of lead, manufacture of pottery and china with lead enamels, etc. In consequence any disease showing symptoms not included in the list, or any clinical picture described in the list but not occurring in an industry mentioned in the second column, does not entitle the worker to compensation.

The third method is that followed in Swiss and Finnish legislation, and limits compensation to those injuries caused "essentially or exclusively" by one of the substances enumerated in the list.

These three different conceptions, however, provide subject for reflection. It would appear obvious that such lists ought to be made the subject of periodical revision and that they must be kept in continuous revision by doctors, employers and workers with a view to detecting at an early stage the occupational types of disease and rendering possible the immediate application of measures of prevention required. In this connection the French list possesses the advantage of constituting a highly useful guide for medical practitioners. Yet it has the disadvantage of fixing artificial limits.

In regard to propaganda it should be recalled that the German list is followed by a circular providing all requisite information as to what is implied by the formula adopted in the first column of the list (without, however, presenting the point of view in question in the form of a restrictive formula).

(c) The third principle involves special legislation such as that adopted, for instance, in Belgium. Compulsory insurance for industrial establishments coming within the law excludes the intervention of insurance companies on the ground that such insurance would eliminate the individual responsibility of the heads of undertakings and creates an insurance fund for providing indemnity for cases of occupational disease entitling the worker to compensation. Under this law a double list has been established giving, on the one hand, the various branches of industry coming within the law, and on the other those diseases which in each category of industrial work entitle the worker to compensation.

The insurance fund is controlled and guaranteed by the State. The annual contribution of heads of industrial undertakings is fixed by Royal Decree.

The Executive Committee entrusted with the administration of the fund is aided by a technical medical committee in which the employers' and workers' interests are duly represented. This Committee proposes cases which it estimates should be subjected to the law and also fixes the designation of disease forms to be mentioned in the list. It further assesses the amount of contributions.

When a worker is affected by an occupational disease contracted in one of the establishments in question he makes his claim for compensation to the fund which, after enquiring into the matter, confirms or rejects it, and having confirmed it, communicates its decision to the worker in question. In the case of a negative decision, appeal may be had to the legal authorities with a view to obtaining an award on the subject.

For details as to liberty in the choice of a doctor, compensation, injury, etc., reference should be made to the law.

There is one serious aspect of the problem which legislative authorities cannot afford to overlook, namely, the "allocation of responsibility" of the employers when the worker becomes the subject of an occupational disease.

The question is certainly more complicated than in the case of an accident. It is merely in the case of a worker who is the victim of an occupational disease having passed from one factory to another in the same industry that the question is not difficult of solution. It is a very different question when the worker affected has passed from a dangerous industry to another offering less occupational risk, or to another of quite different character. It is often difficult to attribute the correct share of responsibility for the origin of the lesion which should devolve on the different occupations, since it is often impossible to ascertain the starting point of the illness.

Further, it is essential to determine up to what point in time the employer is responsible for the injury or the disease contracted in the course of work by a worker whom he has employed. Apart from certain well-known infections, it is at times impossible to determine the exact date of the onset of the disease and the various circumstances which may have influenced its development. However, admitting the possibility of specifying the moment of the first onset on the system, is it always possible to ascertain at an early stage the importance of the sequelae which a given disease may involve? There have occurred cases accurately studied in which pathological phenomena, more especially in the case of chronic poisoning, have occurred after a fixed period (in general a year) and at a time when the patient had left the dangerous occupation.

The question of allocating responsibility for the risk between different heads of establishments in which the patient has been employed during the twelve months preceding the outbreak of the disease constituting another source for an industrial dispute and a lawsuit. In Great Britain, thanks to the special type of judicial institutions of the country, such disputes are, however, fairly rare. But it is not always the case, however. With a view to surmounting this difficulty the Belgian legislative authorities have sought the solution above referred to. They have thus done away with the necessity for
enquiring into the question of individual responsibility by not insisting that compensation should be paid directly by the employer to the employee, and have also reduced to a minimum motives for legal proceedings, by providing for the intervention between the interested parties of a competent neutral body to solve their difficulties.

In regard to the **international aspect** of compensation for occupational diseases, a Draft Convention was adopted in 1925 by the Seventh Session of the International Labour Conference. This Draft is extremely simple. Article 1 demands for victims of occupational disease or their dependants compensation in accordance with the general principles of national legislation relating to compensation for industrial accidents. The rates of such compensation shall not be less than those prescribed by the national legislation for injuries resulting from industrial accidents. Subject to this provision, each Member in determining in the national law or regulations the conditions under which compensation for the said diseases shall be payable and in applying to the said diseases legislation in regard to compensation for industrial accidents may make such modifications and adaptations as esteemed expedient.

Article 2 provides that each Member undertakes to consider as "occupational diseases" those diseases and poisonings produced by the substances set forth in the schedule appended to the Draft Convention (reproduced at the top of this page) when such diseases or poisonings affect the workers engaged in the trades or industries placed opposite in the said schedule and resulting from occupation in an undertaking covered by the said legislation.

This Convention, which came into force on 1 January 1931, was ratified by 1 July 1930 by the following countries: Austria, Belgium, Bulgaria, Cuba, France, Finland, Germany, Great Britain, Hungary, India, Irish Free State, Japan, Latvia, Luxemburg, Netherlands, Norway, Portugal, Sweden, Switzerland, and Yugoslavia.

It is not possible here to enter into other questions connected with the problem of compensation, that is to say training of doctors, drawing up of medical certificates to be forwarded to the competent authority, etc.

**BIBLIOGRAPHY**

There exists a very abundant bibliography on this subject. See the periodical publication of the **INTERNATIONAL LABOUR OFFICE** entitled *Bibliography of Industrial Hygiene* and the report presented to the International Labour Conference in 1934, *Workmen’s Compensation for Occupational Diseases*.

**APPENDIX**

In table I is given a list of the laws and Decrees issued in the various countries in regard to compensation for occupational diseases. It has not been possible to give in this article in their original form the national lists of occupational diseases compensated. It seemed, however, advisable to attempt to assemble in a single table the disease forms inscribed on the said lists (see table III). In order to understand this table account must, however, be taken of the fact that the causes, etc., enumerated in the first column are only intended to facilitate research and that it is the second and third columns which resemble closely the formula adopted by the legislative authorities enumerated in the fourth column. The formulae adopted in the second column therefore correspond to those inscribed by the legislative authorities in the first column of their national list, while those of the third column refer to the formulae which the national authorities have inscribed in the second column of their list.

1 As regards compensation for silicosis, simple or complicated by tuberculosis, in English-speaking countries legislation has developed by several stages, whilst at the outset (1900) it was excluded from the general law on accident compensation in Great Britain. It now figures in a more or less explicit form in all the laws of English-speaking countries. South Africa was called on to combat the disease in an acute form as affecting a single industry (gold mines) and adopted a system of compensation in 1912 which has not ceased to be amended and improved as regards application since that date.

Great Britain adopted the South African procedure in 1918 in regard to the refractory industries and extended it in 1927 to include metal grinding establishments. In 1928, however, the "Various Industries (Silicosis) Scheme" was drawn up (only allowing compensation for total incapacity and death) applying to risks connected with dusts generated by manipulation of quartz, quartzite, granite, sandstone gristone, and chert, excluding ore containing less than 50 per cent. free silica. Finally, other schemes have been drawn up for the pottery industry and the granite industry (compensation for partial incapacity with suspension of work). The law of 1 August 1939 also accords compensation for asbestosis. In Sweden compensation in accordance with the Act of 1930.

New South Wales in 1920 adopted a law compensating silicosis in the case of workers in the Cumberland district, and a special law for the Broken Hill Mines. Amongst the other Australian States Queensland is the only one which possesses a law granting compensation for silicosis. Western Australia passed a silicosis compensation law in 1929 which has not yet come into force.

In Canada, the Province of Alberta granted compensation for miners' phthisis (1925) and Ontario for silicosis (1926 and 1930). The other countries do not mention silicosis directly as a disease entitling the worker to compensation. However the insurance laws in certain of the United States are so drafted that silicosis may be interpreted as coming under the regulations on compensation.

diseases, there is unfortunately a want of intelligent co-ordination, which is obviously the prerequisite of practical results of far-reaching value. Many of the investigations which have been made, under the auspices of either labour or industry, have failed to produce results satisfactory to all concerned for this reason.

A notable exception in this respect is the Health Survey of the Printing Trades, carried on under the authority of the Joint International Council, representing employers and employees. In that survey a large measure of cooperation — official, corporate or otherwise — has been secured with the most admirable results. That survey is a typical illustration of the inadequacy of former investigations to meet modern requirements, for it may be laid down as a fundamental principle of labour relations that the conditions of work must be such as not to predispose to ill-health or premature death.

The principle has been laid down in the Federal Transportation Act that in any arbitration proceedings involving wage disputes, the Board of Arbitration is required to take the hazards of the occupation, or the industry, into account. The most significant practical application of that principle is to be found in the miners’ wage dispute of 1921, when a mass of so-called evidence was introduced on behalf of the Miners’ Union attempting to prove that mining conditions were not only seriously detrimental to health and life, but steadily growing worse. It did not require a large amount of evidence to establish that the contentsions made were not based on statistical enquiries, or on recent data, but largely upon statements of an earlier date. But the case precisely illustrates the danger of drawing far-reaching conclusions from an insufficient basis of fact and information. The nature of all such material, after best, can at any given time only prove suggestive of the probable state of things. The most careful statistical enquiry cannot do more than reveal an approximate state of facts, but it is of the very first importance that no method or means should be neglected to establish the truth of a given situation, beyond the chance of serious controversy.

In the Health Survey of the Printing Trades, these considerations have not been lost sight of. Conducted by an impartial agency, competent to initiate an original enquiry, the required information was obtained from the following sources:

First, a questionnaire was sent to all

---

**Industrial Sickness Statistics in the United States**

Industrial sickness, for the present purpose, may be defined as follows:

**Industrial sickness** is that form of labour impairment of a pathologic nature which can be traced to the vocational activity of the worker affected, and which disables him from the performance of his regular duties for a more or less prolonged period of time.

**Industrial mortality** is that portion of the general mortality which is traceable to the occupation followed at the time of death or previous thereto.

**Industrial efficiency** is that condition of health and strength which yields the largest measure of occupational results, without undue fatigue or bad physical effects.

The use of these terms is rapidly broadening, particularly in connection with workmen’s compensation legislation. In a more restricted sense the terms affect decisions in life and accident insurance, as well as liability legislation not covered by specific statutory requirements. In workmen’s compensation legislation, particularly in English-speaking countries, industrial diseases are as yet as a rule provided for to only a limited extent. The scheduled group of such diseases under the British Workmen’s Compensation Act of 1906, while somewhat extended during more recent years, falls still measurably below the expectations of those whose interests are directly concerned in a broader interpretation.

While there is much activity in advancing knowledge regarding industrial
of the labour organisations representing the essential branches of the printing trades. Second, a somewhat different questionnaire was sent to representative employers; it obviously would have been impossible to cover the entire field, on account of the immense extent of the printing industry and the enormous number of small printing plants, with widely varying conditions. Third, the cooperation of sanitary officers of many of the principal cities was secured, and on the basis of a small blank, inspections were made by qualified officials into the actual sanitary conditions of representative plants, large and small. Fourth, an official of the United States Bureau of Labour, with long experience in the printing trades, was commissioned to visit personally a large number of printing plants throughout the country, reporting upon the shop conditions observed on a visit personally made, based upon an extended knowledge of the situation. Fifth, supplemental to the foregoing, a considerable amount of statistical information regarding mortality was collected: (1) from general sources, such as Boards of Health, or Departments of Vital Statistics, (2) through the mortuary records of principal printers’ labour associations, (3) the experience data of life insurance companies, particularly under group insurance. Sixth, through the cooperation of the resident physicians of two printers’ tuberculosis sanatoriums medical examinations were made and much additional information secured relative to several hundred tuberculous printers, in order to reveal any facts bearing upon a possible occupational origin of the disease. This line of investigation was amplified by the cooperation of several large insurance companies, through the cooperation of non-tuberculous printers, through the cooperation of several large insurance companies, or otherwise. Seventh, through the expert special agent of the United States Bureau of Labour, during those field investigations, nearly a thousand physical measurements were secured of printers, revealing the essential bodily proportions, particularly as regards the chest and the height and age. Eighth, through the cooperation of the United States Bureau of Mines, a number of dust and fume investigations will be made, which are expected to throw much light upon the debatable question whether the air conditions in the ordinary printing shop, or the dust of machine composition, are seriously detrimental to health. Ninth, special information was secured regarding a large number of aged printers, still members of labour organisations; to all such an individual blank was sent, to secure a considerable amount of additional and highly useful information, including the duration of the trade life, the sickness experience, the present condition of health, the occurrence of lung affection, eye-strain, lead poisoning, etc. The average trade life of nearly five hundred such printers was found to be forty-nine years. Tenth, an effort was made to secure special information regarding accidents in printing plants, but most of the evidence in this respect was negative. Through the cooperation of Workmen’s Compensation Boards, or otherwise, much useful information, however, was secured, likely to prove suggestive in further efforts to reduce the accident hazards.

This, in brief, is an illustration of an industrial disease investigation, likely to provide the largest measure of practical results. The conclusions to be derived from the investigation cannot be successfully contradicted, since the evidence was impartially derived from employers and employees and governmental sources.

Industrial sickness statistics are as yet only available in a fragmentary form. The principles upon which such statistics should be collected have not been clearly defined and perhaps are not reducible to generally acceptable terms. So much sickness is of so short a duration that its compensable nature is largely a matter of personal inclination. Many men, at any given time, may be at work, although slightly indisposed. Mere records of absences from work are inconclusive, because they may, or may not, represent sickness, within the sense of the definition generally adopted.

In the Health Survey of the Printing Trades both labour organisations and employers were questioned as to the number of men at work and the number of men absent on account of sickness. On the basis of returns made by 1,489 employers, representing 65,248 employees, the number absent at the time of the enquiry, on account of sickness, was only 423, or 0.6 per cent. The corresponding returns received from 151 labour organisations, representing 35,783 members, showed that 286, or 0.8 per cent., were absent on account of sickness. Both returns are suggestive of an extraordinarily small incidence of sickness, indicative of health conditions conforming, on the whole, to reasonably exacting standards.

It would seem that such a method is more likely to produce practical
results than the experience under compulsory health insurance, or of voluntary sickness associations, which to a certain extent hold out the temptation of malingerers, which may be more or less prolonged.

The wholly unsatisfactory character of American occupational mortality and morbidity statistics is reflected in the treatment sometimes devoted to this subject.

It requires no extended analysis of certain statistical tables to reveal inherent inconsistencies, emphasising the inconclusiveness of the data and the risk of basing far-reaching conclusions upon their significance. Thus, for illustration, combining all ages, the mortality rate of male bar-tenders is given as 6.7 per thousand, while the rate for brewers and maltsters is given as 14.4. Finally, compositors and typesetters are stated to have experienced a mortality rate of 8.3 per thousand, while for confectioners the rate was only 0.8. Such apparent contradictions, obviously opposed to known facts regarding the industries referred to, are worthy of remark.

It would hardly serve a useful purpose to enlarge upon foreign data subject to interpretation on the part of those thoroughly familiar with the conditions under which they have been collected. The standard occupational mortality tables for England and Wales may, however, be referred to as the most trustworthy sources of occupational mortality conditions, while they, of course, preclude definite conclusions concerning the morbidity for particular trades. As has been pointed out, the term "sickness" has not been defined in general usage to the point of general acceptance and extreme caution is therefore, required in comparing the returns of one country with another. There is the utmost urgency of standardising the methods of occupational sickness investigations, so that a better basis of acceptable facts may be secured. It may be suggested that all sickness causing an absence from work of less than three days should be excluded from industrial sickness statistics.

The most useful source of information would seem to be trade union experience, provided such organisations can be induced to adopt statistical methods above serious criticism. Unfortunately, few such organisations have realised the extreme importance of carefully examining the facts of their experience from the medical point of view, being primarily concerned with the distribution of cash benefits to their beneficiaries. There is, however, a wealth of material susceptible of critical analysis, which should be made available to those who are directly concerned with occupational disease investigations.

A striking illustration of the foregoing is the mortality experience of the International Granite Cutters' Union, utilised in the report The Problem of Dust Phthisis in the Granite Industry, published by the United States Bureau of Labour Statistics in 1922. While that investigation was primarily concerned with mortality, there are reasons for believing that it might to advantage have also been extended into the field of morbidity.

In the course of that investigation the remarkable fact was disclosed that while tuberculosis had very considerably declined among the general population, in the stone-cutting communities the pulmonary tuberculosis death rate of granite workers had increased from 3.32 thousand during 1896-1899, to 10.44 per thousand during 1915-1918. But it requires no extended investigation to disclose the inaccuracy of many of the diagnoses of pulmonary tuberculosis, which more properly should have been certified as fibroid phthisis, often without tubercular complications.

The consistency of the trade union mortality experience, revealing a general death-rate from all causes of 20.1 per thousand among granite-cutters of the Barre, Vermont, district, is illustrated by the fact that the corresponding mortality of men in stone and slate quarries of England and Wales during 1890-1892 was 20.3 per thousand; but the mortality from so-called pulmonary tuberculosis among granite-cutters of Barre, Vermont, was 11.84 per thousand during 1911-1917; against 3.62 per thousand among the stone and slate quarry workers of England and Wales. The higher mortality from so-called pulmonary tuberculosis among the granite workers of Vermont is directly attributable to the conditions under which the work is being carried on, which involves the continuous inhalation of large quantities of highly siliceous stone dust.

The granite stone investigation further emphasises the supreme importance of the trade life, in determining
the incidence of particular affections. It was pointed out at the time by Dr. Hoffman that the results suggested the need of a thorough and impartial medical enquiry into the facts conforming to the methods followed by the Miner's Phthisis Prevention Office of South Africa, in view of the conclusion that "the health injuries or consequences of dust exposure in granite-cutting and quartz-mining -- under normal conditions, do not attain the most serious proportions until a workman has been employed at his trade for about twenty-one years".

The Vermont investigation also emphasises the importance of taking into consideration the physique of the workers concerned. From such data as were collected by means of physical examinations, it was stated that the physique of granite workers was normally above the average for occupied males generally, in accordance with life insurance experience, and that, therefore, a physically superior type suffered disastrously as the result of occupational conditions, more or less admitting of remedial measures.

The foregoing illustration must be sufficient for the present purpose, of emphasising the value of a broader method of enquiry into occupational conditions, productive of disease or premature death. It admits of no argument that the problem is an enormous one, particularly in the United States, where the number of persons employed in gainful occupations at the present time is placed at nearly forty-two millions, or 39.4 per cent. of the total population.

There is small inherent value in occupational mortality and morbidity statistics for industries collectively considered, for the effects of injurious conditions invariably fall upon a relatively small proportion of the workers engaged in particularly hazardous occupations. The segregation of such employments is, therefore, of the very first importance, if practical results are to be realised. Thus, for illustration, in the pottery industry, only a relatively small number of workmen are exposed to the actual hazard of lead poisoning, and the same is unquestionably true of printing and the manufacture of electric batteries. If health injurious conditions are to be removed, they must, therefore, be dealt with in a highly specialised manner, as best illustrated by some of the extremely valuable reports on particular occupations, which have been forthcoming from the British Factory Inspection Department. The field which requires thorough investigation is enormous. Many enquiries demand highly specialised, technical training, if the results are to be acceptable to both employer and employee. No advantage is gained by merely pointing out health injurious conditions, unless the cause or conditioning circumstances are emphasised with practical suggestions for their removal or control. It has been shown by the phosphorus match legislation that the statutory prohibition of dangerous processes may result in the radical improvement of conditions heretofore unbelievably dangerous or otherwise bad.

In conclusion attention may be directed to an effort made by the United States Public Health Service to improve the sickness statistics for industrial and other establishments. That office has published a number of important papers, of which a recent discussion on "Sickness among Office Workers" illustrates this principle. The information was obtained through the co-operation of the medical research department of a large corporation in the Middle West.

The average number of persons on the office pay-roll during the year ending 31 January 1921 was 1,289, with women in the majority. A record was kept of the hours lost from work by each person, on account of sickness and injuries and the data obtained were checked through the medical department. The illnesses causing disability were diagnosed through the medical department or with the aid of the family physician, and an attempt was made to include every hour lost from work on this account.

During the year under observation there were 11,259 calls at the dispensary representing 2,751 lost-time cases. The number of eight-hour days absent from work, on account of such sicknesses was 10,450, representing an average of 8.15 days of eight hours each. The most important cause of absences was common colds, represented by 435 cases and 1,393 visits, but the average number of days lost on account of such colds was only 0.50. Another important cause of absences was sore throat, represented by 53 cases, 1,014 calls at the dispensary and an average absence of 0.23 days. Minor injuries come next, represented by 52 cases and 1,153 visits, but the average number of days lost on account of such colds was only 0.06. Influenza caused 403 cases of illness and 2,520 days' absence, representing an average time loss of 1.97. Other illnesses are of minor importance.

It is obvious that such an experience is not representative for industrial workers, but it is suggestive of the pos-
sibilities of securing better data for men and women at work in more dangerous or unhealthy occupations. It is hardly necessary to point out that to be strictly accurate and comparable all such information should be collected separately for men and women. In the case of the present investigation it is stated that 65 per cent. of the employees were women.

A more important investigation for the present purpose is a preliminary report concerning Morbidity Statistics as an Aid to Preventing Illness among Miners, by R. R. Sayers, Chief Surgeon, U.S. Bureau of Mines, as Chairman of a Sub-Committee on Preventive Illness, appointed by the American Institute of Mining and Metallurgical Engineers. The report contains the following statement:

All operators are interested in knowing how much working time is lost by the employees and how much of this absenteeism is due to sickness. Many of the larger companies, and some of the smaller ones, have the requisite organisation to determine the effect of different kinds of work and working conditions on those exposed in terms of frequency and severity of disability. Some plants now secure this data, and use it: others secure it, but make little or no use of it. One lead smelter in the United States has a full-time medical and safety organisation which makes physical examinations of all applicants for employment and at intervals thereafter. Sickness records are kept of all illness. This company decreased the yearly incidence of lead poisoning from 87 cases to 35 cases in four years. However, they had not compiled and analysed their records during the period, but on doing so found that the decrease in the number of cases was chiefly among those occurring about the blast furnace. At this point the number of cases was decreased from 47, occurring during a year, to 5 cases during a like period. The analysis of the records further showed that there had been little or no decrease in the number of cases occurring about the preroasters and charge floor — 24 cases as compared with 22 cases per year at the end of the period. A physical examination of each of the employees of the above departments was made at once by the plant physician and over 60 per cent. of the total number were found to be ledared. The conditions in the three departments were investigated and practical means taken to eliminate the hazard.

It is not feasible to reproduce the forms or blanks used in connection with the suggested investigations, but it will be sufficient for the present purpose to point out the direction in which American thought concerning the subject is gradually developing. There is now a clearer recognition of the importance of the sickness factor in industry and a better appreciation of the practical value of preventive methods. All of this, of course, implies at the same time the development of employees' medical and hospital service work, including the physical examination of employees and their periodical re-examination, as occasion may suggest.

In conclusion may be cited the following remarks by Dr. Sayers, as emphasising perhaps to best advantage the modern viewpoint of joint management, in its relation to health and longevity, now widely met with in the United States of America:

A plan is now being devised for the systematic utilisation of such morbidity records as are being accurately kept. About once in every six months a representative of the Public Health Service plans to visit those companies which are keeping sickness records, go over some of the records to see that the work is being properly carried out, help to overcome difficulties that may have arisen, and suggest an appropriate line of analysis of the data.

In return, the service expects co-operation from companies in making morbidity data available for the study of industrial hygiene and the advancement of industrial medical work. The results of some of the studies the Service will want to publish, and the assistance of different companies will be needed in the work of making the data available for the purposes suggested. A condition is considered "good" or "bad" as based on experience elsewhere, or too often on theoretical and general grounds. Groups of men are given physical examinations and placed on jobs usually upon rather general considerations, or conclusions are drawn from the presence of specific defects, as to the effect of occupation. Because of inadequate data, and at times unsuitable methods, conclusions doubtless have been reached that have been unjust to the industry, and, on the other hand, probably serious conditions have been overlooked because the right kind of methods have not been used for discovering them.

The continuous record of the occurrence of ill-health for each employee affords a sound and thoroughly practical method. It is in line with the principles of scientific research. The sickness record of an employee is a dependable measure of his health, provided that illness of short duration be recorded, even though some diagnoses be statements of symptoms only.

It seems appropriate in this connection to refer very briefly to a standard method of industrial sickness reporting, based upon investigations on the part of the United States Public Health Service. The Service recommends two plans for recording and reporting sick-
ness among industrial employees and sick benefit associations, formulated by a special committee on industrial morbidity statistics, of the Vital Statistics Section of the American Public Health Association.

Plan A provides for an individual personnel card, which is to be kept for every employee and to be taken into consideration, whether the individual becomes sick or not. The card suggested is as follows:

MODEL FORM FOR PERSONNEL AND SICKNESS CARD—FACE

<table>
<thead>
<tr>
<th>1. Name of employee.</th>
<th>2. Check No.</th>
<th>3. Date this record begins</th>
<th>4. Firm No.</th>
<th>5. Date employment ended.</th>
</tr>
</thead>
<tbody>
<tr>
<td></td>
<td></td>
<td></td>
<td></td>
<td></td>
</tr>
</tbody>
</table>

11. Departments and occupations in plant.

From— To— Months. Department. Occupation. Possible injurious conditions.

12. Former occupations outside of plant.

13. Remarks:

The card on the reverse side contains the following information:

MODEL FORM FOR PERSONNEL AND SICKNESS CARD—REVERSE SIDE

Record of Absence from Sickness and Non-Industrial Injuries

<table>
<thead>
<tr>

<tbody>
<tr>
<td>Beginning— End—</td>
<td></td>
<td></td>
<td></td>
</tr>
<tr>
<td></td>
<td></td>
<td></td>
<td></td>
</tr>
</tbody>
</table>

18. Remarks:

Form A-1-1919—U. S. Public Health Service.

When personnel cards of any other form are already kept, uniformity in sickness records may be secured by certain modifications.

It will be observed that these cards conform to actuarial methods, as in general use with life and sickness insurance companies. It is explained that:

From these personnel cards monthly tabular statements can be made showing the number of workers, the number of cases of sickness occurring among them, and the sickness rate per thousand persons, for any group of workers.

By means of certain mechanical aids for identification, the utility of this kind of record can be very materially enlarged. Thus, for illustration, a chosen indication for any illness by means of a red or a blue marker can be attached at the time of entry, to the card, and removed at the end of the month.

The reports required by the Public Health Service, from plant managers or officials of sick-benefit associations, are expected to contain the following information:
There are some additional forms, showing a list of cases of disabling sickness each month, listed separately, but these do not seem to require extended consideration.

The two reports in question provide for the monthly tabulation of the incidence of sickness and its severity, in terms of sick days, of each disease and of all diseases, as may be worked out from the available material. It will be granted that however simple the arrangement, it will meet all ordinary requirements. Special sickness investigations can easily be derived from these fundamental sources, if suggestive of more extended investigation.

Plan B of the United States Public Health Service is a much more simplified method, designed for plants and sickness associations, which find it impossible to keep personnel cards for each employee. It, however, affords a record from which a monthly statement can be made of the number of employees or members of sickness associations, employed in the various operations of the department with which they are connected. This form, however, will often prove insufficient for practical purposes and for special research. Its final analysis general sickness data are of no practical value in connection with investigations that aim at the ascertainment of causes or conditions responsible for the occurrence of particular occupational affections. It is, therefore, to be hoped that the form recommended by the United States Public Health Service will be generally adopted, though subject to modification and improvement in the light of subsequent experience.

Dr. L. F. Hoffmann
(Boston, U.S.A.)

OCCUPATIONAL DISEASE STATISTICS IN EUROPE

The diseases which may result from an occupation may be divided into two principal groups. First, those in which it cannot directly be determined whether they are the result of the occupation, because they are as likely to be due to other causes (e.g. bronchitis, pneumonia), or because the injury caused by the occupation merely creates a tendency to the disease (e.g. phthisis). Second, the diseases which are directly caused by the health risks of the occupation and may therefore be ascribed to it without question, is to say, occupational diseases in the more limited sense — so-called “technopathies” (e.g. pneumoconiosis, anthrax, occupational poisoning). If the term “occupational disease” is taken in the wider sense, including both groups and therefore also tuberculosis, the statistical methods must obviously allow for the differences between the two.
In the first group, it is not possible to distinguish between cases of illness and death connected with the occupation from those not so connected. Consequently, the data in the records of sickness and death must be worked up. Only a higher rate permits of the conclusion that the occupation is a contributory cause, but contemporaneous social, economic, and local influences must also be taken into account. In considering occupational diseases in the more limited sense the object must be to cover all cases of sickness or death in question and relate them to the section of the workers exposed to these dangers. It follows that in the first case use must be made of general morbidity and mortality statistics, while in the second special investigations are necessary, which either may be connected with general statistics, or owing to the rareness of these have to be undertaken separately.

**Dust Hazards.**

Simple dust, not mixed with poisonous materials, such as is inhaled in several occupations, sometimes in large quantities, gives rise to nasal catarrh, inflammation of the throat, bronchitis, pneumonia, or the permanent infiltration of coal, iron, sandstone or silicate dust in the lungs. Frequently, a clinical examination is not sufficient to distinguish between pneumoconiosis and phthisis. The former is not a tubercular disease, but may lead to its development, and is frequently classified under phthisis in mortality statistics. Diseases due to the inhalation of poisonous dust belong to the second group.

Occupational mortality statistics can provide detailed indications only if they cover the causes of death. The only statistics available are the English calculations of mortality made for several decades back, the Dutch statistics for 1908-1911 and the Swiss for 1888 to 1900. The chief difficulty in using these statistics is to make the classifications of occupation in the census and the mortality returns agree. In spite of the various objections which are continually being raised against these statistics, they offer a useful basis for considering the hazards in many occupations. More restricted investigations are often made, but unfortunately the statistical calculations are frequently erroneous.

The most frequent mistake made is that the causes of death due to diseases are calculated as percentages of all deaths. The results of this can be approximately correct only when the general mortality is equally high. Otherwise the results may give quite a false impression. To take an example from the English statistics for 1900 to 1902:

**DEATHS DUE TO PULMONARY TUBERCULOSIS**

<table>
<thead>
<tr>
<th>Age-group</th>
<th>Agricultural labourers</th>
<th>Inn-keepers</th>
</tr>
</thead>
<tbody>
<tr>
<td></td>
<td>Per 1,000 living</td>
<td>Per 100 deaths</td>
</tr>
<tr>
<td>25-30</td>
<td>1.13</td>

<td>0.77</td>
<td>1.08</td>
</tr>
</tbody>
</table>

The figures show that the mortality from phthisis is very much higher among innkeepers than among agricultural labourers: the percentage figures give quite a wrong impression. A similar remark applies to mortality statistics. It follows that cases of death and disease must always be related to the number of living persons.

In view of the large differences in the age distribution of the persons belonging to the various occupations, this must be taken into account in mortality statistics, as otherwise serious misconceptions would arise. This is less so in the case of the morbidity statistics, as the number of cases of illness does not differ so much with age as that of deaths, but even here the age distribution must be taken into account. The English statistics for 1900 to 1902, for

---

1 Since the preparation of this article for publication the methods referred to in connection with mortality statistics for England and Wales have been somewhat modified. The Registrar-General's Decennial Supplement for England and Wales, 1921, describes a change in methods of tabulation followed in the 1921-1923 Report. This change includes a modification in the nature of the population used as standard. Formerly the total male population aged 25-65 was employed, but now there is taken as basis that of occupied and retired civilian males aged 20-65. The reason for extending the age by including the group 20-25 years is stated to be the belief that the average worker has at the age of twenty been long enough subjected to the environmental influences of his occupation to make definite influence upon his mortality possible, and the reason for substituting males engaged in or retired from a civilian occupation for the former total male population is that since the population in each occupation dealt with consists of occupied and retired civilians alone it is therefore more appropriate that the standard of comparison should be similar.

As it has not been possible to reconstruct the present article on the basis of these changes attention is here drawn to the fact that the tables, etc., are in accordance with the former practice.
instance, show the following figures for the age-group 25-65 years:

<table>
<thead>
<tr>
<th>Age-group</th>
<th>Crude death-rate</th>
<th>Standard death-rate</th>
</tr>
</thead>
<tbody>
<tr>
<td>Coal mining</td>
<td>10.75</td>
<td>12.46</td>
</tr>
<tr>
<td>Shipbuilding</td>
<td>12.15</td>
<td>11.51</td>
</tr>
</tbody>
</table>

The differences in the two calculations may be explained by the difference in the age distribution, which was as follows:

**AGE DISTRIBUTION PER 1,000 WORKERS**

<table>
<thead>
<tr>
<th>Age-group</th>
<th>Coal mining</th>
<th>Shipbuilding</th>
</tr>
</thead>
<tbody>
<tr>
<td>25-35</td>
<td>427</td>
<td>351</td>
</tr>
<tr>
<td>35-45</td>
<td>289</td>
<td>272</td>
</tr>
<tr>
<td>45-55</td>
<td>189</td>
<td>219</td>
</tr>
<tr>
<td>55-65</td>
<td>95</td>
<td>158</td>
</tr>
</tbody>
</table>

Since in the age-group 25-65 the frequency of phthisis does not vary so much in the different decades, the crude death-rate gives approximately the right order for the different occupations, as regards mortality but it cannot be an exact measure of mortality. For instance, in England in 1900-1902 the phthisis death-rate figures for the age-group 25-65 years were as follows:

<table>
<thead>
<tr>
<th>Age-group</th>
<th>Crude death-rate</th>
<th>Standard death-rate</th>
</tr>
</thead>
<tbody>
<tr>
<td>Shipbuilding</td>
<td>3.56</td>
<td>3.50</td>
</tr>
<tr>
<td>Coal miners</td>
<td>3.60</td>
<td>3.10</td>
</tr>
<tr>
<td>Coal miners</td>
<td>3.90</td>
<td>3.75</td>
</tr>
<tr>
<td>Textile workers</td>
<td>2.54</td>
<td>2.72</td>
</tr>
<tr>
<td>Shipbuilders</td>
<td>2.41</td>
<td>2.27</td>
</tr>
<tr>
<td>Domestic servants</td>
<td>1.45</td>
<td>1.75</td>
</tr>
<tr>
<td>Fishermen</td>
<td>1.66</td>
<td>1.62</td>
</tr>
<tr>
<td>Farmers and farmers' sons</td>
<td>1.39</td>
<td>1.07</td>
</tr>
</tbody>
</table>

Owing to the comparatively small numbers of persons in the higher age-groups, the crude death-rates are too low for coachmen, coal miners, textile workers, and domestic servants, while for the opposite reason they are too high for shipbuilders and farmers. A similar remark applies to morbidity rates.

The method of calculation is quite simple. The number of males living at the census and aged between twenty-five and sixty-five, yielding a mortality of 1,000 in the census year and the years preceding and succeeding it, was taken as the standard population. For the 1901 census this standard population was for England and Wales 71,005 persons. This figure was then divided in proportion to the figures obtained by the census for each age-group: 25-35 years, 35-45 years, etc. In each occupation covered by the census, the annual mortality rate for the occupied and for each age-group was calculated on the basis of the census returns of the population, and of deaths registered during the three years 1910-1911-1912 in the middle of which the census took place. Then by multiplying the above standard population at each age, and adding for each occupation the figure for each of the four age-groups thus ascertained, a figure is obtained, which represents the comparative mortality, which is accurately comparable with the 1,000 deaths amongst the general population, or with the analogous figures obtained similarly for any of the other occupations.

The following results are obtained for coal-mining and shipbuilding:

<table>
<thead>
<tr>
<th>Age-group</th>
<th>Crude death-rate, 1900-1902</th>
<th>Standard death-rate</th>
</tr>
</thead>
<tbody>
<tr>

<td>71.005</td>
<td>10.75</td>
</tr>
</tbody>
</table>

Taking the crude rates, the mortality of brewers was higher. Taking the standard rates, it was lower, although the differences were small. They are much larger in the case of respiratory organs, which increases rapidly with advancing age. The figures shown in the table in the next column are taken from the English statistics for 1900-1902.
The English statistics give the standard rates by equating the mortality for all men in 1900-1902 to 1,000 (it was 14.083 per thousand), which gives a death-rate from respiratory diseases of 195 in coal-mining and 161 in shipbuilding. The differences between the crude and standard death-rates would be still larger if persons over sixty-five years of age were included.

The number of expected deaths may also be calculated, but this requires a knowledge of the original data. Assuming that the mortality in the individual occupations is the same as for all men, the death-rate is calculated, the number of expected deaths equated to 1,000, and the proportion of recorded deaths calculated. The English figures for 1900-1902 of deaths due to respiratory diseases in the coal-mining and shipbuilding industries were as follows:

<table>
<thead>
<tr>
<th>Age-group</th>
<th>Death-rate of all men</th>
<th>Shipbuilding</th>
<th>Coal-mining</th>
</tr>
</thead>
<tbody>
<tr>
<td></td>
<td></td>
<td>Number of workers</td>
<td>Number of deaths</td>
</tr>
<tr>
<td></td>
<td></td>
<td>Recorded</td>
<td>Expected</td>
</tr>
<tr>
<td>25-35</td>
<td>6.724</td>
<td>61,347</td>
<td>47</td>
</tr>
<tr>
<td>35-45</td>
<td>1.699</td>
<td>47,550</td>
<td>73</td>
</tr>
<tr>
<td>45-55</td>
<td>3.380</td>
<td>38,360</td>
<td>104</td>
</tr>
<tr>
<td>55-65</td>
<td>7.182</td>
<td>27,639</td>
<td>126</td>
</tr>
</tbody>
</table>

In the shipbuilding industry the number of deaths due to respiratory diseases per thousand expected was 922, in the coal-mining industry 1,072. Here, too, it will be seen that the number falls below the expected figure in shipbuilding but exceeds it in coal-mining. If the shipbuilding death-rate is taken as 100, the coal-mining figure will be 116. The calculated standard rates above give the proportion 100 to 122.

In morbidity statistics the cases of phthisis cannot be separated out reliably, as they are recorded under various names (bronchial catarrh, pulmonary inflammation, pulmonary hemorrhage, pulmonary complaints, etc.). It may lead to gross error to try to include cases recorded in sickness fund statistics and classified under different diagnoses. Teleky introduced a very wide classification under phthisis for the sickness statistics of the Rhenish sickness funds: spitting blood, pleurisy, pulmonary disease, pulmonary complaints, bronchitis (prolonged cases of relapse, especially in persons of over fifty years of age). In any case it is advisable to make use of the death-rate statistics as a check. It is therefore better to limit the statistics to those of respiratory diseases. When the number of the acute diseases (angina, bronchitis) is very high it is unimportant whether the cases diagnosed as phthisis are included. It must always be remembered, however, that these diseases are very frequently caused not merely by the inhalation of dust, but also at work in the open air or in overheated rooms.

Sickness funds have no difficulty in establishing the number of cases of illness, but it is not so easy to determine the average membership by age. This requires a census of the members by age and sex, and in seasonal trades an annual census is not enough. One could be taken also at the beginning and one at the middle of the year, so that the three sets of figures would give an average age distribution for the year. The average of the monthly membership figures would give an annual mean. It is more reliable to calculate the number of days of sickness per member; by dividing this total by 365, the number of the average working complement is obtained. This procedure was used for the important statistics of the Leipzig District Sickness Fund. In determining the risk of accidents, or of occupational poisoning and infection, sometimes only the number of days to which such risks apply is used, i.e. about 300 days.

A comparison of the morbidity in different sickness funds is not possible, unless they have the same regulations concerning the payment of sickness benefit, from the first or a later day, on Sundays and holidays, concerning the period of payment and similar matters. A comparison of the morbidity in different trades will mostly have to be confined to one and the same fund. The extent to which the morbidity may differ for different funds in a small district has been shown in Teleky’s statistics for the Rhenish Sickness Funds, and elsewhere.

A third method of determining the frequency of phthisis in an occupation is to examine the whole body of workers employed. Occasionally Lorder-line cases the results of such an examination are very uncertain.
Besides the actual examination of the lung, there should also be a tuberculin test and X-ray photography. The results of different examinations cannot be compared unless they are made by the same person. This method allows only of establishing rough differences.

Although nowadays the dust risks in many occupations have been very much reduced by exhaust appliances, etc., there are still several occupations in which the workers' lives are exposed to serious risks from the formation of dust. Organic dust (flour, wood, wool, or cotton dust) is much less dangerous, as also coal dust, which, strictly speaking, belongs to this group. Tobacco dust is more dangerous, presumably owing to its nicotine contents. Inorganic dust has still the most serious effects in some occupations. The risk run by plasterers and brick and cement workers are not so great, but they are very serious in the case of stone-cutters, china-and pottery workers, basic slag grinders, cutters, file-makers and glass-cutters, and especially in work in which the dust is mixed with poisons such as lead. The first table in the next column shows some of the worst examples from the English statistics for 1910-1912, compared with the favourable figures for miners.

### Ratios in Per cent. of Tuberculosis Deaths to Total Deaths in Occupations Exposed to Mineral and Metallic Dusts

<td>1.28</td>
</tr>
</tbody>
</table>
The data on which some of the figures are calculated are not very numerous, so that for some occupations the standard deviation is large. Such an incidental cause is probably the reason for the excessively high mortality of glass-cutters from phthisis.

The following figures are taken from the morbidity statistics of the Leipzig Sickness Fund and apply to male employees liable to insurance. The standard rates per 100 members have been calculated for the age-group 15-74 years on the basis of the age distribution of all such members. The morbidity involving incapacity to work was as follows during the year:

<table>
<thead>
<tr>
<th>Occupation</th>
<th>Phthisis</th>
<th>Respiratory diseases</th>
<th>Both</th>
</tr>
</thead>
<tbody>
<tr>
<td>Compositors</td>
<td>1.39</td>
<td>6.09</td>
<td>7.48</td>
</tr>
<tr>
<td>Tobacco workers</td>
<td>1.62</td>
<td>6.97</td>
<td>8.59</td>
</tr>
<tr>
<td>Stone-cutters</td>
<td>2.44</td>
<td>10.30</td>
<td>12.74</td>
</tr>
<tr>
<td>Metal polishers and grinders</td>
<td>1.61</td>
<td>7.82</td>
<td>9.43</td>
</tr>
<tr>
<td>All occupations</td>
<td>0.78</td>
<td>5.65</td>
<td>6.43</td>
</tr>
</tbody>
</table>

In occupations with a high death-rate from phthisis all the branches of the trade are not equally exposed to the risk of this disease. Among cutters, for instance, the grinders run greater risks, in china factories the actual china workers, etc. An effort should therefore be made to establish separate statistics for the more affected branches in such dangerous undertakings. This has been done for instance by Kölsch and Thiele for china factories. Thiele publishes the following figures for four German china factories for 1914-1919:

<table>
<thead>
<tr>
<th>Occupation</th>
<th>Number of workers in full working complement</th>
<th>Number of workers in full working complement</th>
<th>Number of workers in full working complement</th>
<th>Number of workers in full working complement</th>
</tr>
</thead>
<tbody>
<tr>
<td></td>
<td></td>
<td></td>
<td></td>
<td></td>
</tr>
<tr>
<td>Tobacco workers</td>
<td>637</td>
<td>8.60</td>
<td>0.47</td>
<td></td>
</tr>
<tr>
<td>Stone-cutters</td>
<td>348</td>
<td>5.91</td>
<td>0.35</td>
<td></td>
</tr>
</tbody>
</table>

Both came to the conclusion that pneumoconiosis was to be found after five years' work, after which it increased rapidly in frequency. Thiele found that out of 63 workers who had been employed for over thirty years, 45, or 71 per cent., suffered from this disease.

### Occupational Poisoning

The ideal to be aimed at is to cover all cases of occupational poisoning. Unfortunately, it is far from realised anywhere. As a rule, the only cases of acute poisoning which become known are those involving an interference, perhaps small, with working capacity. It is generally impossible to establish the existence of occupational poisoning without a medical examination, but frequently doctors are not sufficiently trained in industrial hygiene to recognise all cases of such poisoning, especially the rarer kinds. It has therefore been justly urged in many quarters that doctors should be better trained in industrial hygiene, an observation which applies equally to all civilised States.

There are various methods of arriving at the number of cases of occupational poisoning.

### Compulsory Notification

Hitherto this has been introduced in only a few States, amongst others in Switzerland, the Netherlands, England and certain of the United States, France and the U.S.S.R. It is a well-known fact that even where notification is compulsory, all cases are far from being notified. It would be wrong for
this reason to give up such notification or to reject its introduction, but it should be made to cover only poisonings which can be definitely and easily diagnosed. The statistical material thus obtained will not be large but it will give an approximate idea of the frequency of poisoning in individual undertakings and an indication of increase or decrease. In England, the notified cases are classified by occupational groups. Thus, in 1920 the number of notices of lead poisoning per thousand workers was 26 in white lead factories, 27 in accumulator factories, 20 in tinning factories, 16 among painters, 2 among filemakers, and 0.4 among printers. From 1900 to 1929 the undertakings liable to notify in Great Britain gave notice of 13,774 cases of lead poisoning, involving, 1,815 deaths (see article "Occupational Diseases: Definition and Compensation"). The relatively high figure of deaths suggests that mainly serious cases were notified.

**Sickness Fund Statistics**

These can only be considered in countries in which insurance is compulsory. If sickness funds are to be in a position to supply at all reliable statistics, the sickness certificates must contain under a separate head particular information about occupational diseases, and a medical diagnosis must be made at the end of the illness, since at the beginning the doctor is often unable to give a definite judgment. As already explained, membership figures are necessary, based on a proper calculation of averages. A separation into age-groups is desirable, but is not so important as for diseases due to dust. It is very important that at least in large undertakings there should be a classification by the branch of occupation, as not all workers in the undertaking are equally exposed to the risk of poisoning. Sickness fund statistics give always the number of cases of illness, not of sick people. Thus a relapse is counted as a second case. Often the chronic sequelae of lead poisoning such as nephritis, diseases of the vascular system, nervous complaints, are classified under the head of diseases of the organs affected. Among others, Teleky has drawn particular attention to this point in his work on industrial lead poisoning in Austria.

A few examples may be given from the German and Austrian sickness fund statistics. In the important Leipzig statistics, which cover the period 1887 to 1905, the figures for the printing trades, tinsmiths and painters are higher and lend themselves to more detailed statistical treatment. The total number of cases of poisoning in the individual trades are given, but in this particular connection it may certainly be taken for granted that they are all cases of industrial lead poisoning.

For a thousand members subject to compulsory notification there occurred during the year the following cases of lead poisoning:

<table>
<thead>
<tr>

</tr>
</tbody>
</table>

The figures speak for themselves. The differences in the age-groups are small, so that the standard rates differ only slightly from the crude rates. There are wide differences for the separate occupations in the printing industry. The actual printers are least exposed to risk. Assistants are not included in the table; the figures for them are even lower. It may be added that out of 3,332 cases of chronic lead poisoning there were only 29 deaths during the whole period under consideration. The average period of incapacity for work due to lead poisoning was 34.8 days.

1 It should be stated that compulsory notification of lead poisoning among painters (since 1904) as well as the occurrence of numerous cases during the operation of dismantling old ships has affected the totals for the subsequent years.
According to Hahn, the number of cases of sickness from lead poisoning in the Berlin District Sickness Fund from 1901 to 1909 per thousand men members was as follows for the printing trades:

- General
- Journeymen and apprentices
- Assistants
- Typefounders

Teleky supplies the following figures for the Vienna Trade Associations’ Industrial Sickness Fund:

<table>
<thead>
<tr>
<th>Cases of Sickness from Lead Poisoning per Thousand Members, 1902-1906</th>
</tr>
</thead>
<tbody>
<tr>
<td>Painters and varnishers</td>
</tr>
<tr>
<td>Printers</td>

</tbody>
</table>

In Germany, a classification by undertaking was made in the chemical industry, first by Grandhomme and Leymann. Subsequently, Curschmann compiled statistics for 1909-1910, at the request of the Trade Insurance Association for the Chemical Industry. The number of workers averaged 52,000, and the number of cases of occupational illness in the year was 181.5 or 3.4 per thousand. The workers were classified into various groups; no cases of occupational diseases were found among office or women workers. The following figures were calculated for the remaining groups:

<table>

General Statistics of Causes of Death

Where the causes of death are notified by doctors, these statistics may give information as to the cases of poisoning which are more likely to be fatal. Detailed figures are available only in the case of the English occupational mortality statistics. In England, from 1910 to 1912, 292 deaths among men were ascribed to lead poisoning, or 0.8 per 100,000 persons living of over fifteen years. The absolute figure was highest for painters, with 140 deaths. The proportion per 100,000 living was highest in lead ware factories where it was 106.2, in the zinc industry with 77.9, among painters with 24.6, potters with 21.3, file makers with 18.3, and glass workers with 12.3. In the Dutch occupational mortality statistics, all cases of poisoning are taken together, but the statistics give the impression that in cases of chronic lead poisoning the complicating diseases are recorded as the causes of death, for the figures apply to a hospital. They give, however, a general idea of the occupations which are liable to serious poisoning. An investigation of this kind was made by Kaup for the cases of lead poisoning in Prussian hospitals from 1904-1908.

Medical Examination of Groups of Workers

This provides no information on acute poisoning, but brings to light cases of chronic disease. It was the only way by which Teleky could establish reliable statistics of the frequency of phosphorus necrosis, which has now almost disappeared. An examination of this kind was made in Bavaria. According to Abelsdorff, over 5,000 painters (masters and journeymen) were interrogated as to their illnesses involving incapacity for work during the period 1907-1910; 691 or 13.8 per cent. had suffered from some disease due to lead poisoning. The following particulars may be given:

General Statistics of Causes of Death

Hospital Statistics

Although these have the advantage of certain diagnosis, they are not very suited to statistical treatment as it is unknown what proportion of the sick workers or women workers. The following figures were calculated for the remaining groups:

<table>

</table>

Only a few lead-colour factories were covered by these statistics. In these there were more cases of poisoning.
of death from poisoning in lead occupations are very low.

Other Occupational Diseases

There are several other occupational diseases which cannot be discussed in detail here, such as occupational eczema, caisson disease, glass makers’ cataract, occupational myopia, tumour of the gall-bladder in tanneries, chimney sweeps’ cancer and other tumours due to permanent irritation, X-ray disease, etc. A brief note may be given of some of the more important.

Ankylostomiasis

The cases of this disease in tanneries, brush factories, etc., are so isolated that figures of its frequency cannot be established unless its notification is made compulsory. If individual undertakings are examined, those occupations which are alone exposed to infection must be separated out. For instance, according to Smyth, in the 57 cow-hide tanneries in Pennsylvania, only 614 of the 7,458 workers were exposed to infection, of whom 59 suffered from anthrax in the period 1916-1920, or 1.9 per cent. per annum. In the 19 goat-hide tanneries, 426 of the 5,881 workers were exposed, and 32, or 1.5 per cent., fell ill.

Miners' Nystagmus

The data on the frequency of this disease vary considerably according to whether slight cases are included or not. If they are, Ohm estimates that 10 per cent. of all miners suffer from nystagmus; and that the serious cases are rare. According to Llewellyn, the figures for England rose when compensation was enforced. The only method of obtaining information on the frequency of nystagmus is to examine all the hewers.

Ankylostomiasis

This disease is widespread in warm countries. In the temperate zone it is an occupational disease of miners and brickworkers. It is easy to establish its frequency by an examination of all the workers for eggs in the stools; the campaign against the disease is on this account easily waged.

Conclusion

The statistics of occupational diseases like medical statistics in general, are still very open to improvement. The results of valuable investigations in individual countries have been published, giving an approximate view, but it is still far from possible to compare the figures for the different countries, whether they relate to morbidity or mortality. Nor is it at all probable that a change may be expected soon, for even if the principles of international statistics were agreed, their proper compilation would depend on several conditions. The first thing that can be achieved is at least to make the investigations in the different countries on uniform lines. This involves the compulsory notification of those occupational diseases, in the more limited sense of the term, where the cause of illness may be clearly defined; and in countries where workers’ insurance is compulsory, or there are important factory sickness funds, the obligation of the fund to notify a specified authority of all cases of occupational disease, and in the death statistics to indicate specially any causes of death which may be connected with an occupational disease in the more limited sense (e.g. poisoning, anthrax).

The compilation of occupational mortality statistics, such as that customary in England for the last seventy years, should be general where possible, for this procedure alone allows of a proper establishment of the mortality from phthisis for different occupations. It is essential that the generation of doctors now growing up should be given training in regard to occupational diseases which might be included in their ordinary curriculum. It is however still more important that these doctors who already have a practice, and are more likely to have to deal with cases of occupational disease, should attend continuation courses in industrial hygiene. Any man who wishes to become an industrial doctor must obviously receive a thorough training in this respect. The medical faculty in general will keep in touch with the latest developments in regard to this question, by maintaining up-to-date knowledge of conditions through publications and lectures relative to the problem of occupational diseases and their probable development.

A consciousness of the defective knowledge of occupational diseases does not constitute a reason for relaxing the efforts to improve the statistics on the grounds that they can never be made perfect; on the contrary, this should act as a spur to extend such knowledge and make it as complete as possible.

1 The mortality figures by age-groups are taken from the statistics on occupational mortality for workers with at least ten years' experience, published in 1909 by the Census Office in the United States.

2 The mortality figures quoted in the first line of each group, and referring to workers with upwards of fifteen years' experience, are taken from a publication by L. G. Dublin and represent data furnished by the Metropolitan Life Insurance Company, Industrial Department, for the period 1911-1913 (U.S. Department of Labour. Bureau of Labour Statistics, Bulletin No. 207, 1917).

According to the returns of the Metropolitan Life Insurance Company (Industrial Department) for the period 1911-1913 the average age at death by occupation was as follows:

### Men

- Bookkeepers and office assistants: 36.5
- Engine men and trainmen (railway): 37.4
- Plumbers, gasfitters and steam fitters: 39.8
- Compositors and printers: 40.2
- Teamsters, drivers and chauffeurs: 42.3
- Machinists: 43.9
- Textile mill workers: 47.6
- Iron moulders: 48.0
- Painters, paper hangers and varnishers: 48.6
- Cigar makers and tobacco workers: 49.5
- Bakers: 50.6
- Coal miners: 51.3
- Labourers: 52.8
- Masons and bricklayers: 55.0
- Blacksmiths: 55.4
- Farmers and farm labourers: 56.5

**Average for all occupations specified:** 47.9

### Women

- Clerks, bookkeepers and office assistants: 36.1
- Store clerks and saleswomen: 28.0
- Textile mill workers: 33.9
- Dressmakers and garment workers: 42.0
- Domestic servants: 49.1
- Housewives and housekeepers: 53.3

**Average for all occupations specified:** 54.1

Lee K. Frankel, of the Metropolitan Life Insurance Company, has studied the mortality and morbidity statistics of the Local Sickness Fund of Leipzig (1887-1904), from which he extracted the following figures, presented at the Detroit Conference in 1913. There are given hereunder the figures relative to the occupational groups cited above:

### Italian Statistics

The National Fund for Social Insurance has studied the causes of illness amongst its members during a period of four years. The records comprise 21,000 sick or retired members. 20,515 of the cases having been followed closely and made the subject of detailed study, 16,606 of the latter were men.

The following diseases affecting men and women, and expressed as percentages of 100 causes of sickness, show values as hereunder:
Infections and poisoning 1.48  
Diseases:  
Blood and nutrition 3.25  
Nervous system 13.25  
Respiratory passages 9.00  
Circulatory system 34.19  
Digestive system 3.37  
Urinary-genital system 2.00  
Locomotory apparatus 4.94  
Skin and tissues 0.63  
Violent accidents 3.88  
Pulmonary tuberculosis 9.61  
Other forms of tuberculosis 1.47  
Tumours 2.22  
Hernia 3.78  

Total 100.00

For 100 sick members of all ages, sickness showed the following percentages per age-group:  
- 20 years of age and under: 0.34  
- 21-30: 4.40  
- 31-40: 6.12  
- 41-50: 8.40  
- 51-60: 22.45  
- 61-70: 58.39  

An analysis of the different causes of sickness gives the following figures for men, for diseases of the circulatory apparatus: 7,014 cases (3.96 per cent. for those under fifty years of age; 17.63 under sixty years of age, and 77.45 between sixty-one and seventy). Separating occupational groups these diseases were found to occur in the ratio of 50.69 per cent. amongst industrial workers; 16.62 per cent. amongst labourers and others; 12.78 per cent. amongst domestic servants, and 10.20 amongst workers engaged in agriculture hunting and fishing.

As regards nervous diseases there occurred amongst the men 2,283 cases: 8.72 under the age of forty years, 11.52 under fifty, 31.32 under sixty, and 48.44 under seventy. Cases were more numerous amongst the "industrial workers", followed in order by "agricultural workers", "labourers", "domestic servants".

Tuberculosis and other tuberculous diseases totalled 1,381 for the men and 590 amongst the women. The proportion of men suffering from incapacity for work was as follows: under the age of twenty, 1.73; under thirty, 22.15; under forty, 25.80; under fifty, 20.27; under sixty, 18.32; and under seventy, 11.73.

For women the proportions were respectively 3.40, 37.45, 21.70, 18.98, 13.05, and 5.42.

For both sexes these diseases affected the group of "industrial worker" in the proportion of 60.02 per cent., "labourers" in that of 11.16, "agricultural workers" 9.53, and "domestic servants" 8.93.

**Respiratory diseases** attacked 1,858 persons of both sexes and, whilst they affected only 3.97 per cent. of the members under forty, 5.17 in the age-group 41-50 were affected, 17.0 in the age-group 51-60, and 66.74 in the age-group 61-70.

The order of frequency as regards occupational category was as follows: "industrial workers", "labourers", "agricultural workers", "domestic servants".

For further details see the study made by Emilia Sorrentini appendix No. 4, 1926, of the periodical *Le assicurazioni sociali*, Rome.

**Swedish Statistics**

Occupational morbidity for the period 1913-1916 (figures relative to 100 of the standard population) are given in the following table:

Clinical Examination

French: Interrogatoire de l'ouvrier. —
German: Befragung des Arbeiters: —
Italian: Interrogatorio dell' operato.
—Spanish: Interrogatorio del obrero.

When a medical man undertakes the
examination of a worker (child, young
person or adult), he ought to follow the
dictates of modern medicine and hy-
giene and consider the possibility of
risk, even where no disease is rec-
ognised as occurring in connection
with the occupation.

Before commencing, the medical man
put a series of questions sug-
gested by the trade or special occupa-
tion of the worker. He should ask
his patient questions, remembering the
action that different substances he may
be called upon to handle, as well as
the special processes used in the fac-
tory, can exercise on the system. He
should never lose sight of the risks
which may be suspected of affecting
the health of the worker. He should
be able to envisage rapidly the pro-
blems which the technical processes
involve, in order to arrive at an
etiological diagnosis by the same me-

 Method of deductive reasoning, almost
unconscious and automatic, which will
lead him to form his ordinary diag-
nosis. It should be remembered that
Hippocrates, in the earliest dawn of
medicine, realised the importance at
the start of asking the patient about
his family history. After many cen-
turies a notable advance was made by
Ramazzini, for whom a knowledge of
the occupation of the worker was
not a matter simply of curiosity or a
dry addition to the clinical history of
the patient. He started with an exact
knowledge of industrial maladies and
sought out in the various occupations
the elements which might explain the
subjective and objective symptoms in
the individual and the extent to which
these symptoms could be attributed to
the occupation.

To-day these data relating to the past
history of the worker are a little too
simple to suffice. A medical examina-
tion is even desirable for persons
apparently healthy before commencing
employment as well as periodically
during its course, and especially when
a transfer to other work occurs.

A thorough knowledge of the family
and personal history will give the
medical man the necessary data for
determining the adaptability of the
subject's resistance to the occupation
in question. A knowledge of the
habits and customs of the subject
which may vary considerably from the
usual will enable the physician to make
suggestions and give advice which
'gether may help to start the patient
on sound lines.

It is unnecessary to insist on the
value of information as to the health
of the parents and members of the
family, and of illnesses contracted
during childhood. Nowadays it is in-
dispensable on the other hand to
request information as to excessive zeal
in sport and to put questions on the
subject of important diseases which
the patient has survived: how they
variably, the period of convalescence,
medical supervision throughout their
duration, etc.
Among the maladies and anterior troubles to which special attention should be given are the following:

(a) **Acute articular rheumatism:** possibility of recurrence, endocarditis, and especially myocarditis more or less circumscribed and capable of manifesting itself much later in life (granulomas of Aschoff-Tawara). The precursory and occasional phases of chronic arthritis should not be lost sight of.

(b) **Pharyng-o-tonsilitis:** possibility of albuminuria, and relapses with nephritis and rheumatism.

(c) **Typhoid fever:** possibility of the patients being carriers and dangerous disseminators of germs; exposure to affections of the abdominal organs, especially when the person in question indulges to excess, and does not follow the prescribed diet during the period following convalescence.

(d) **Scarlet fever:** possibility of the kidneys being affected and predisposition to kidney disease.

(e) **Dermatitis:** erythema, eczemas, possibility of allergic states.

(f) **Venereal and syphilitic diseases:** a negative reply to the question has no value even when made in good faith. Among workers in large industrial towns, for example, it was found that of 100 positive Wassermann reactions 66 occurred amongst persons who were ignorant that they had contracted the disease (Devoto, Milan).

(g) **Diseases and affections which might be considered as precursory to a disease of a tubercular character** (pleurisy, adenitis, periostitis).

(h) **Tremor:** possibility of hereditary syphilis, endocarditis, neuropathy.

It is wise to enquire if the individual has suffered from accidents, their frequency, importance and consequences; whether his brothers and sisters have also been subject to accidents. In the case of workers in the transport industry, enquiry should be made if they have suffered from repeated accidents. The medical man should verify whether the subject has lost weight and in some cases (e.g. poisoning by carbon bisulphide) he should look at photographs taken at a year’s interval, to see if there is any evidence of wasting.

When it is a question of work at high temperature or in a very humid atmosphere, the doctor should make enquiries as to the function of perspiration from the skin (whether it is abundant) and as to the sensation of thirst, nature of the liquids drunk (water or other drinks).

In the same general way questions should be addressed as to whether work has been done in foreign countries or in mines, or whether the father of the subject has practised one of these trades and whether when young the subject in question went with his father to work. The doctor should satisfy himself as to whether the workman was fit for military service and, if he was not, what was the reason for his discharge; if, during military service, he has kept in "good health", "better health" or "poor health" as compared with his civilian life; as to whether he has been rejected by an insurance company.

When it is a question of a married workman, it is desirable to know the date at which marriage was contracted, the wife’s profession, whether there are children or not, their state of health and occupation, whether it is or is not the same as their father’s. If some of the children have died enquiry should be made as to the age at which death occurred and its cause; enquiry should also be made as to any miscarriages or premature births.

When the patient is a woman the doctor should enquire of her as to the date of commencement of menstruation, regularity or irregularity, if any, in regard thereto (pain, haemorrhages), date of marriage and pregnancies, number and state of health of children, and miscarriages, if any. He should enquire further as to the deliveries were normal, and if the menstrual functions have been disturbed since pregnancy and whether industrial work has been excessively trying during the periods of menstruation, pregnancy and nursing. In the case of a patient who has had miscarriages it is necessary to ascertain very tactfully, without of course noting down whatever replies may be elicited, whether all miscarriages were involuntary. Finally, it is necessary to ascertain also the husband’s occupation and to determine the absence or presence in the past of venereal diseases (Wassermann). In many cases it is advisable to have the advice of a gynaecologist.

A doctor who, in examining a young girl, is led to suspect the existence of a former or actual pregnancy should not pursue his enquiry further unless a very urgent reason exists for going more deeply into the question.

Subsequent to these questions of a rather general order the doctor should pass on to questions of an occupa-
When he is aware of the industry or occupation of the patient under examination, he will be able, except under special circumstances, to form an idea of the diseases which such work may cause or has already caused in the case of his patient. This pathology may be classified as follows:

(a) Poisonings. — The precise questions the doctor should put to sick persons exposed to the risk of industrial poisoning must be obvious. He ought to take into account the special occupation, nature of the environment, as well as all that relates to the workman: his personal cleanliness, his observation of prophylactic measures at work, etc. It must be confessed that in some cases the concomitant action of several noxious causes may make the diagnosis very difficult and that, in others, the use of new products or of those the toxic action of which is not known may create difficulty in finding out what the cause of the damage has been.

(b) Infections. — This group is dominated by ankylostomiasis, anthrax, glanders, tuberculosis (cutaneous) (see these articles and the article “Infections”).

(c) Pulmonary pathology due to dusts. — The questions should be directed towards the special work of the workman (in mines, quarries, etc.), the environment of the work, organisation of preventive measures (ventilation, breathing apparatus, humidification, periodic medical inspection, etc.), and the nature and quantity of the dust.

(d) Pathology due to physical and meteorological causes, etc. — This section comprises very varied industrial conditions: very hot atmospheres, hot and humid atmospheres, cold temperatures — when the heat-regulating centres of the individual are strained to the utmost in order to maintain the physiological temperature of the body (Hill, Dorno); occupations where disagreeable smells are produced which may end by setting up general gastric pathological symptoms; work setting up increase or diminution in arterial pressure in consequence of the accomplishment of more or less arduous efforts; operations that are always the same and therefore monotonous; those demanding constant attention; those bringing into play special irritative stimulation of the skin, etc.

Finally it is desirable to ask the patient if he has knowledge of any malady or symptoms analogous to those from which he is suffering amongst the members of his family or amongst his companions at work.

With the object of facilitating the work of the industrial physician, lists or tables have been prepared where the industrial diseases are enumerated together with their most important symptoms.

Some of these publications occasionally give an alphabetical list and beside each symptom are enumerated those industrial diseases in which it is possible for them to occur.

Prof. L. Devoto
(Milan).

Circulatory System

Occupational pathology of the cardiovascular system is very important from the point of view of industrial medicine. Nevertheless it has not, and cannot, possess clear and precise outlines and does not exhibit premonitory signs to the medical man, since neither pathological anatomy nor clinical experience have furnished, up to the present time, as does electro-cardiography, positive data relative to the earliest changes in the myocardium. Clinical experience has for long led to suspicion and even recognition that, however far from constituting acute myocarditis and interstitial myocarditis; experimentally they have been shown to occur in the cardiac muscle of tired rats, proving that such alterations are capable of being repaired and eliminated (Cesa-Bianchi).

At the present time it is possible to determine, by means of electro-cardiography, the functional capacity of the heart of an athlete, for example, and to forecast his chances of success in a race; but it is not yet possible to construct a picture of the initial alterations in the myocardium which is at a result of work, circumscribed modifications are produced in the myocardium (similar to those which Aschoff has discovered in acute articular rheumatism, etc.). Observations, made during the war, point to the probability of such slight and sparse alterations, which however are far from constituting acute myocarditis and interstitial myocarditis; experimentally they have been shown to occur in the cardiac muscle of tired rats, proving that such alterations are capable of being repaired and eliminated (Cesa-Bianchi).

The above preamble is of import since occupational pathology of the heart relates mainly, if not even exclusively, to the heart muscle, its vessels and nerves, and since there is reason to believe that this pathology, which is in course of attaining great importance, would be still more valuable if it were possible, by clinical and etiological diagnosis opportunely effected, to apply the requisite individual measures of prophylaxis and restoration.

Here it should be noted that one substance at least, namely lead, has notoriously the power of causing chronic lesions of the heart muscle; but even here its action develops so slowly that the symptoms are only produced very late, that is to say, when renal and arterial changes have occurred; and, in this case, it is impossible to control a phenomenon which most often depends on a series of organic changes which have been completed in the past.

Apart from lead, occupational pathology of the circulatory system does not depend for its existence on any specific single morbid agent, as is the case with certain diseases in regard to which prophylaxis and therapeutic treatment are so much the easier and more certain the better the determining cause is known. The factors in the causation of cardio-vascular pathology which have to be borne in mind are many and varied, and are here more than elsewhere related to the constitution of the individual, his previous state of health, conditions of work, etc. Particularly in the case of peasants, for example, sight should not be lost of the special configuration of the ground (whether in a plain or on a mountain), the state of technical development of agricultural work, etc.

As no specific causes exist, so, the lesions of the circulatory system are likewise not specific. On the other hand, there is quite an ordinary common pathology which may be due exclusively to work in itself, whilst in other cases it develops more or less rapidly under the influence of ordinary and common co-ordinated actions more or less strictly related to occupational activity.

In this category may be enumerated: cardio-vascular lesions observed in subjects suffering from occupational disease (e.g. lead poisoning, ankylostomiasis, pneumoconiosis, pulmonary emphysema among musicians who play wind instruments, etc.) and in whom the cardiac alterations are mostly (excluding: lead poisoning) only the indirect consequences of a pathology which had indeed at its outset an occupational character, but of which the cardiac troubles cannot be considered as of this nature; the alterations in the heart peculiar to certain kinds of manual work and those due to fatigue or voluntary over-exertion (excess of sport); alterations due to narcotic substances; diseases due to accidents, and to syphilis of professional origin; in so far as it affects the cardio-vascular
apparatus (Ayerza's disease is an example of this kind); heart troubles due to electricity.

As regards this last group, when the electric current is of low tension it produces an action on the cardiac muscular apparatus which brings about fibrillary contraction and this, if it is prolonged, causes death (Prevost, Battelli, d'Haluin); in these cases of essentially cardiac reaction, as soon as the heart shows signs of fibrillary contraction the arterial circulation fails, the respiratory apparatus which becomes disordered and gasping respiration precedes death.

Changes in the heart and death due to electricity belong rather to the domain of the pathology of accidents, but it is useful to recall here that clinical examination brings out in relief the great importance of constitutional differences, individual and momentary, in the reaction of the organism to electric currents.

Occupational cardio-vascular pathology ought to offer vast possibilities for prophylaxis; but, with so many varied factors at work all directed towards a common pathology, it is not possible to present a hard and fast picture. It cannot be repeated too often that industrial pathology of the cardio-vascular system is not specific in its manifestations; it is industrial in its etiology and in the manner of its development, since the occupation involved plays a part, perhaps even the major part, in its causation.

From the clinical and anatomopathological point of view, there are known myocarditis, endocarditis, aortitis, arterio-sclerosis, vascular atheromatosis, syphilis, endocarditis, arterio-renal insufficiencies, and nephropathia (certain cases of nephritis, nephrosis, nephroptosis).

First must be placed myocarditis, or rather, myocardopathias — those reactions of the cardiac muscle induced by alterations more or less extensive, at times but slightly extensive, more or less stable, which must not be overlooked, however, when it is a question of manual labour and the many mechanical actions which it involves. These lesions occur in individuals, more or less experienced in manual work, who have been subjected to extraordinary, intense and prolonged effort, and those who have been exposed to poisons and infections of an occupational or non-occupational character. But it is persons of feeble constitution or those with less organic resistance, admitted to work demanding more than an ordinary test of their powers, who are the first to fail.

In early or latent cases of this kind, adequate medical supervision may avert disagreeable occurrences. Such medical supervision is also likely to succeed in the case of individuals suffering from pronounced cardio-arterial disease; the symptoms and sufferings of such cases are considerably relieved and they may attain an output almost equal to that of healthy persons (observations during the war showed that there are cardiopathies capable of sustaining every kind of fatigue). To quote only recent writers, the working at the same time as eating; Berinson, Coombs, Cotton, Hirschberg, Mock, Moon, Phipps, Raimond, Sheppard, Stein, White, Wilson, Wolfe, who assert that occupational activity is possible for heart patients, provided they do not exert themselves unduly. Where there is good compensation these cases can be maintained in a good state of health.

A group of factors which might be classified together under the heading of "excesses" exercise, even under normal conditions, a marked repercussion on the health of the individual and his output. Among these factors: abuse of alcohol and tobacco and sexual excess; over-feeding of all kinds, as well as excess in sports, in which many workpeople now indulge. But mention should also be made of some strange combinations, such as speaking at the same time as eating; making a speech immediately after eating; excessive effort; drinking too much, even between meals or before going to bed, etc., which are in themselves capable or acting prejudicially and of upsetting still further the already eranged action of the heart. And this concomitance of causes may assume still further complication. It suffices to recall in this connection the effect upon workpeople under the influence of an industrial poison, such as lead, which affects the arteries and upsets the metabolism of uric acid; or again alcoholic absorption, which disturbs the functions of the liver and elimination of uric acid, and thus leads definitely to a diminution in the resistance of the cardio-renal system. And the same can be said in regard to nicotinic diseases, etc.

During the war "soldier's heart" was the subject of much study. Cotton, Lewis and Thiele were able to connote a group of maladies with a special symptomatology, which came on gradually or suddenly during the time of training or active service in the trenches.

The hypothesis advanced by these experts regarding the influence of
work could not be shaken by some cases which did not present case histories proving serious fatigue or strain. Cotton, Lewis and Thiele were able, from the past history of these soldiers, to discover some infectious malady which had paved the way for the appearance of "irritable heart" ("soldier's heart"), characterised by an exaggerated irritability after slight fatigue or a moderate stimulus. These phenomena are said to be sufficiently common even among civilians and represent, according to Mackenzie, an expression of general exhaustion rather than affection of the heart.

But other factors have been noted as assisting if not preceding this symptomatology: the abuse of tobacco by soldiers during the war, especially among those who had not been smokers (Galli, Romberg, Michell), the existence of a pre-basedowian state and finally a congenital predisposition among those who had not been smokers (Galli, Romberg, Michell), the existence of a pre-basedowian state and finally a congenital predisposition.

While all these excesses are capable of showing their effect on the normal individual, they are sure to react more intensely on individuals in a state of cardiac inferiority (organic inferiority, unsuitable work, excess).

This is why, from the point of view of prophylaxis and occupational hygiene, it is the duty of the medical man to try to discover any abnormal manifestations of the cardio-vascular system in an apparently healthy workman with an unfavourable previous history.

On the other hand, when examining a workman who has been ill or complains of suffering, a thorough and detailed examination should be effected with a view to furnishing as complete a diagnosis as possible. The duty of the medical man comprises points which are often less delicate, since he has to reply specifically to the following two questions:

(a) Can the worker suffering from a cardio-vascular complaint which is not acute be rehabilitated?
(b) What output can an individual affected with a cardio-vascular disease effect without prejudice to his condition?

To the first question it is now possible to answer that a cardiopath can be maintained in a state of perfect equilibrium. The reply to the second question is not so easy. The causes which habitually act on the heart directly by altering the myocardium, after a short or long period, are mainly those of a mechanical origin, acting either alone or in conjunction with other factors.

The importance of these causes is brought out by the teachings of experimental medicine, which show the relation, to a large extent, between industrial fatigue and cardio-vascular pathology:

(1) Severe fatigue causes alterations in the muscle fibres of the heart which are remediable by rest and good food, provided they have not progressed too far; in which latter case they are irreparable. The supra-renal capsules become altered similarly in severe fatigue (Cesa-Bianchi) and in this state soon cause repercussion on the blood pressure and functions of the heart.

(2) In severe fatigue there is a marked neutrophile polynucleosis, accompanied by transitory changes in the gases of the blood (excess of carbon dioxide), due to a modification of the leucocytary functions (Ciovini). The experiments of Aiello show that the leucocytosis disappears as muscular exercise proceeds and even before a state of fatigue has been reached; this leucocytosis, however, need not bear any relation to the more or less abnormal organic state produced by muscular effort, but may be regarded as a defensive reaction on the part of the organism against the changes in organic equilibrium that fatigue might bring about.

(3) During intense muscular work acetone is produced together with an increase of the antitryptic power of the serum of the blood (Preti).

(4) Periods of intense fatigue among farm labourers (e.g. harvest time), produce noticeable lowering of the cardiac force and of the blood pressure, which does not last and disappears in the weeks of relative rest that follow.

(5) Fatigued animals show an increased susceptibility to electric currents (Aiello, Pugno). The vegetative nervous system participates in the fatigue symptoms. The sympathetic cervical ganglions show subsequently fine and constant alterations following on fatigue (Aiello).

(6) During fatigue the blood ferments undergo important changes and the sedimentation time of the red blood cells is reduced (Sereni).

All this explains why fatigue effects and exhaustion are more or less recorded by an organism according to general or monovisceral conditions and so much the more so where there also exist poisoning or infections, present or past, which reinforce such effects.
Mention must also be made of some morbid accompanying conditions, the pathogenic co-operation of which explains the diversity of their symptoms. Industrial poisoning of the respiratory tract is increased when pre-existing damage has been done to the respiratory or circulatory apparatus, as the expectoratory phase in these cases is reduced; in like manner, the effects of fatigue under similar conditions exert a more serious effect on the cardiovascular apparatus. For this reason the trained medical man must not confine his action to making an accurate diagnosis of heart disease but must also so adjust the occupation, the diet and the medical treatment offered to the patient as to ensure the preservation of a state of compensatory equilibrium of the heart, with, further, a certain reserve in favour of the cardiac functions.

In studying the etiology and pathology of a disease of the heart and blood vessels, much importance must be attached to heavy and trying work on account of the sustained effort demanded. Such effort entails maladjustment as the workman advances in age and as other factors diminish the resistance of his system.

According to several authors, the effort required by certain instruments (contrabass and tenor violin) and by singing is said to cause violent haemorrhage and rupture of the pulmonary artery (Diennerbroek's case of a flute player), the condition being favoured by the bent position of the upper part of the body (contrabass, tenor violin, etc.). Recently, however, various authors have denied this source of injury as occurring for instance among singers (Thousing and Lohfeldt).

Considerable importance must be attached to the effect of those infectious diseases which cause definite change lesions in many individuals, principally of the heart muscle. The consequences of such diseases contribute their effect to that of the trying work in question which is resumed once the disease has terminated, by increasing the lesions and intensifying the sensitiveness of the myocardium to hard work. See also article "Occupational Diseases: Respiratory Apparatus", for emphysema of the heart.

Poisons such as lead, arsenic, phosphorus, etc., have a selective action on the myocardium whenever the heart is in any way damaged. Injuries, falls, etc., only set up a first slight tearing, disturbing the continuity of the endocardium, but on this site strictly limited inflammatory processes develop, which become later on the starting point of later endocardial lesions (Ranelletti).

Digestive troubles, visceral displacements, flaccidity of the left side of the diaphragm, combined with dyspeptic atony and dilatation of the stomach exercise in general a mechanical and even a toxic action on the cardiac functions and tissue.

The environment in which persons suffering from heart disease work should receive careful attention: as far as possible, they should not be exposed to abnormal conditions of atmospheric pressure (rarefied or compressed air), unduly high or low temperatures, or to abnormal conditions of the chemical constitution of the air (excess of carbonic acid gas, presence of sulphurised hydrogen, carbon monoxide, etc.) (Ferrannini).

Similarly, the position assumed at work should be chosen so as not to hinder maintenance of the circulation in a relatively stable state of equilibrium, by more or less artificial compensation.

In persons suffering for the first time from an acute infectious disease, before any obvious symptoms suggesting endocarditis had developed, the electrocardiogram showed that the heart had been affected in some way or other in 28 per cent. of these cases (Burnett and Pilz), whereas physical examination only revealed changes in 3 out of the said 28. These changes, however, were not definite in all cases and disappeared in the majority.

The following conclusion would appear to be justified: microbes and their toxins set up in the myocardium small inflammatory degenerative centres, susceptible of later growth or resulting in involution and cicatrisation; in similar manner there is reason to believe that excessive effort or the exercise required in trying work may lead to the formation of slight and very limited changes, the development of which is also favoured by a dyscrastic condition or by acidosis.

A long time ago Munzigcr and others described "peasant's heart", known under the name of "Thüiniger Weinherz", a special form of heart disease also found in other countries. Thus, for example, the condition in question is found amongst the peasants of Upper Valtelline (Italy), in Liguria, etc., who have developed and cultivated the famous vines and pastures on the steep sides of their mountains, and who have several times a day to climb up and down hundreds of steep steps roughly cut out of the rock, with heavy loads on their backs. The fate of these workers is sure; they develop diseases
of the heart at a certain age, death being accelerated by acute broncho-
neumonia or other acute condition.
All medical men who have had to treat persons who, after severe effort in sports, have suddenly shown lesions of the circulatory system with dilatation of the heart (disappearing after a week's rest and appropriate treatment), must recognise the possibility of acute myocarditis, both benign and circumscribed, occurring as the result of intense and prolonged effort followed by complex troubles of metabolism. At the clinic for industrial diseases in Milan there have been received for treatment messengers, steel forgers, porters, miners, etc., in whom pro-
longed and intense overpressure had set up cardiac changes, which, by reason of the symptoms as well as in the evolution and favourable termina-
tion, could most easily be explained as the result of myocardi
t changes. The
myocardium behaves like many other organs; improvement follows benign and circumscribed inflammatory les-
sions when the cause that has produced them has been completely and rapidly removed; this fundamental fact ought to serve as a guide to the medical man in his timely intervention (Dvon-
sto).
Histological observations, it is true, have shown the absence of lesions in the myocardium among persons showing fatigue of the heart as a result of effort (Reiche). But these researches require to be more extensively pursued, utilising the technique which modern science has made available.
The nature of cardiac affections varies according to the age of the sick person; this is confirmed by statistics of Myriam Lincoln (1924) in accordance with which the following analysis into different forms of heart trouble was obtained from 80 observed cases:

<table>
<thead>
<tr>
<th>Age groups</th>

According to the statistics of the Registrar-General in England, published in his Decennial Supplement, which appeared in 1927 (for the period 1921-1923), the mortality from diseases of the circulatory system taken altogether does not appear to differ very much from the general mortality. Excep-
tion, however, must be taken to the group of unskilled workers for which the mortality figure was 1,199 as com-
pared with the standard 1,000 for all occupied males.
The extremes of the above figures are: 369, minimum for the group of game-keepers, and 2,375, maximum for the groups of tin and copper miners employed under-
ground.
The same statistics give the follow-
ing figures for valvular heart disease:

Arterio-sclerosis is one of the principal causes of death among diseases of the circulatory system. Of 100,812 deaths of this description (including aneurysm) among all occupied and retired males, 23,364 (23 per cent.) were due to arterio-sclerosis.

But it is always necessary with statistics as to frequency of heart disease in different occupations to interpret them with great caution. It must be remembered in particular that persons so affected try to find a trade suitable to their state of health and they take it up as soon as they have left a trade in which it is impossible for them to continue. In mortality statistics, however, the registration of death naturally only shows the last occupation. Therefore there would be an inclination to incriminate a trade which may really be reckoned amongst the least injurious to health, if statistical data, alone, are considered without discrimination. Another difficulty encountered in statistics of heart disease is that there may be united under one occupational heading very varied processes or operations differing widely in their action upon the circulatory system (Ferranini).

In practice the development towards heart affections generally occurs in the following way: a person accustomed for many years to hard work in a particular industry comes to find that he cannot perform it with the same ease as formerly; he has difficulty in climbing, in carrying weights, in running; sometimes he has difficulty in breathing after food, even when it is not in excess of what he is accustomed to; he has trouble in dressing himself rapidly, in bending to pick up an object from the ground. These movements are accompanied by an increase in the number of respirations and pulse rate. Physical examination may show hypertrophy of the heart and a murmur confirmed by a radiograph. This may be a case of incipient myocarditis or endocarditis, developing concomitantly with arterio-sclerosis extending as far as the kidneys. All this is the result of a life of intense labour, which may also have been aggravated by abuse of tobacco, alcohol, etc. This very simple picture may be further complicated by the effects of infectious diseases which have preceded it and paved the way for lesions set up by fatigue. What happens thereafter belongs to the domain of internal medicine: extension of the trouble, partial rupture, later complete, loss of compensation, degenerative changes, pseudo-anginal attacks or anginal attacks, etc.

</table>
On the other hand the condition just described may remain stationary or improve, as the heart muscle has powers of recovery and reserves. But it is necessary to examine the workman carefully, taking all factors into consideration, and to eliminate all causes liable to influence the heart detrimentally; at first to reduce the length of the working day, at any rate for a time. In life on the land, the heart can sustain intense hard work daily for some weeks (harvest time) provided that rest periods follow (in the months during which the work diminishes and when there is a possibility of a better diet, fruit, etc.).

Attention may now be directed towards a scrutiny of the means available for making a functional diagnosis of heart cases: to certify that the heart is sound in an individual, permitting him to undergo fatiguing work, to participate in sports, etc. Such diagnosis has been considered in the past and still is considered as a rich opportunity for acquiring means of examining in detail the anatomo-physiological conditions of a heart showing evidence of deterioration.

Certain more or less complicated methods of effecting such diagnosis have been proposed, but, according to Devoto, they are not of practical use in judging of the state of the heart when it is a question of response to demands proportional to normal activity.

In fine, the questions to be answered are: how far is the heart of an individual compromised who has recovered from an infectious malady and sustained heart injury thereby? Can such an individual continue to follow an occupation involving heavy work? Can he be employed in a caisson? Can he engage in aviation?

These questions have to be answered by the methods of practising physicians, that is, by means of questions, by clinical examination and with the aid of some quite simple auxiliary methods. Among the questions which can usefully be asked are those having reference to (a) prevailing family maladies (rheumatism, occupational diseases, etc., affecting the parents); (b) personal history (previous infectious maladies); (c) particular constitutional signs in the individual (tendency to spinal curvature, whether he has outgrown his strength, etc.).

Such a procedure is so simple and natural that it is unnecessary to insist on it. In effect it is not always easy to participate in heavy work demanding participation of important groups of muscles, including the heart muscle (Pieraccini). Under these circumstances the hypertrophy is a normal one; in the other it is pathological.

Further, apparently no data exist which would justify the definite statement that fatiguing work causes pathological changes in the heart in cases where the organ was healthy on commencing the work. On the other hand, it may be affirmed that heart weakness or simply idiopathic hypertrophy can be found when the hard work has been commenced during the school age or shortly after leaving school, as well as in cases where, as has happened, the workman resumes work too soon after suffering from an infectious disease, that is before complete recovery has been effected (Brezina). Cases of idiopathic hypertrophy have been described especially by Giuffre, who has observed this condition in five out of eleven fishermen whom he examined at Sferracavallo. Mosso, Heuschen and others have noted the same phenomenon in Alpine climbers and skiers.

It is a very delicate matter to detect the fundamental cause responsible for hypertrophy or which probably gave rise to it. Similarly, it is necessary to determine in a very thorough manner whether the subjective and objective symptoms are due to lesions of the cardio-vascular system rather than to one of these following conditions which often have important repercussions upon the heart: cesophagial affections; aero-phagia, wind, adhesions, abdominal ptosis, extensive in the fibres of the myocardial vessels, if it does not constitute an absolute contra-indication, merits, at any rate in the absence of tangible signs of a heart lesion, a meticulous use of the electro-cardiograph. Indeed, workmen who have resumed their fatiguing work after having suffered from one or more infectious diseases seek medical advice some time later thereafter with abnormal heart signs: painful palpitation, cardiac hypertrophy, myocarditis, cardiac insufficiency.

An opinion on the state of the heart of an adult engaged in fatiguing work is sometimes difficult in practice. This is due to the fact that an enlarged heart, recognisable on percussion, palpitation and by radiography, is not sufficient evidence of a condition either pathological or heralding disease. Distinction must be made therefore between cardiac hypertrophy due to compensation, which is useful and indispensable for overcoming internal resistance, from that which is necessary in work demanding participation of important groups of muscles, including the heart muscle (Pieraccini). Under these circumstances the hypertrophy is a normal one; in the other it is pathological.
OCCUPATIONAL DISEASES

— 450 —

CIRCULATORY

colitis; (b) liver and kidney diseases; (c) nervous diseases.

In the meantime, some authors have suggested special methods for recording the activity of the heart muscle as a whole, without any special attention to the occupational factor, but in determining cardio-vascular pathology from an occupational point of view they are apt to supply data too late to be of practical use, since well-conceived methods of clinical research diligently pursued suffice for determining accurately the relation between the heart and the vessels on the one side and the occupation on the other, without necessitating the use of a complicated equipment. Further the so-called functional methods of diagnosis in practice meet with special difficulties for several reasons: (1) they do not eliminate the psychical factor, which plays a great part in the examination of cardiac functions; (2) their results to be significant must register a notable departure from the average, yet amongst young people very contradictory data may be found; (3) in a subject who is not highly educated, experiments of a novel kind are both frightening in themselves and almost always inconclusive.

The part played by the psychic condition becomes more important once those tested are aware that they are being submitted to fatigue tests. Besides, the eventual reaction of cardiac debility provoked is a consequence of exercises differing widely from those effected in course of ordinary work. Current experience has shown and still shows that simple and precise methods are those which help the medical man in estimating cardio-vascular conditions in a workman occupied in fatiguing tasks (Devoto). In the same way when effecting a test recourse should be had to the simplest and most natural methods — thus, the subject should be asked to climb a ladder, to deliver a message rapidly, to run quickly along a passage, hold the breath during thirty seconds after an average inhalation, to bend the hips on the legs several times and at the same time extend the arms, to get up quickly from a prone position, etc. These simple measures should not be suggested in a solemn manner but as extremely simple' things should not be suggested in a solemn manner but as extremely simple' things; in estimating cardio-vascular conditions it is more expedient to take these counts later. The test of the haemoclastic crisis can be made after a short effort or the Czermak-Wenckebach test can be applied (compression of the pneumogastric nerve in the neck) bearing in mind Hering's interpretation (eventual sclerosis of the carotid). The assertion of Eimer and other authors that auscultation of the heart has no value should be accepted with reserve.

On the other hand, attention must be paid to certain facts which seem to herald practical results: thus, for example, in a workman with a sound heart, excessive exertion causes diminution in the volume of the normal organ or increases it without any anatomical changes: on the other hand, in cases where the myocardium is altered, a dilatation takes place (Kaploun). When it is necessary in quite special cases to know an individual's capacity for resistance when called on to carry out exceptional efforts, recourse may be had to the electrocardiograph which will enable diagnosis to be made.

It can really be said that the study of the subjective condition of the workman considered in conjunction with the results of habitual observation of the physical symptoms (including a radiograph and if possible an electrocardiograph) as well as determination of the blood pressure interpreted in the light of conclusions drawn from recent and former past history constitutes the basis of the examination. With the deductions drawn from these fairly precise sources a diagnosis can be made in each case, and accurate replies can be furnished to questions put by workpeople, employers or by the conscience of the examiner himself.

So far as concerns the special case of athletes, methodical examination of blood pressure before and after the test enables an opinion to be given as to their efficiency and their training. A low maximum blood pressure at the start would appear to be an unfavourable sign (Aiello).

BLOOD VESSELS (ARTERIES, VEINS)

The pathology of the arteries is essentially that of arterio-sclerosis. Intense and continued efforts react not only on the heart but also on the arteries, which gradually suffer the condition known as arterio-sclerosis, more or less diffuse. Apart from the mechanical effect producing this condition there are effects of changes of a chemical nature brought about as a result of exaggerated physical activity (Pieraccini, Boveri, etc.); often certain
toxic substances (lead, alcohol, nicotine, coffee) exercise a preponderating or concomitant action; toxic-infectious factors arising from various acute and chronic maladies, and in particular syphilis; finally, factors of a psychological nature (intense mental work, overpressure, anxiety, worries, etc.).

The extreme consequences of diffuse arterio-sclerosis, whether associated with high blood pressure or not, are known and need not be insisted on here. The trades which require a limited and circumscribed activity but at the same time necessitate intense manual work produce arterio-sclerotic manifestations of a local nature (Baeumler, Pottain, Taisson), and along lines of hardened serpiginous arteries can be brought out clearly by radiography (Pieraccini), especially among dressers of stone, turners, shoe-makers, polishers, ironers, laundry-workers, etc. Among the last-named account should be taken of exposure to cold (Devoto).

From the examination of 500 coal miners, D. Elliot and W. Arnott Dick-son (1929) were led to the conclusion that the circulatory apparatus in this class of worker shows at all ages an extraordinary predominance of thickened arteries, limited in cases examined to the innermost layers, and that this condition was not accompanied by an increase in blood pressure, while the constant factors of importance accompanying it were: (a) inhalation of air that had undergone change as to the amount of carbon dioxide; (b) the absence of natural lighting; and finally that the high rate of mortality found among miners might be due to the frequency of arterio-sclerosis.

Aneurism is often found associated with an arterio-sclerotic condition, especially when at the same time syphilis is present or traumatism in certain predisposing personal factors. Be-nassi reported in 1925 two cases of sudden death during work from spontaneous rupture of the aorta.

Arterial resistance is increased the further the arteries are from the heart and the smaller their calibre (Haller). Consequently the aorta and especially the region of the aortic arch are the parts most exposed to dilatation, because they are the parts most directly and perpendicularly affected by the blood column.

Among peripheral arterial lesions, mention should be made of those resulting from work in compressed air (see article "Compressed Air") and in particular work with pneumatic tools (see article "Pneumatic Tools"). Some cases of writers' cramp are due to sclerosis and atheromatous degeneration of the brachial arteries (intermittent angiosclerotic dyskinesia). This is an affection resembling claudication, met with among women workers whose hands and arms are exposed to cold (Dettermann).

Functional affections of the capillary circulation have been described by Meyer-Brodantz and Wollheim (1929) among workmen employed on machines for beating hides in the leather industry. Examination of twenty work-ers showed the presence of a tendency to muscular contraction under the influence of mechanical action and of cold, similar to the affection met with in the form of "dead fingers". The authors regard this as an industrial malady due to violent and frequent vibration of the machine for beating the leather (see article "Pneumatic Tools").

Phenomena in regard to capillary circulation accompanied by a fall of blood pressure, alteration of temperature, etc., have been reported in cases of anaphylactic shock. Arduous work, finally, seems to have an influence on the blood pressure; reduced pressure has been recorded at the end of the week's work (Rogowski).

The occupational pathology of the veins is relatively simple and indeed it may be said to have lost importance since the improvement in conditions of work (shorter hours, seats provided at work, etc.). Not long ago, especially in districts where women were recruited for industrial work at an unduly early age, varicose veins of the legs were frequently met with. Evidently a prolonged standing posture predisposed these lymphatic and thin girls to venous stasis with involvement of the capillaries, sensation of painful tension in the legs, occurrence of oedema towards evening, etc. (Devoto).

Dilatation of the haemorrhoidal veins is found, especially among persons who are obliged by their work to remain seated (teachers, tailors, shoe-makers, etc.) or standing. Great importance cannot be attached, on the other hand, to work as a cause of varicocele, which is often found to be present even at the entrance examination.

Special attention must be paid to the problem of varicose veins in the legs and especially varicose ulcers of the leg 1, which both old and modern writers consider to be closely related to occupation as regards etiology. The old view of the French school which laid the blame on arthritic constitution

---

1 The following notes referring to varicose ulcers of the leg are according to an original report by Prof. ULMANN, Vienna.
has now been replaced by the theory of stasis developed by Ferd. Hebra, P. G. Unna and Th. Biliroth. A prolonged standing, or a burden placed on the leg beyond the resisting capacity of the veins of the lower limbs ends by weakening the valves of the cutaneous veins first and of the muscular veins afterwards; stasis favours the engorgement of the venous ramifications deprived of such valves and brings about oedema which may or may not be accompanied by characteristic pain. The stasis is not always uniform; it generally affects both legs and brings about itching, which leads to scratching, excoriations, erosions, infection and to varied forms of eczema and moist or hyperkeratotic lichen. These manifestations are met with affecting indifferently workmen and others, but they certainly may be brought about or aggravated by certain industries. Among women, besides these general causes, pregnancy must be borne in mind.

The most important factor, however, lies in individual predisposition, often of early occurrence, and clearly noted as limited to certain families, being handed on from one generation to another. This lack of resistance capacity in the veins is still considered as a point of departure for pathological manifestations. In women the relaxation of the venous tissues during pregnancy and perhaps the effect of injurious substances arising from metabolism in the suppression of ovarian functions, increases the predisposition to slackening and dilation of the veins.

Delater and Huegel consider that these varicose conditions are a final result of disturbed endocrine action resulting from dilatation of the walls of the veins. Under the name of "varicose syndrome" G. Nobil has drawn up a table showing all the characters of the dermatoses resulting from stasis — varicose veins, oedema, haemorrhages, secondary pigmentations and ulceration.

Although the correlation of varicose or "gravitation" ulcers with many occupations has been long recognised, some authorities consider that even without the influence of such occupations it would develop in particular individuals, but it is nevertheless true that an occupation imposes a special strain on the veins and may even be held to be a cause of an eczema, an excoriation, an infection, an injury, a burn, some abnormal development of a sore after a wound, the evolution or commencement of a chronic ulcerative process, a necrosis or an ulcer, not necessarily a varicose ulcer of the leg. Without the predisposing factor, and without the presence of varicose veins, this is certainly exceptional, with a resulting tendency to scepticism in regard to the purely occupational origin of such affections.

Numerous statistics, however, prove quite certainly a markedly high incidence of ulcers of the leg in certain occupations (very high percentage among locomotive mechanics, Moscow, 1926, Memorski). The trained physician who is called as an assessor before a tribunal to determine the causation of a varicose ulcer of the leg or advanced varicose veins in the leg is bound to raise the question of the past existence of prolonged muscular effort of an occupational nature, such as would be capable of increasing any predisposition to the formation of ulcers if not to set them up of itself, or, on the other hand, the existence of a single or repeated injury of thermal or chemical origin which might start the formation of the ulcer.

This question becomes the more difficult from the point of view of legal compensation since the dividing line between an accident and an occupational disease is no longer so clear in the case under consideration as it formerly was.

For the factory surgeon or physician as opposed to the pathologist, the genesis of the lesion is more important than its form and severity (Hasselmann).

To determine the influence of an external factor favourable to the development of an ulcer is extremely difficult in the case of an ulcer in the leg. Great differences certainly exist between the venous network and the existence of varicose veins in different occupations. An occupant of a job involving arduous work, it is possible to estimate the effect of the effort on the state of the vessels and even between that of the right and left sides or vice versa, according as the person is right or left-handed. Anatomical conditions may have an unfavourable influence in the case of a worker engaged in heavy work (e.g. the length of the lower limbs, or, consequentially, on the weight of the body in the case of work done standing, there occurs dilatation of the walls of the veins, the formation of flat-foot and painful cramps). Considerable muscular effort, especially during voluntary movements, movements necessitating balancing on one foot, continual walking in the case of waiters, unilateral activity) drives the blood of the muscles into the cutaneous veins and so favours the
formation of varicosity. According to the nature of the occupation, all kinds of lesions tend where predisposition is present towards the formation of ulcers or what is still more frequent accelerate the development of such ulcers. Thus it becomes impossible, except in special cases, to distinguish between constitutional factors and accidental factors that have determined or aggravated such conditions among workpeople. A certain number of individuals may have suffered from them even before taking up work in the factory and there is scarcely sufficient justification for excluding them from work even in the case of an industry involving particular risks of injury to the feet or legs. Further, bakers, tanners, smiths, carpenters, had no relation to varicose veins because of the lack of muscular movement in the lower limbs (Nobl).

In Mongol countries, particularly among Japanese, consequent on, or even primitive sitting with crossed legs; varicose veins are comparatively rare (G. Nobl), in contrast to the Java-nese, among whom ulceration of the leg is almost a national disease (Roeg-holt).

Old and recent statistics show at first that both sexes are affected to approximately the same extent, and further that pregnancy does not have the particular influence sometimes attributed to it. Nobl found in 47,540 cases of ulcerated legs (old and recent statistics of the Prague and Vienna hospitals), 29,165 men and 18,375 women, that in 1907 the sickness insurance societies of Vienna showed 16,832 days of sickness among employees of restaurants and tramways 11.7 per cent. In addition to the constitutional and hereditary factors, account, should therefore be taken of the mechanical factor with the conclusion that both are of equal importance.

As the results of 1,984 observations on subjects between 20 and 60 years of age belonging to most varied occupations, S. Diez (1929) concludes that there is no excess of varicose veins in industries likely to create obstacles favouring stasis of the blood in the circulation of venous blood in the lower limbs.

The origin of varicose veins should be sought in constitutional, congenital or acquired factors, anatomical or functional, rather than in unfavourable conditions created by certain industris in the peripheral circulation. These occupations, and particularly sedentary occupations, may, however, aggravate a condition already established by the action of constitutional factors. According to Diez, varicose veins are not therefore an industrial disease; on the other hand, certain industries are incompatible with such a condition.

Ravogli (Cincinnati) has reported that among male workers with a high incidence for ulceration of the legs, he found 284 day labourers, 27 porters, 40 vehicle drivers, 23 cooks, 22 hairdressers and coopers and 1 colporteur.

Among 195 women, there were 117 engaged in house-work, 36 were unemployed and 27 were in charge of households.

The importance of the role played by occupation is also revealed by a statement of the number of days lost: in 1907 the sickness insurance societies of Vienna showed 16,832 days of sickness for 636 persons (357 men and 279 women); for the period 1908-1912, 70,003 days of sickness; 4,600 sick persons, of whom 784 were women, who underwent treatment of ulcers, 50 days' duration for each case (Nobl). Following the example of Vienna, Berlin and other towns have provided consultation rooms for affection of the legs, thus eliminating, to some extent, the necessity of having to lie up, loss of working time, and incapacity so frequent in the past.

At the present time even severe ulcers are cured by this treatment. It is only in the case of thrombophlebitis, progressive ulcers, loss of tone or great
irritability that it is necessary to stop work and lie up with the leg in a raised position for weeks. On the other hand, deep ulcers, which are often unrecognized, require prolonged treatment in cases of thrombophlebitis.

Some exactitude in the diagnosis of these different forms of varicose veins and ulcers is necessary to-day for practitioners in industry. Incipient ulcers should be considered and treated separately from advanced ulcers. Thanks to early intervention, capable workers with a tendency to excessive ulcers should be considered and treated separately in the practitioner's consulting room by means of the present-day methods available.

Mention should be made of certain complications, such as the flaccid, sluggish, indurated ulcer, healing with difficulty, immobility and elephantiasis of the foot, haemorrhages and rupture of varicose veins, limpethe eczema, erysipelas and other acute infections, inflammations, etc. These complications are of practical importance, especially when it is a question of ascertaining cause and effect as regards the occupation and the lesion. Pain, affected with various scars or elephantiasis showing considerable functional impotence, with a tendency to traumatic necrosis and occasional infections, should be regarded with caution from the point of view of working capacity, since it is impossible to cure such cases without resting the injured limb. The most important complication is acute and chronic eczema, whether it takes the form of a primary condition with the possibility of infection leading on to ulceration, or of a secondary nature due to ulcers and varicose veins already existent; if neglected, both cases may lead to incapacity for work and prolonged suffering involving considerable expense. Regular medical supervision will prevent the occurrence of such complications.

Ullmann, Oppenheim and Kennedy have found in addition efflorescences of "lichen ruber" occurring alongside varicose veins. Often enough cancer may occur as a complication of an ulceration of the leg and A. Jung has described recently the case of a man with two ulcers which developed into cancer.

Treatment belongs to the sphere of the medical practitioner.

Persons with cardio-vascular lesions are entitled to receive compensation for the condition as arising out of occupa-

**Respiratory System**

The interchange of gases between the body and the surrounding air is effected, in the case of human beings, by the circulation of air contained in the lungs. Inhaled air always carries with it small particles of dust, especially particles of
coal, which come from the fuel used for heating and lighting. This accounts for the well-known black colouring of the lungs, which is found in autopsies on all adults who have passed their lives in large cities.

In a great many industries the workers are simultaneously affected by fumes and dust resulting from work, e.g., during the preparation of chloride of lime, the respiratory apparatus is simultaneously exposed to the action of lime dust and of chlorine. This article will be confined to the study of the effects of fumes and dusts which actually find their way into the respiratory system, since all the forms of poisoning caused by these substances, as well as the diseases brought on by infectious dusts, are dealt with in special articles.

**Sources of Danger**

**Gases.** In various industrial operations a number of gaseous products are used or liberated, which may have an injurious effect on the respiratory apparatus. Amongst others are the halogens (chlorine, bromine, iodine) and their combinations with hydrogen (hydrochloric and fluorhydric acids), sulphurised hydrogen, ammonia, chlorine of ammonia, nitric acid and the so-called “nitrous” fumes, sulphur dioxide, phosgene, acetic acid, formaldehyde, acrolein, and fumes from smoke. These same gases, as well as such intermediary products as cyanide of phosgene, fluorine of dimethylarsine and of diphenylarsine, and sulphide of dichloethylene, are chiefly met with in war gas factories.

The effects of gases are extremely complex, for not only do they act on the nervous system, the mucous membranes of the nose, the larynx, the bronchial tubes, the bronchial muscles, the alveolar epithelium and the capillaries of the lung, but all these influences react on each other. In addition, there are the modifications of the respiratory caused by chemical alterations in the blood.

All acids stimulate the respiratory centre, and thus, at the beginning of their action, increase the absorption of the poison. Even narcotic fumes, before paralysing the respiration, exercise a stimulating action on the respiratory centre. But, while the fumes irritate the mucous membranes, by stimulating the trigeminal and the sensory fibres of the pneumogastric, they produce a reflex paralysing action on the inspiration and this causes sneezing, cough, closing of the glottis and contraction of the bronchial muscles. Vomiting also belongs to these reflex phenomena which have a protective influence by diminishing the absorption of the injurious substances.

A combination of these stimulating and paralysing actions brings on the terrible dyspnoea which characterises several of the acute poisonings — for example, poisoning by hydrocyanic acid — which persists up to the moment of loss of consciousness.

If such narcotic gases as carbon dioxide, protoxyde of nitrogen, ethylene or acetylene are mixed with gases which irritate the mucous membranes, the protective reflexes which paralyse inspiration are further depressed. Ammonia, by its liposoluble action, has a narcotic effect, and this results not only in increasing the danger from toxic gases, but it also favours a long period of latency with no sign of ill-health until the appearance of the symptoms.

The action on the capillaries of the lung is chiefly demonstrated, in a good many cases, by the appearance of pulmonary oedema, caused, for example, by ammonia, or of a severe hyperaemia of the lungs, accompanied by capillary haemorrhage, such as components of arsenic set up.

These primary lesions are followed by secondary foci of broncho-pneumonic inflammation, and this inflammation does not, as a rule, manifest itself until after an interval of apparent health. This period of latency is very characteristic, lasting, as a rule, a few hours, and even, though rarely, some days. A man who has been working in an atmosphere containing such dangerous fumes as nitrous fumes, without feeling any ill-effect beyond sneezing and coughing fits, goes home as usual, has his supper and goes to bed without feeling ill in any way. During the night or in the morning, he is suddenly seized with faintness, dyspnoea, and cough, accompanied with abundant expectoration of blood-stained and muco-purulent discharge, indicative of pulmonary oedema. This acute attack may develop rapidly and either end fatally, or pass off. But even in the case of a recovery, chronic inflammatory results are very often left behind, localised to the bronchi, or to parts of the lung weakened by previous illnesses. In obliterating bronchitis may then be observed, or a chronic pneumonia, or a pulmonary induration, or, finally, a vicarious emphysema in parts of the lung which, up to that time, have been unaffected.

**Dust.** Whereas the physical and chemical laws which control gases are accurately known, the physical properties of the various kinds of dust
which constitute industrial dust are far from being defined, for they have only recently been studied. Molecular and capillary phenomena assume the greatest importance when dealing with small particles; on the other hand, these phenomena are of minor import when the mechanical laws governing solid bodies of large dimensions are in action. It is a recognised fact that the former of these are charged with electricity, that they are surrounded with minute atmospheres of condensed gases which adhere closely to them; that numerous substances are hydrophile, attracting large quantities of water, whereas others are hydrophobe, rejecting every trace of water. Various substances, although they are hydrophobe, absorb liquid carbohydrates and fatty oils (general lyophilia); thus, charcoal and carbonate of lime are hydrophobe, and amorphous silicates and humic acids are, intensely hydrophile. By treating soot with benzol it becomes hydrophile, and, on the contrary, if silicates are heated they become crystalline and lose most of their hydrophile property. Silicates can also be made hydrophobe by being thoroughly mixed with very finely powdered charcoal.

As regards inhalation, importance need only be attached to the dust which remains suspended in the air.

The quantity of this dust depends: (1) on the size of the particles, their specific weight, the shape of their surfaces, and their hydrophilia; (2) on their electrical state; (3) on the rapidity of air currents during work; and (4) on the composition of the air, especially with regard to the degree of humidity of the air and the presence of electric currents.

The amount of water held by dust depends, in the main, on its chemical constitution; but the shape of the particles also makes a difference, irregular and concave surfaces attracting more moisture than a convex surface. It is impossible to discern under the microscope whether the particles of a particular kind of dust are crystalline or amorphous; it is a case of internal structure, which can only be elucidated by a radio-spectroscopic examination.

The local and chemical action of dust, as well as its general toxic and immunising action, depends in the first place on its solubility in the fluids of the body. The smaller the particles are, the greater is their solubility and their power of reacting chemically. Further, their solubility is much influenced by the presence of other substances. Thus silicic acid (SiO₂) is soluble in water in the proportion of 1 : 10,000; this solubility is much increased by oxygen, carbon dioxides, alcalis, organic substances and humic acid. Among the natural ores of silicic acid, quartz is the most difficult to modify and opal is the easiest.

The absorbent action of dust must be recognised, as well as its purely chemical action. When a hydrophile dust — e.g. amorphous silicate, which is intensely hydrophile — absorbs water from the tissues of the respiratory organs, it causes a local necrosis. In the same way, serious consequences may result when substances that are important to life are extracted from protoplasm by lyophilia.

Then again, particles of dust may convey irritant and toxic substances in a gaseous or liquid form, these substances adhering to the particles and penetrating with them into the tissues and causing chemico-tactical actions, necrosis, inflammation and allergic phenomena.

In comparison with these fundamental physico-chemical and biological actions of dust, the lesions caused by certain sharp-edged particles seem of quite secondary importance. And yet, in the past, it was believed that these sharp-edged particles caused all the trouble.

Pathology

The Upper Respiratory Tracts

For occupational affections of the nose and larynx see article "Occupational Diseases: Ear, Throat and Nose".

The affections of the bronchi and of the lungs cannot be studied on pathological-anatomical lines, for the typical forms — bronchitis, lobular pneumonia, lobar pneumonia, pleurisy and emphysema — may be found in the same patient, and may even co-exist with tuberculosis. Therefore, there shall be dealt with here the syndromes and symptoms, which are most important from a practical point of view, without trying to carry out a strictly systematic study of the whole.

Occasional emphysema is found in occupations: (a) which are carried on in the open air, the workers being exposed to all weathers; in these cases there is found a succession of relapses after bronchitis or chronic bronchitis, e.g. among foresters and gardeners; (b) occupations in which dust is raised, even though these occupations do not
bring about pneumoconiosis, as the result of chronic bronchitis or relapses after bronchitis, as for example among scavengers, and those who sell and handle scraps of cloth and rags, rag-pickers, and workers in factories making up jute sacks for millers and bakers; (3) in which occupational asthma are observed, with frequent crises, developing into a permanent condition of asthmatic, pulmonary disension; and (d) which expose the workers to the inhalation of irritant gases and dust. It is then a complication of an obliterating bronchitis, the emphysema affecting the parts of the lung untouched by fibrosis.

In all the cases there is evidence of the "emphysematous heart", characterised by definite dilatation and thickening of the walls of the right ventricle. In addition to the clinical picture of the pulmonary lesion, there is gradually seen to develop the clinical picture of a fatal cardiac disorder, with serious dyspnoea, cyanosis and dropsy.

Laennec's theory, which attributes emphysema to the use of wind instruments, has not been confirmed by recent research. As a matter of fact cases of emphysema have not been proved to be especially numerous among professional musicians and glass blowers.

A typical occupational disease is the pneumonia which attacks workers who handle basic slag (see that article) as well as farm labourers who scatter it on the fields. Bacteriological examination has indicated the presence of the diplococcus discovered by Fraenkel-Weichselbaum.

Cases of acute lobar pneumonia are also numerous among miners and crushers of limonite (Fe₂(OH)₃) ferric hydrate). The acute lobar form is generally caused by inhaling irritant fumes. Acute and chronic cases of catarrhal pneumonia are frequent as complications of pneumoconiosis, in which the lesion, especially in the case of miners, often turns to induration and to the closing of the lymphatic passages, impeding the reabsorption of the exudations of the alveoli.

Various writers have attributed primary tumours of the bronchi and of the lungs to the inhalation of dust. Certainly "Schneeberg" disease — pulmonary cancer from which the workers in the cobalt mines of Saxony suffer (see article "Cobalt") — must be reckoned as an occupational disease, although the etiology is not yet clearly established. In the United States of America it appears that cases of carcinoma of the lung have been observed among petrol refiners, and that this resembles the cancer of the skin caused by paraffin.

Pulmonary haemorrhage may occur in extremely varied microchemical pneumoconiosis; the bleeding is of broncho-pneumonic source, and also comes from bronchiectasis, from cavities or from a blood vessel perforated by a pulmonary calculus. Of course haemoptyses may also be due to a tuberculous complication. In the case of stonecutters suffering from pneumoconiosis and tuberculosis, blood-splitting is more often found when the stones cut are hard. Fatal haemoptyses have been observed after the rupture of a lymphatic anthracotic gland, simultaneously into the left bronchus and into the aorta or else into a bronchus and a pulmonary artery.

**Diseases due to dust.** — The best classification — according to Sternberg — of the effects of dust is as follows: diseases due to: (a) an allergic action, affecting the organism, causing asthma; (b) local chromatism from soot or tobacco; (c) a local microchemical reaction, as in silicosis, chalciosis and pneumoconiosis in the strict sense of the term; (d) a local colloidal reaction, as in amylosis of the bronchi; and (e) infections, such as anthrax, tuberculosis, pneumonia, pneumomycosis and psittacosis (?).

Further research is necessary before it is certain how far occupational dust can activate an infection or prevent it, or act as an agent in the development of a carcinoma.

There may be provisionally classed as anaphylactic or allergic asthma various pneumoconiosis, some of which are well recognised, whereas others have as yet been but little studied. They are accompanied by pruriginous forms of dermatosis, described, partly, as distinct diseases of the skin.

The problem of occupational asthma is the same as that of occupational anaphylaxis. 1

---

1 At the outset the term used was "pneumoconiosis" (Zenker, 1866).
In many of the cases the occupational character of the disease is clearly defined. The anaphylaxis is caused by the pollen of gramminaceous plants, dust from threshing oats, from hackling hemp and flax, from jute or cotton when opening the bales, or from flour, causing millers' and bakers' asthma.

Cases of asthma of the same variety have been observed in chemists and upholsterers, caused by such chemical products as aspirin, arszenobenzoles, ipecacuanha or lead, as well as in persons who come in contact with dust of animal origin, such as feathers, down and animal scales and hairs. In one case the asthma was caused by sepia bone reduced to powder for preparing the mould into which the goldsmith pours the molten gold (Ancona).

In the case of furriers who use "ursol", asthmatic attacks as a rule occur only in those who prepare or handle black furs, after several years of work, during which they may have experienced no ill-effects. Simultaneously or independently of the asthma, cutaneous lesions may make their appearance — urticaria, acute and chronic eczema, and erysipeloid forms, which have also been found in persons who wear furs dyed with "ursol" (see article "Paraphenylendiamine").

Cases of asthma have also been observed in florists, horticulturists and fruit pickers; they may also be accompanied by pruriginous dermatitis, and these cases are based on allergy acquired by the inhalation of vegetable dust, which often contains an acarus — the pediculoid ventricosus, its secretions and excretions. This acarus lives in parasite form on the larvae of certain insects (Sitotroga cerealella, Tinea granella, etc.), which are themselves parasites on cereals. (See also article "Flour Mills").

Bridge in 1926 drew attention to cases of coughing among workmen in malt-houses, which were attributed to the presence in the malt dust of mycella and spores of Rhizopus nigricans.

Fits of coughing came on after work, and were accompanied by a sensation of constriction in the thorax, and by abundant expectoration in the morning.

Silk-spinners' asthma, caused by handling silkworms' cocoons (Bombyx mori) is accompanied by inflammation of the eyes and a pruriginous dermatitis (mal des bassines) (see article "Silk").

As is well known, it is a question of proteins that are not completely homogeneous nor heterogeneous; they act on persons who are predisposed; and successive introductions of these proteins start the anaphylactic attack.

This predisposition is facilitated by a thymic, thymolymphatic or arthritic constitution; it consists essentially of a feeble colloidal equilibrium, known as Widal's colloid diathesis. Here, under the stimulation caused by minute quantities of the substance which has become sensitised or anaphylactised, an instantaneous change in the physical and electrical arrangement of the protoplasmic colloids takes place.

Among the pneumomyceses may be quoted the cases described in 1927 by Nussbaum and Benedikt of tumours of the lungs of occupational origin due to a penicillium.

Kovacs, of Budapest, in 1930 reported a special disease of the respiratory apparatus in workers engaged in gathering red pepper (paprika). The symptoms resembled those of tuberculosis; radiography showed a picture of diffuse broncho-alveolitis. There has also been noted bronchiectasis, at times very serious, as well as pleural lesions. Examination of the sputum is essential for differential diagnosis. The disease was at first attributed to dust raised by manipulation of the product in gathering it; but since the disease did not occur amongst workers handling the product during the processes of sorting and packing, etc., it is considered that the bronchial lesion is due to the fine spores of the parasitic moulds on the plant.

In the pneumoconiosis caused by soot, which is found amongst coal-miners, chimney sweeps and stokers on trains, the lungs are very black but are free from sclerosis. In the pneumoconiosis due to wood charcoal (Traube) the lungs are not thickened, which is also the case with coal-miners' lungs when the seams do not penetrate hard rock. Experiments on animals have given the same results. So it seems that it may be concluded that coal alone cannot cause pulmonary fibrosis. Arnold has described these disorders under the name of "anthracosis simplex"; pneumoconiosis caused by tobacco can probably be grouped under the same heading. A red coloration of the lung with silicotic fibrosis is found among men who work on haematite, and a green coloration among men who work on steatite. Siderosis, that is black or red pneumoconiosis, due to iron, discussed in the past, as well as pneumoconiosis due to ultramarine, are only rarely seen now, owing to the improvements brought about in industrial processes. These diseases were, in fact, silicosis.
Diffuse fibrosis of the lung, caused by continuous inhalation of dust, comes under the term "pneumoconiosis". According to Devoto, all pulmonary diseases due to dust come under the term "pneumoconiosis" and, setting aside the anatomo-pathological conception or an anatomo-pathological analogy, there must be included, according to more modern interpretation, bronchitis, peribronchitis, the so-called asthmatic disorders of occupational origin, pulmonary fibrosis, and, lastly, pulmonary emphysema, chronic bronchial pneumonia, the changes caused by dusts, and such forms of tuberculosis as miners' phthisis and bakers' phthisis, even where dust alone is not responsible, but only so in combination with other factors.

In the pure chalicosis that affects stoncutters, cement-makers and potters, the lung is thick and heavy; the pleura is thickened and of grey colour; it sometimes adheres to the costal pleura and its free parts are marked with little compact nodules the size of a pinhead, surrounded by numerous little pigmented zones of a dark colour. The pulmonary tissue is sprinkled with little compact nodules and with large, hard, confluent nodules. Isolated nodules, consisting of bundles of connective tissue fibres, concentric or placed spirally, sometimes in hyaline degeneration, are only slightly vascularised. The outside layers are strongly pigmented with coal, coming sometimes from heating and lighting, and sometimes inhaled in industry, at the same time as stone dust. The structure of the nodules is analogous to that of cheloids on the skin. The part of the lung which is not affected by fibrosis is generally emphysematous.

In continental Europe stonecutters' pneumoconiosis has become somewhat rare, for, in monumental building, freestone is being increasingly replaced by artificial stone.

Indurative anthracosis — a form of chalicosis complicated with anthracosis — is very widespread, especially among ironfounders, who inhale dust from stone and graphite during the preparation and demolition of moulds, as likewise among miners. In slight cases the lungs exhibit black compact bands and spots; in more serious forms, the whole lung is blue-black or intensely black and hard, sometimes with cavities which are probably due to the necrosis of fibrous tissue, but perhaps also to suppuriation from bronchiectases. The combination of pneumoconiosis with tuberculosis is very common, and highly competent specialists are inclined to think that pneumoconiosis, especially among miners, is generally the result of the combined effect of dust and a tuberculous infection. It is at any rate certain that in particular cases of anthracosis with cavities the most minute microscopic examination has not revealed any tuberculous lesions.

It is very probable that "chalicosis" is only another name for silicosis, and that pulmonary fibrosis is caused by inhaled silica dust, which originates either from natural ores or from such artificial articles as glass and china, or even from coal, of which silica in the form of sand may be a constituent.

Dust is carried into the alveoli of the lungs by the force of the inspiration, whence it is removed into the lymph channels by phagocytosis.

Dust found in expectoration is either found in the free state or encased in the cells. If the inhalation of dust is stopped for prolonged periods, it may be largely eliminated from the lung and specially localised in the lymphatic glands. But the fibrosis remains.

The clinical picture of pneumoconiosis is not clearly defined. Subjective disorders, as a rule, only appear when there are complications, after a chill or an accident, in the course of acute bronchitis or of an acute crisis in chronic tuberculosis. Devoto and his followers have emphasised the frequency of latent pulmonary lesions caused by dust. This latency does not signify that there is still functional or organic integrity of the pulmonary tissue, for this integrity in reality no longer exists, or rather, one should say, it is only present in normal conditions of health, as a true and typical cause of lessened resistance when any intercurrent pulmonary affection, such as pneumonia, occurs. Diminution in resistance of the pulmonary tissue invaded by dust is a real fact, and not an abstract conception of a functional nature. In the first phase the respiratory activity is affected; in the second, the cardiac functions. Dyspnoea is the chief symptom. Yet the workers retain their capacity for work, and only experience difficulty in breathing when their work requires great exertion. After a certain lapse of time a dry, hacking cough appears, with pains in the chest and limbs, slight haemoptysis and a rise of temperature. The objective symptoms are those of emphysema; there is not, as a rule, any decided dullness. Bäumler's sign of a narrow zone of dullness on the left sternal edge is not often found. As
the case progresses, symptoms of chronic bronchitis become predominant, and finally those of cardiac impairment or of tuberculosis. Hoarseness is due to laryngitis or to paralysis of the left recurrent laryngeal nerve, due to pressure from lymphatic nodules. The onset of serious lesions requires, on an average, an "effective period" of ten years.

The radiological picture is not an expression of the dust deposit, but of fibrosis. In the early stages of the illness an accentuation of the hilum shadow is observable, and a very slight haziness in the peripheral part of the pulmonary area which is normally clear. The pattern of the hilum zone becomes more linear, and divides up into segments as the illness develops. The symmetry of the hilum shadow is often compared with the picture of a butterfly. Little patches of shadow scattered all over the pulmonary area look like a picture of a "snowstorm", with radial bands across. The apices, as well as the lower lateral parts of the lungs generally remain free (see fig. 51).

Heavy shadows may be observed, as well as shaded patches in the form of large nodules. There is no completely characteristic radiographic picture.

Dust from iron, silica and coal throw particularly pronounced and characteristic radiological shadows. In pure siderosis the lung is riddled with in-

numerable little patches as small as millet seeds, but these are clearly distinguishable from tuberculosis and carcinomatosis by their far greater density, and by their clearly defined outline (Schaab).

Most of the men who worked at sand-blasting, i.e. cleaning steel castings by means of a sand jet, prior to the use of up-to-date apparatus used to present a serious condition with fatal issue. But in such cases, the clinical symptoms are now greatly reduced, for in the first period all are agreed in recognizing simple laboured breathing; in the second period a desquamative catarrh with dyspnoea; and in the third period a pseudo-emphysematous condition with infiltration, fibrosis and mucopurulent expectoration (Denet-Kravitz).

A case of pulmonary siderosis was described by Rist in 1923 as affecting a workman who had worked all his life in metallurgy, exposed to the inhalation of iron dust. He suffered from pulmonary fibrosis, without emphysema, and without any pulmonary lesion in the parenchymatous focus; he had only an accentuation of the hilum shadows. Breathing was permanently quickened, and vital capacity was reduced; basal metabolism was normal, but a moderate degree of cyanosis was present with a slight increase in red blood cells. Five years after giving up his occupation the expectoration still gave iron reactions (1.5 mg. of iron per 100 grm. of expectoration), but contained no bacilli.

As regards pulmonary fibrosis caused by asbestos (see that article) mention will here be confined to pointing out that one case of asbestosis was reported by Fahr, of Hamburg, in 1914. It was the case of a workman who died from chronic pneumonia, in whose pulmonary tissue microscopic examination revealed the presence of numerous crystals which were held to be asbestos crystals. A similar case had been reported in 1906 by Marchand and Riesel, but they were doubtful as to whether what they found was not the residue of haemoglobin.

In Great Britain, a great deal has been written on the subject. The first fatal case of asbestosis was described by Montagu Murray in 1906. The man referred to died in 1900, and Murray remarked, in his report, that during the next seven years he had never come across another case. Eighteen years later, in 1924, W. E. Cooke described another case, the symptom findings of which he reported in 1927, and announced the discovery of "curious bodies" which he had detected after examining the lung micro-
were described in detail by Stuart Macdonald in 1927. Anatomopathological study enabled him not only to detect an extensive fibrosis of the lungs, but also changes due to pulmonary tuberculosis. The co-existence of these lesions raised the question as to whether the fibrosis was a result of the inhalation of asbestos dust, or partly a reaction from the tuberculous infection. In 1928, Macgregor, of Glasgow, drew attention to an asbestos worker being treated for pulmonary tuberculosis. An inquiry was instituted with the object of studying the effect of his occupation on the illness. A certain number of asbestos workers were selected and examined, both clinically and radiologically; subsequently the enquiry was extended to the whole of the staff, attention being paid to the various processes of the work. Meanwhile, the death of an asbestos worker was reported, and the autopsy revealed extensive fibrosis of the lungs, and no tuberculosis. The diagnosis disclosed again the "curious bodies" of Cooke. Since then I. M. D. Grieve has carefully observed a group of asbestos workers. In 1928 two other fatal cases were reported, one of which was that of a native working in an asbestos mine in Southern Rhodesia. According to Stewart, of Leeds, and A. C. Haddow, the "curious bodies" referred to by Cooke can be found in the fluid removed by puncture in the expectoration, and, after death, in the pulmonary juice.

In 1927, Oliver, Cooke and Stuart Macdonald described a case of asbestosis; Oliver and Haddow another case; and in 1928 F. W. Simson, of Johannesburg, observed four cases among native workers of Southern Rhodesia. Mavrogordato's experimental research has emphasised the fact of the presence in the lungs of golden-yellow coloured bodies, similar to those found in the lungs of persons who have died from asbestosis. The opinion is that these bodies are fibres of asbestos that have become altered.

In 1929 several other reports were read at a meeting of the British Medical Association at Manchester, as well as other results obtained from the examination of asbestos workers. W. B. Wood carried out a special radiological examination of fifteen workers; S. R. Glyne investigated the nature of the "curious bodies", which he judges to be asbestos fibres, round which a substance has been deposited — probably blood pigment.

An enquiry on the incidence of asbestosis was published in 1930 by the English Factory Medical Inspection Department. Out of 363 workers who had been in the asbestos industry for some time, and were medically examined, 105 were suffering from asbestosis (Merewether and Price). The clinical findings and radiographical appearances of these men were described in 1930 by Merewether, who stresses the extensive impairment caused in the lungs, leading up to a fatal issue, and the presence of fine generalised X-ray shadows over both lungs. But of 30 asbestos workers examined in 1908 by Scarpa, 29 were suffering from pulmonary tuberculosis and died in the course of the twelve months which followed the first visit made by the writer.

For details as to fibrosis caused by talc, see article "Talc.

The diagnosis of pneumoconiosis is based on the nature of the occupation, the duration of the illness, the subjective symptoms, the clinical examination and especially on the radiographic picture. It is fairly easy to make a differential diagnosis from emphysema, pleural thickening, pulmonary echinocosis, diseases of the heart or aneurism; but it is more difficult to differentiate between this and pulmonary carcinoma, actinomycosis, aspergillosis, penicilliosis, pulmonary syphilis and, particularly tuberculosis. This is often only possible after long observation and frequent examination of expectoration. In these days it is important to look for silica in the expectoration (Campbell). This is easy to understand, for tuberculosis is not only a complication of pneumoconiosis, but, in the miners' occupation, it is quite accurate to speak of a definite form of tuberculo-silicosis or silico-tuberculosis (Watkins-Pitchford). (See article "Tuberculosis and Silicosis").

Statistics

While respiratory diseases do not always constitute occupational diseases in the strict sense of the word, they figure among the pathological affections which cause the most considerable loss of working days. Thus, in the United States, according to the returns of thirty-five sickness insurance societies, comprising about 100,000 persons, 47 per cent. of all the diseases for which sick pay was accorded from 1921 to 1926 were due to respiratory affections. It should also be noted that it is the more serious affections which are especially concerned, the societies only accord payment when the disease has caused absence from work for eight days or over.

In a large American electric power and light company, about three out of six days lost yearly by the personnel on
account of disease were due to respiratory affections. On the clinical form
being investigated, it showed that 70 per cent. of the absences were due to what
is commonly called a cold, which caused incapacity for work in 4 out of 10 men,
and 7 out of 10 women yearly. The incidence of such other respiratory diseases
as were noted to occur with a definite frequency, like influenza, tonsillitis and
throat affections, varied according to season, with a maximum about the month of
February and a minimum about the middle of summer. Incapacity for work for
eight days or more among a group of workers of the company in question for
the period 1921-1926 gave the

As regards silicosis from respiratory diseases, according to the *Decennial
Supplement* of the English Registrar General for the period 1912-1923, it seems
that the mortality is closely associated with the social condition, and that it
depends on whether respiratory diseases include tuberculosis or not. The table
reproduced below in two parts, A and B, shows the occupational groups with the
lowest and highest rates of mortality from respiratory diseases:

### A. OCCUPATIONS WITH LOWEST MORTALITY

As regards silicosis, see articles "Silicosis-Tuberculosis" and "Gold Mines". It is, however, interesting to mention here that whereas in 1915, out of 3,136 gold-
minters of the Transvaal, 32 per cent. were affected with pneumoconiosis, a systematic medical examination of white workers — organised in 1916 — has disclosed a percentage of 5.7 in 1916-1917, of 4.65 in 1917-1918, and of 4.6 in 1918-1919.
The percentage after the new laws had been put in force:

After the new laws had been put in force, the percentage fell to 3.28 in 1920-1921, and to 3.22, 3.23 and 3.72 for the following years. It may be added that these statistics include the slight cases, as well as the most advanced, which constituted, in 1916-1917, 0.4 per cent., and, in 1923-1924, 0.02 per cent. (Watkins-Pitchford).

LEGISLATION

Pulmonary affections are compulsorily notifiable in the Netherlands when they affect persons employed in the following industries: glass-making, industries which include work on glass by the rise of the industries: glass-making, industries which are notifiable; in the Netherlands when they notifiable; in the Netherlands when they notifiable; in the Netherlands when they notifiable; in the Netherlands when they notifiable; in the Netherlands when they notifiable. In France, cases of anthracosis from coal dust are notifiable; in Pennsylvania, cases of anthracosis, without any specification; in Poland, silicosis; in France, pulmonary affections from siliceous, calcareous and argillaceous dusts. Among the affections specified in lists for compensation in different countries, those which are concerned with the respiratory passages are:

1. The list of respiratory affections is given according to the terminology used in the different legislative texts.
Asthma from the dust of Acacia melanoxylon ("Blackwood") in Southern Australia. Phthisis in bakers and millers in Queensland; in grinders in Ontario and Germany; in miners in South Africa, Ontario, Alberta, Western Australia, Queensland and New Zealand. Anthracosis or pneumoconiosis in Argentina, Bolivia, Brazil, Chile and New Zealand (for miners with silicosis and tuberculosis); in Germany (for silicosis and pneumoconiosis complicated by tuberculosis); in U.S.S.R. (for miners and polishes; as well as the silicates); in Ontario and Alberta (for siderosis, silicosis and lithosis). Silicosis: Great Britain, Queensland, New Zealand, Ontario (cutting stones and grinding metals); Alberta (for miners, quarriers, cutters and polishers of stone or metals) and Germany. Siderosis: Argentina (steel smelting) and Bolivia. Tobacnosis: Brazil, Argentina, Bolivia. Pulmonary affections from basic slag or standstone: Germany (grinding of metals, the china industry and mines). Cancer of the lung (Schneeberg disease): Germany. Pulmonary sclerosis: Bolivia. Tuberculosis: Argentina and Brazil (see above Anthracosis). Pulmonary tuberculosis: Bolivia, New Zealand (mines).

A New English law of 1930 includes the extension to asbestosis of the compensation laid down for silicosis. See also article "Tuberculosis and Silicosis". As regards the upper respiratory passages, see article "Occupational Diseases: Ear, Throat and Nose".

Digestive System and General Metabolism

Most occupational diseases connected with the digestive organs are brought on through industrial poisons or occupational infections. These etiological factors, as well as the important problem of nutrition, are discussed in the corresponding articles. Other forms of disease relating to the digestive organs do not present any very noticeable variety, but develop according to the usual picture of ordinary illnesses. There is no doubt that here lies the reason they do not receive the attention they deserve, although sometimes they may give rise to very serious trouble. The injury may extend to all parts of the digestive organs, and may cause organic, as well as functional, disorders.

THE OESOPHAGUS

Diseases of the oesophagus are rare, and more searching investigations should be made on this subject. According to American and European statistics, cancer of the oesophagus occurs more often in men than in women (in the proportion 3.5 to 1); the reason for this may perhaps be found in part to be due to occupational risks. In China, the frequency of this disease may be attributed, especially in the case of coolies, to the consumption of hot rice and alcohol; for as is known, these are both chemical and thermic irritants. It is an interesting fact that cancer of the stomach and oesophagus is very common in the Telf district of the Tyrol, where the chief sources of ichthyol are found.

THE STOMACH

The hydrochloric secretion of the stomach is one of the most powerful means of protection, particularly against pathogenic germs which originate in the alimentary infections, but are capable of being killed by hydrochloric acid; per contra arrest of the flow of this secretion favours infectious intestinal diseases. This arrest of hydrochloric secretion may be an occupational lesion, and neither it nor its consequences should be neglected. On the other hand, recent researches have shown that hydrochloric secretion is important from another point
of view, as regards industrial pathology.

Although intellectual work does not increase, to any appreciable degree, the expenditure of energy, it is known that strenuous muscular work, if sufficiently prolonged, lowers the alkalinity of the blood plasma, and increases the acidity of the gastric juice. When the muscular work ceases, the alkalinity of the blood increases, and corresponding diminution takes place in the acidity of the gastric juice.

Thus it is seen that the secretion of gastric juice protects the organism against fatigue; and, consequently, the absorption of food not only supplies the body with the necessary number of calories, but, by increasing the hydrochloric secretion, it readjusts the balance of hydrogen ions in the blood, and thus removes the sensation of fatigue. Food that is rich in albumens is most effectual in increasing the hydrochloric secretion. Here is to be found an explanation of the instinctive desire for such food experienced by men employed on exhausting work who absorb on an average 65 grm. of albumen a day, apart from the fact that lack of albumins quickly induces malnutrition, as has been proved in the case of Zittau weavers.

Occupational diseases of the stomach may be of primary or secondary origin. The latter are chiefly due to the fact that, on account of occupational causes, the teeth are defective, or else they are brought on by one of the numerous forms of stomatitis which involve as sequelae acute and chronic gastritis.

Among primary diseases of the stomach are found nervous complaints, catarrhs, hypochlorhydria, ulcers, carcinoma, and infections.

One of the chief factors in the etiology of diseases of the stomach is irregular feeding, as has been observed in the case of commercial travellers, country doctors and others. Besides this the part played by alcohol must be taken into account in the case of workers connected with inns and hotels, night workers, and especially those whose work is exhausting. For alcohol, while it masks sensations of fatigue,同时也 preserves the premature expenditure of strength. Recent experiments have shown that alcohol prolongs the duration of secretion and increases the acidity — both for hypo- and hyper-hydrochloric stomachs. In this connection mention should be made of those men who drink liquids used for polishing, particularly cabinet makers who suffer from chronic gastritis caused by lacquers.

Gastritis is found in industries in which the workman's stomach is irritated by fresh and highly seasoned meats, especially among men employed in knackers' yards, and often in trades where the workman swallows vapour that contains acids or caustic alkali. This applies particularly to margarine factories, soap refineries and candle factories, where the workmen imbibe, in addition to alkaline vapour, fatty acids, e.g. lactic acid, acetic acid, palmitic acid, stearic and margaric acid (Grun). These substances not only neutralise the gastric acids, but open the way to processes of fermentation and putrefaction, and by destroying the sterilising property of the hydrochloric acid facilitate the development of infectious intestinal diseases, often followed up by intestinal catarrh and catarrhal jaundice. Finally it should be pointed out that men working in high temperatures, e.g. glass blowers and men at gas works, who, on account of the heat, take large quantities of cold drinks, as well as those men whose abdomens are exposed to cold, such as men who work in water, raft drivers, etc., often suffer from gastro-intestinal troubles.

Complaints arising from the gastric secretion, as well as the formation of tumours, may be due to mechanical, chemical or thermic causes. Since it is admitted that ulcer of the stomach, in particular, can develop from gastritis, the aforementioned factors can then be considered as predisposing.

In the case of cooks, ulceration may develop as a result of hyperacidity produced by the constant taking of hot, rich food. This form of ulcer, although its existence has often been denied, is quite possible, though perhaps less common than is generally thought. But it is worthy of note that ulcers of the stomach are found in chlorotic persons and in beginners and apprentices. In reference to this it is important to bear in mind that psychic condition, overstrain and mental excitement may play an important part in the development of this complaint. But the theory, which is accepted at the present time, of the formation of an ulcer on a neurotic basis admits a constitutional foundation and so occupational risks are not so much an etiological factor in this illness as an auxiliary cause; for this reason in cases of haematemesis and in cases of gastric ulcer account must be taken of external and internal injuries.

Dealing with internal injuries there must be placed at the head of the list the swallowing of sharp-edged particles of dust by metal turners, stone cutters, and the like.
As regards external traumatism, unless predisposition plays a part, it must occur daily, or repeatedly, in order to produce ill-effects, e.g. the bent position of the tailor's or shoemaker's body when at work. Some American statistics (Friedenwald and Morrissom) which deal with 200 cases of ulcer of the stomach attribute 2 per cent. to this cause. The development of an ulcer as the result of a single injury, such as carrying heavy loads, or a fall from a height, is a very rare occurrence, and it may be assumed that this is rather a case of making manifest the existence of a latent ulcer. German statistics (Ebstein) show among 157 cases of ulcer of the stomach 6 cases due to injuries (3.8 per cent.). Cases seem more common where confusions of the stomach are concerned.

The question of cancer developing on the foundation of an occupational injury is still less understood than that of ulcers. It is only possible to consider those cancers that are grafted on an ulcer, which, according to Haberfeld's statistics, form 16 per cent., and, according to Orator's statistics for 1925, 10-15 per cent. of all carcinomata. If it be admitted, with Kaufmann, that 3.8 per cent. of ulcers of the stomach are of traumatic origin, and that about 5 per cent. of these will become carcinomatos, it follows that, out of 10,000 cases of ulcer, 380 have a traumatic etiology, and, of these, 19 will eventually develop into carcinoma.

Ochsner's work (The Relation between Filth and Cancer) in which the author asserts that cancers of the skin are commoner among men than among women, and that they are situated on those parts of the body exposed to dirt, such as the face, hands and ears, may be verified. In the same work the author points out that cancer of the stomach is found among Japanese agriculturists, who use excrement as manure, in the proportion of 53.2 cases per 100,000 inhabitants, whereas this disease is unknown among the Eskimos.

As regards the part played by traumatism in the formation of cancer of the stomach, it may be affirmed that a single injury can never start cancer. It is possible, however, that the effect of traumatism on the body is to prepare the way for the development of cancer which has a strong affinity for ulcers and irritated parts. Nevertheless, it is quite probable that a carcinoma of the stomach, which already exists is only aggravated or made apparent as the result of a lowering of resistance, caused either by industrial poisons, by the inhalation of gas, fumes or dust, or else by underfeeding and overwork. The same considerations apply to traumatism which may increase the growth of malignant tumours already existing, whatever be their nature or their localisation.

Neurosis of the stomach plays a still more important part, all the more important because it is partial manifestation of a general neurasthenia. At this point there must be considered the etiological factors due to neurasthenia, the emotion which is aroused by the feeling of responsibility, or by work carried on under the pressure of necessity. Various other factors may of course come into play, e.g. physical and mental overwork, irregular feeding, or excitement day by day; all such things should be taken into consideration — it is very difficult to make a diagnosis — for affections of the stomach are independent of the act of digestion, and of a fixed diet.

In conclusion, it is found that industrial diseases of the stomach, with the exception of forms of neurosis, which are really symptoms and seldom diseases sui generis, are not numerous, and belong partially to the domain of hypotheses which need to be studied more thoroughly.

Intestines

Constipation and its sequelae are the chief occupational diseases of the intestines. As the industrial poisons which affect the intestines will not be considered in this article, the most important point to examine here is atonic constipation. It is not merely the nature of the food (a subject not dealt with in this article), but also the style of life which leads to this form of constipation; for the movements of the body — more than anything else — ensure regularity of the intestinal functions (Strassburger). This form of constipation is found in persons who lead a sedentary life, such as coaches and writers; commercial travellers also suffer from this complaint owing to their long railway journeys.

Another point is that women working in factories are often unduly modest and so bring constipation trouble on themselves. It is important to persuade them not to be so foolish. This complaint is also found in young
In times past, it was accepted as a medical fact — which is somewhat overlooked by modern practitioners — that hernias only formed progressively by the gradual stretching of the fibrous parts, and that intra-abdominal pressure has to be of some years' duration before effecting the stretching of the inguinal orifice which results in a hernia. The sudden development of a hernia is very rare. The prolonged effect of intra-abdominal pressure due to a man's occupation frequently brings on an interstitial inguinal hernia, due to a pre-existing peritoneal pouch, which may become an external hernia. This may also be suddenly brought on by an unusual increase of abdominal pressure. Great physical exertions repeated daily are among the chief causes of hernia.

Kauffmann classifies as follows the traumatisms that are effective at once: first, direct action on the abdomen by blows, shocks or falls; second, slipping or falling when in the act of lifting, carrying or throwing heavy objects or loads; third, efforts made to hoist one-self out of some deep place after falling in, or to raise oneself to a standing position when kneeling or holding some heavy load. These are more or less accidental causes, which bring on a sudden increase of intra-abdominal pressure; they belong to the same group as physical efforts and overstrain, and are conducive to the production of hernia by bringing to light a hernia already existing or by making worse a hernia that is in course of formation.

As well as internal and external inguinal hernia there occurs femoral hernia, often with no symptoms; also umbilical hernia and epigastric hernia, as well as hernias of the lateral walls of the abdomen and in the region of the kidneys, the etiology of which is the same as that of inguinal hernia.

Internal hernias are uncommon and this fact is important for the reason that invagination of these hernias, which develops with symptoms of strangulated intestinal obstruction, is difficult to diagnose.

The most common of these internal hernias is the diaphragmatic, which is produced through a diaphragmatic hernial sac formed by the peritoneum or pleura, in contrast to false hernias, the most common of which occur by the passage of an intra-abdominal organ into openings between the abdominal and thoracic cavities; both forms occur chiefly on the left side of the diaphragm (Strassburger).

In addition there should be mentioned duodenal-jejunal hernia (penetration
of the intestine into the duodenal sac), hernia into the omental cavity (by the opening of Winslow), hernia of the intersigmoid sac, hernias of peritoneal pouches and hernias of the parajejun al sac. These hernias, although difficult to diagnose, should be mentioned here.

**Vascular System**

Another occupational disease brought on, or at least influenced, by the occupation is dropsy. This condition was recognised in medicine in ancient times, but its importance has been specially emphasised in modern times, particularly by Walko, and it should be mentioned here on account of its intestinal symptoms. This disease occurs more commonly in men than in women, in the proportion of 3 to 1. Its development depends chiefly on hereditary and constitutional factors, but also on an unhealthy kind of life, which is for the most part sedentary.

This disease is chiefly found among clerks, among people who work in offices, and among those whose work is of a sedentary nature. Up to the present time, very little attention has been paid to these conditions of work, and it would be a good thing if precautions against this disease could be taken in the case of tailors, shoemakers and office clerks. It often shows itself by serious digestive troubles of every kind, and by anaemia; it develops in people who lead sedentary lives. In these cases there is congestion of blood in the abdomen and interference with the flow of venous blood, as a result of the kind of life, or of some constitutional weakness of the vascular system. The next thing one observes is a condition resembling collapse and an increase of arterial pressure. But these cases may also indicate dyspeptic complaints which cause loss of flesh. Gymnastic exercises and hydropathic treatment are useful for preventing this occupational condition.

Arteriosclerosis of the intestinal vessels resembles general arteriosclerosis in its etiology, and so may be passed over in silence in this article. In the same way that the circulatory system may be affected by the abdominal cavity, so the heart may cause most serious intestinal disorders. This explains how, after a great physical effort, a failure of the valves of the heart to act may bring on embolism of the mesenteric artery, with intestinal gangrene, and a fatal issue from peritonitis — though this is rare.

**Abdominal Musculature**

Flabby muscles, which are commonest among women who have had a good many children, display, especially when the abdominal pressure is increased by work, a tendency to enteroptosis with displacement of organs, and also to plethora and its consequences. Massage of the abdominal muscles and eventually the use of the Bergonie apparatus are recommended as preventive measures. At all events, working women who suffer from flabby muscles should avoid heavy work, and the same advice holds good for any one who suffers from constitutional weakness of the abdominal wall, from ruptures, fistulas or scars which are imperfectly healed.

**Liver**

Except in cases of poisoning, occupational diseases of the liver are not, as a rule, primary affections. There should first be mentioned cirrhosis of the liver which is found very commonly not only in what are called the alcoholic trades, but also amongst other categories of working men who consume large quantities of alcohol; men who work either at very high temperatures or at very low ones, or in a dusty atmosphere, or who handle poisons. But chiefly to be considered are men who do very heavy work, and take alcohol to dull their sensation of fatigue. Various opinions concur in holding that cirrhosis of the liver may have a traumatic etiology, in the same way that aggravation or rupture of varicose veins in the oesophagus may be the result of accident or of a physical strain.

Passive congestion of the liver may also be looked upon in a certain sense as an occupational disease: first, because the circulatory system is often out of order, especially in the case of men doing heavy work, with congestion of the liver as a result; secondly, because sedentary work, especially in the case of women workers, often brings on passive congestion of the liver with the formation of biliary calculi, besides plethora and stomach troubles.

**Pancreas**

Injury to the parenchyma of the pancreas is produced in the same way as injuries to the liver; traumatisms may cause necrosis, and, according to Von Noorden, eventually diabetes. As regards this latter disease it is pretty certain that predisposition is its essen-
tial starting point, and that certain occupational factors, e.g., emotions or intellectual overstrain, are only intensifying or determining causes.

Fortunately in these days a young man suffering from diabetes need no longer be a burden to the community. For, as has been learnt, chiefly from Jaksch’s experiments, based on the discoveries of Banting and Best of Toronto, it is quite possible to restore to a young man suffering from diabetes his capacity for work, by teaching him how to regulate his diet and how to make use of insulin. Jaksch’s clinic is almost entirely filled with ordinary workmen, who, with the help of Trommer’s test, have been giving themselves insulin injections for years and, thanks to a suitable diet, keep up their capacity for work. The social problem of restoring certain diabetic patients to become active members of the community is no longer an impossible one; it is only a question of distributing insulin free, or at a greatly reduced price.

DISEASES CAUSED BY LACK OF VITAMINS (DEFICIENCY DISEASES)

Under this heading, for simplicity of classification, are grouped diseases due to nutritional changes, which are caused by the lack or deficiency of a substance, or of a group of substances, or, perhaps, simply of a physico-chemical condition of the food, necessary in minimum doses to nutrition (Weill and Mouriquand).

These diseases, due to lack of vitamins which English and American bio-chemists call “food accessory factors”, are chiefly beri-beri, scurvy and pellagra.

Beri-beri, characterised by a poly-neuritic syndrome, or by an oedematous syndrome generally associated with cardio-vascular complaints, is a disease associated with the lowest classes of society, and is found chiefly among the Chinese coolies. It is also observed among certain classes of Japanese workmen, among the poorest classes of the Malay Archipelago, in South America and South Africa. The consumption of decorticated or polished rice is the chief cause of this disease.

Nocht has described a form of beri-beri observed among German and Norwegian sailors, who live on sailing ships for months at a time. This form is characterised by oedema of the lower limbs, with paresthesia, cardiac enlargement and weakness, and digestive troubles. It often ends fatally.

The disease is due to the consumption, almost exclusively, of preserved viands, and is often associated with scurvy.

Bad hygienic conditions are also considered by some authorities to be important factors in the disease.

Scurvy, which in peace time is in these days an unusual disease, appeared in the form of serious epidemics during the war, when populations and armies suffered from general dietetic restrictions, or from privation of fresh foods. In days gone by, the by-product was the appanage of long sea voyages, besieged populations, armies on the march, and Polar explorers. The same may be said of ergotism, which of yore was so common among rural populations that it was given the name “Morbis ruralis”. The progress attained by the modern flour-mill industry has made this illness rare.

Among disorders of nutrition connected with a man’s occupation pellagra should be placed first. It is considered in these days to be due to a lack of vitamins, and is attributed to the consumption of deteriorated maize. It is a very common complaint among the rural populations of Southern Europe, Asia Minor, Lower Egypt, Algeria, Tunis, and also of the Southern States of North America. The endemic foci have remained unaltered for more than a century, and the disease affects agricultural labourers almost exclusively. In Rumania the ratio between the pellagrous peasants and town-dwellers is as 50 to 1. The disease, which has been thoroughly studied by Italian experts, is characterised by the following three symptoms: (1) erythema; (2) digestive troubles; and (3) nervous troubles. The erythema appears on those parts of the skin exposed to the sun, as pellagra makes the skin very sensitive to the action of the sun’s rays (“mat del sol”); the skin peels, goes a dark colour, and the surface becomes rough and parchment like—hence the name pelle agra or rough skin. The erythema is accompanied by giddiness, depression, dyspepsia, diarrhoea, and, especially, by pain in the hands and feet, and a reeling gait. The digestive troubles show themselves by salivation and dyspepsia, and by a condition similar to that of dysentery, which may lead on to loss of flesh and finally death. Nervous troubles are both motor and psychical; they are manifested as quick reflex movements, by muscular fibrillary tremor, by parasthesias, pruritus, paresis, paralyses, muscular atrophy, ataxy, conditions resembling tetanus and meningitis, by nocturnal blindness, psychoses, and mental disturbances.
These diseases can best be combated by improving the food of the poorest working classes. Pellagra undoubtedly exerts a harmful influence on the germ plasm.

**Prophylaxis**

The principle of prevention being better than cure is above all true when dealing with industrial diseases of the stomach and intestines. It is for instance so easy to prevent chronic constipation and all its accompanying troubles, the least serious of which is disinclination for work. This complaint is chiefly connected with the sedentary occupations, and the following principles should be instilled into the classes of workers involved. First, the foundation of their diet must be made up of vegetable food, rich in cellulose, for instance black bread, soldiers’ bread, Pumpernickel (Westphalian bread); secondly, some leisure time must be devoted to physical exercise in the fresh air, and some mild sports must be taken up, e.g. gymnastics, riding, cycling, swimming or boating. It must, however, be borne in mind that constipation is equally common in the occupations calling for a lot of exercise, such as among agriculturists, officers and postmen, but in this case the constipation is caused by a spasm of the intestines and the treatment for this is rest, antispasmodics and a soothing diet. The prevention of chronic constipation is possible and necessary, not only with a view to the elimination of such toxins as indican, which diminish the capacity for work, but because in this way serious illness may be avoided, illness which may affect other parts than the intestines (according to Eichhög; iridocyclitis, for example). In preventing constipation the risks of cancer of the rectum, which may be provoked by hemorrhoids or constipation, are also being reduced.

There will not be described in this article the therapeutics of chronic constipation, which in some respects resemble the prophylaxis. But it may be said in passing that the same measures of prevention must be taken for abdominal plethora, and that particular care must be taken when there is hereditary predisposition. Sedentary occupations need to be balanced by physical exercise and stimulation of peristalsis.

As regards pellagra it is unnecessary to enumerate here the regulations made by various countries (Italy, Austria, Hungary, etc.) for combating this disease. Suffice to say that, as regards avitaminoses, beri-beri appears on the list of occupational diseases which are granted compensation in Yugoslavia (only for sailors), and scurvy amongst sailors is compensated in Germany.

It is unnecessary to discuss here the therapeutics of industrial gastro-intestinal diseases, for they are exactly the same as for other internal disturbances. But a few words may be said as to their industrial orientation.
